In order to study the effect of kinds of gas on size of bubbles which generate from a gas sparger, frequencies of bubbles which generated from a horizontal single nozzle were measured. Figs.13 -15 show the effect of kinds of gas on *N* and V for 7 and 10 mm nozzle, respectively. It is clear from these figures that *N* and *V* don't depend on kinds of gas.

Conclusion

1) E_G increased with increasing gas density and was correlated. The reason why EG increases with gas density may be because bubbles of smaller gas density coalesce into larger bubbles more easily at the same superficial gas velocity.

2) The gas holdup data of Ozturk et al. (1987) for H_2, He, N_2, Air, CO_2 gas -xylene system were correlated by nearly the same equations as those in this work.

3) Frequencies of bubbles which generated from the 7 mm and 10 mm I. D. horizontal nozzles did not depend on kinds of gas at the same gas flow rate.

Abstract

Simulation of dynamic performance of ozone dissolution into pure water and ozonation treatment of surfactants in a semi-batch bubble column reactor by CFX 11.0 software was done using a two-fluid Eulerian model. Turbulence was modeled by the SST model. The results of simulations showed a good agreement with experimental results of this work and Uchiyama et al.(2007).

1 Introduction

Recently, much attention has been paid to environment. In order to keep clean environment, waste gas and liquid must be completely treated. Ozone is a strong oxidizer and has been widely used for treating water and wastewater. Surfactants are predominant pollutants of wastewater and must be decomposed. There have been many researches about decomposition of pollutants by ozone. Uchiyama et al. (2007) studied the dynamic performance of ozonation treatment for nonionic surfactants SS-90 (Polyoxyethylene Alkyl Ether) in a bubble column and simulated the experimental results by using the tank-in series model. Recently, CFD has developed remarkably because of development of cheap efficient PC and good software. Simulation by CFD is very useful for research, design and scale up of bubble columns. In this work, rate of ozone dissolution into pure water was experimentally measured, and simulation of dynamic performance of ozone dissolution into pure water and ozonation treatment of surfactants in a semi-batch bubble column reactor by CFX software was done. The simulation results were compared with experimental results of this work and Uchiyama et al. (2007).

2. Experiment and Simulation

2.1 Experimental apparatus and method

The bubble column used was made of transparent acrylic resin. Its inner diameter and

*Corresponding author.Tel.+81-046-291-3083. E-mail: yamasita @ chem. kanagawa - it.ac.jp.

height were 0.16 m and 1.0 m, respectively. The gas distributor was a perforated plate. The diameter, number and pitch of holes of the perforated plate were 0.5 mm, 193 and 5 mm in order. Oxygen gas from an oxygen cylinder was used as a gas and ultra pure water was used as a liquid. Liquid was used in a batch. Ozone was generated from oxygen gas by an ozone generator (PO-10 by Fuji Electric). Concentrations of ozone in gas and liquid were measured by ozone meters OZ-1 and OZ-2 by TOA DKK. A liquid pump was used to improve liquid mixing in the bubble column. All runs were done at room temperature.

2.2 Simulation

Commercially available CFD code-CFX 11 (Ansys Inc.) was used to solve the differential equations involved in two-fluid Eulerian approach. Two bubble columns were used as the simulation models. A 16 cm I.D. and 90 cm tall bubble column with 10 mm mesh was used for the simulation of dynamic performance of ozone dissolution into pure water. A 10 cm I.D. and 100 cm bubble column with 10 mm mesh was used for the simulation of dynamic performance of ozonation treatment of surfactants. The gas inlet was 10 mm and set in the center of bottom of the bubble column. The condition of the gas outlet (= top of the bubble column) was degassing condition. Turbulence was modeled by the SST model. The liquid was fed in a batch. The bubble diameter was 5 mm.

In case of pure water, the interfacial transfer of ozone between the gas and the liquid is modeled as follows:

$$dC/dt = k_L a(C^* - C) - k_d C \quad (1)$$

where k_d is the rate constant of ozone self decomposition in the liquid phase.

In case of water with the surfactant, the rate of change in dissolved ozone is given by

$$dC/dt = K_L a(C^* - C) - k_d C - b\, d(TOC)/dt \quad (2)$$

$$d(TOC)/dt = -k_1(TOC) \quad (3)$$

$$k_1 = 3.75 \times 10^6 Y^{0.29} Q_g^{0.67} \exp(-47800/RT)(TOC)_0^{-0.835} \quad (4)$$

where b represents the consumed ozone per *TOC* degradation rate and b = 3 was used. The third term on the right-hand side of Eq.(2) represents loss of ozone in the liquid phase due to oxidation of the substrates.

The volumetric mass transfer coefficient $K_L a$ was estimated on the basis of the empirical correlation proposed by Shah et al. (1982) for oxygen transfer from air to water.

$$K_L a = (D_{O3}/D_{O2})^{0.5}\, 0.467 U_G^{0.82} \quad (5)$$

where U_G is the superficial gas velocity.

Henry's law constant *H* was given by Miyahara et al. (1994)

$$H \text{ (in kg/ m}^3\text{Pa)} = 1/\{1.4 \times 10^9 \exp(-2.62 \times 10^3/T)\} \quad (6)$$

3 Results and discussion

3.1 Dynamic behavior of ozone dissolution into pure water

Fig.1 shows contours of ozone dissolution into pure water at superficial gas velocity U_g = 0.166 cm/s. The concentration of ozone increased with time. Fig.2 shows comparison

between the simulation and experimental results of dynamic change of ozone concentration with time. At small time experimental concentrations increased much slowly than simulation ones because the experimental bubble column had a 4 dm^3 gas chamber under the perforated plate. However, simulation concentrations became nearly equal to experimental ones at large time.

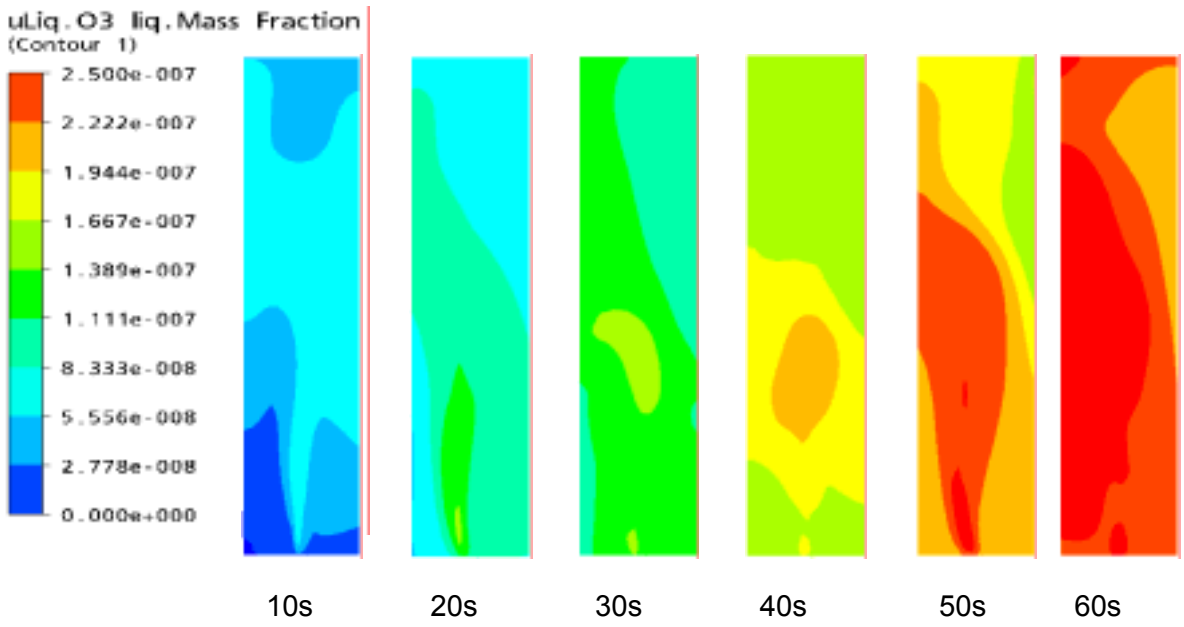

Fig.1 Contours of dissolved ozone concentration in the bubble column at U_g = 0.166cm/s in case of water with no surfactants.

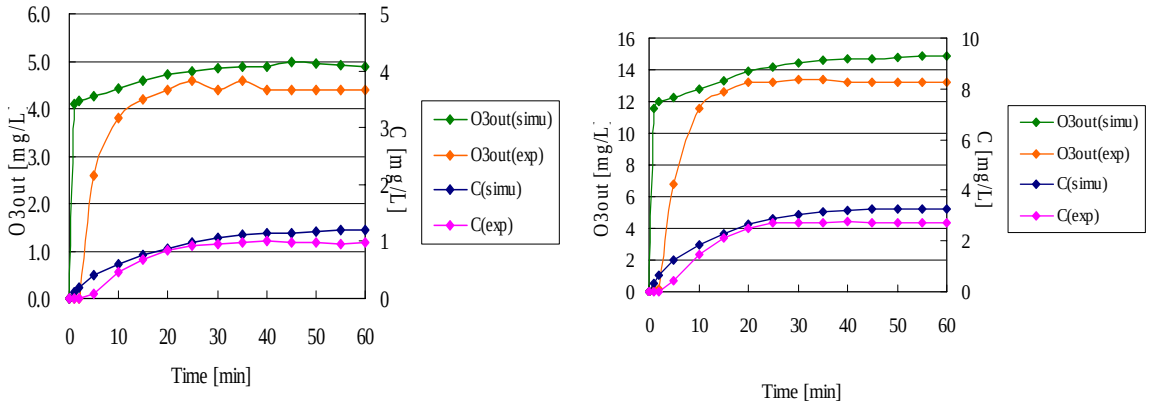

(a) Y_{in} = 5 mg / L (b) Y_{in} = 15 mg/L

Fig.2 Comparison between simulation concentration and experimental ones at U_g = 0.166 cm/s. Y_{in} means ozone concentration in the gas at gas inlet.

3.2 Dynamic behavior of ozone dissolution into water with SS-60

Figs.3 and 4 show 5 snapshots of contours of dissolved ozone and *TOC* in the water at U_g =

0.166 cm/s, respectively. Concentrations of ozone in the water increased with time. However, *TOC* decreased with time because surfactants reacted with ozone.

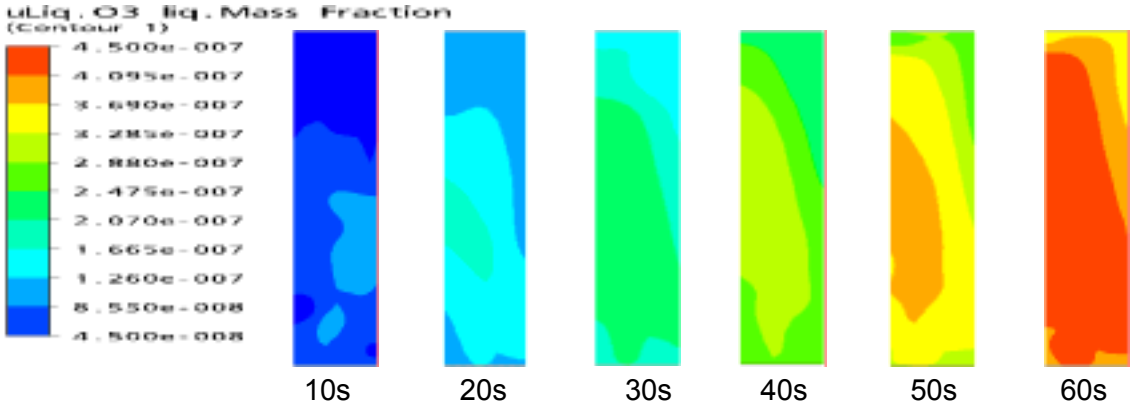

Fig.3 Contours of dissolved ozone in the bubble column with time at U_g = 0.106 cm/s, Y_{in} = 25 mg/L and *TOC* = 7.16 mg/L.

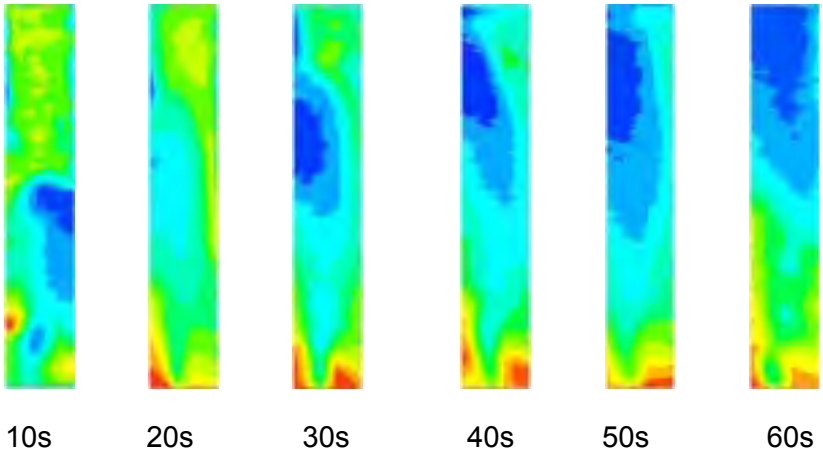

Fig.4 Contours of *TOC* in the bubble column with time at U_g = 0.106 cm/s, Y_{in} = 25 mg/L and *TOC* = 7.16 mg/L.

Fig.5 shows the dynamic behavior of *C*, *TOC* and Y_{in} at U_g = 0.106 cm/s, Y_{in} = 15 g/m^3 and *TOC* = 7.16 mg/L. (a) shows the simulation results in this work and (b) shows the experimental results by Uchiyama et al. (2007). It is clear from Fig.5 that the simulation results show a good agreement with experimental ones of Uchiyama et al. (2007).

Fig.6 shows the effect of Y_{in} on $TOC/(TOC)_0$ at U_g = 0.106 cm/s and *TOC* = 7.16 mg/ L in the range of Y_{in} = 10 – 25 mg/L. $TOC/(TOC)_0$ decreased with increasing Y_{in}. Though the experimental results of Uchiyama et al. (2007) decreased linearly with time *t*, those of simulation results in this work did not decrease linearly with time. This reason is not yet clear.

Fig.7 shows the effect of ozone gas flow rate Q_g on $TOC / (TOC)_0$ *at* $(TOC)_0$ = 7.16 mg/L and Y_{in} =10 mg/L in the range of Q_g = 0.25 – 1.0 L/min. $TOC/(TOC)_0$ decreased with increasing Q_g.

Fig.8 shows the effect of $(TOC)_0$ on the ratio *TOC* at Y_{in} = 25 mg/L and Q_g = 0.5 L/min (U_g = 0.106 cm/s). *TOC* became larger with increasing $(TOC)_0$. The simulation results showed a

good agreement with the experimental results of Uchiyama et al. (2007).

4. Conclusion

Simulation of the dynamic performance of ozone dissolution into pure water and ozonation treatment of surfactants in a semi-batch bubble column reactor by CFX 11.0 software was done using a two-fluid Euler-Euler model. The simulation results showed a good agreement with experimental results of this work and Uchiyama et al. (2007).

Keywords: Gas-Solid Flows, Coherent Structures, Particle Interaction
Topic: Advancing the chemical and biological engineering fundamentals

Abstract: The purpose of this research was the study of flow structures and the contact between phases in a two-phase confined jet. Flow structures are related to quasideterministic strutuctures (large-scale), randomly distributed in space and time. Analysis of the contact between the phases in such structures allows the identification of different mixture behaviors mainly due to gas-particle and particle-particle interactions. A pentagonal plexiglass chamber was used as a confined system to investigate these phenomena. Three different nozzles were used to feed air at the top of the chamber, but just the central nozzle was loaded with particles between 10μm and 200μm. The other two were used to increase the interaction between the phases at the chamber. An optical technique known as Phase Doppler Anemometry (PDA) was used to measure the instantaneous velocity of the particulate phase and particle diameter in five different axial positions of the jet nozzle. Radial profiles were also obtained for each axial position. The data analyzed were presented in terms of mean velocity, fluctuation velocity known as rms velocity, turbulence intensity and interparticle arrival time (in terms of Chi^2 distribution and deviation number). The experiments were carried out under different conditions, such as initial velocity (all nozzles), particle distribution (central nozzle) and gas/particle load ratio (central nozzle). These investigations rovid important information on local flow structures and their effect on the macrocospic and turbulent transport of particles between the jet center and the jet contour regions.

1. Introduction

The study of large-scale coherent structures (LSCS) and the contact between phases in gas-solid two-phase flow can be attributed to their technological importance to many industrial processes. Particles in finite gravity tend to accumulate in two types of regions downward flows sandwiched between counter-rotating quasi-streamwise vortex tubes and regions beneath the vortex layers with negative spanwise vorticity. This accumulation of particles may be a problem in the jet mixing processes, causing efficiency to be lower when a good mixture of particles is required. However, if coherent structures are suppressed and incoherent structures dominate the flow, a higher efficiency of mixture may be obtained, mainly due to the chaotic behavior of the incoherent particulate phase, avoiding cluster formation. Based on an application of the interparticle arrival time methodology proposed by Edwards and Marx (1995A, 1995B), this work aims to analyze the flow structure of the dispersed phase in a two-phase jet under different flow and

[1] Corresponding author. E-mail: mori@feq.unicamp.br
[2] Corresponding author. E-mail: ufri@iwt.uni-bremen.de

operational conditions. Due to effects of interference of the tracer particles on the dispersed phase measurement, addressed by Gillandt *et al*. (2000) and Hussainov *et al*. (2000), it is the objective of this investigation to study the particle cluster formation just in relation to the particulate phase, thereby avoiding unnecessary measurements. Moreover, also aims this work to identify physical regions and operational conditions were LSCS occur and within cluster structures. A summary of the interparticle arrival time analysis developed by Edwards and Marx (1995A, 1995B) and improved by Heinlein and Fritsching (2004) is presented in Heinlein and Fritsching (2006).

2. Theory

A summary of the interparticle arrival time analysis developed by Edwards and Marx (1995A, 1995B) and modificated by Heinlein and Fritsching (2004) of the interparticle histogram and its acquisition are presented in Heinlein and Fritsching (2006). The theoretical interparticle function is compared with the experimental interparticle distribution function and particulate flow steadiness or unsteadiness is assessed, where

$$h_{th}(\tau_j) = \frac{\lambda^2 (T-\tau)\exp(-\lambda\tau)}{\lambda T - 1 + \exp(-\lambda T)} \text{ and } h_{\exp}(\tau_j) = \frac{H(\tau_j)}{N\Delta\tau_j}.$$

The statistical analysis of the Chi^2 test is used to obtain the significance, or confidence level, at which the experimental results can be argued to be the same as the theoretical values. In a Chi^2 analysis, the random variable χ^2, the deviation of the observed values from the corresponding expected values, can be measured and can determine the validity of the hypothetical model (Luong and Sojka (1999)). Once Chi^2 has been determined, the hypothetical model can be accepted or rejected depending on the desired significance level.

3. Experimental Setup and Measurement Device

An air compressor supplies a stream of filtered and dried air to the measurement system, which four different lines, as shown in Figure 1. The first line or the main line was connected to the mixture chamber where particles were loaded from a particle deposit, forming a mixture of gas/particles to be fed in through the central nozzle. The second line provided a small amount of air for particle deposit, which was kept at a positive pressure of 0.4bar. When a positive pressure was not achieved, particles were not able to flow through the 1.5mm orifice due to the opposite pressure of the main line. This orifice regulated a constant particle feed into the mixture chamber and consequently the mass load ratio. The third and the fourth lines were used to feed air into the measurement section (confined jet) through two different nozzles, one on the left and the other on the right side of the central nozzle. These three nozzles were located side by side at the top of a closed chamber and were the only entrance, characterizing a confined flow. The main characteristics of the chamber three inlets at the top each with a diameter of 12mm (left, central and right), one outlet at the base (entire base) and a height of 1 meter. Both lateral nozzles were used to supply air at different velocities in order to investigate the flow instabilities due to the presence of different local velocities in the chamber, and consequently local flow structures. Inside this chamber, different radial profiles were obtained at five different axial distances from the jet nozzles, providing data on the mean velocity, rms velocity, turbulence intensity and interparticle arrival time. The data were acquired at each point by a PDA system, which is a nonintrusive and highly accurate measurement device.

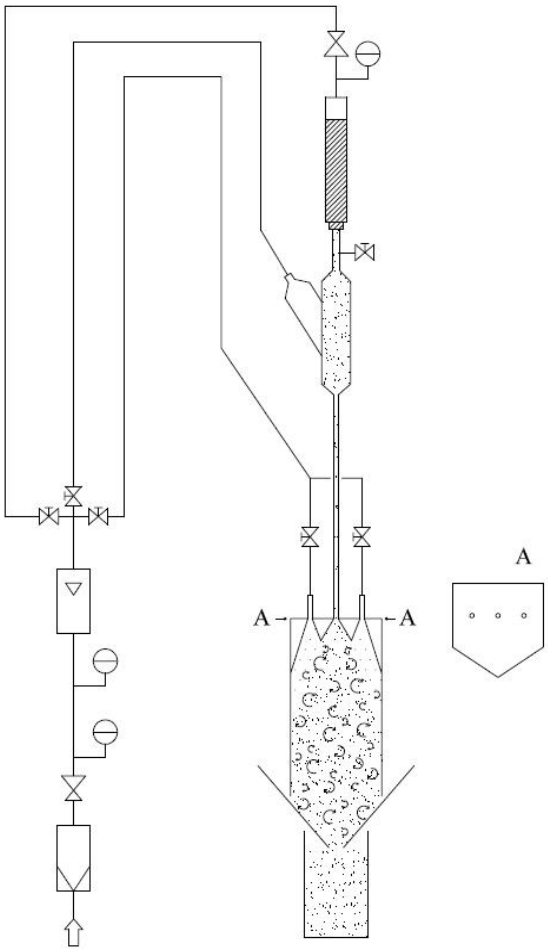

Figure 1 – Experimental setup of the confined two-phase jet.

The PDA measurements were conducted in refractive mode at an off-axis angle of 30º. The particles used during the experiment were spherical glass beads. The instantaneous velocities acquired by the PDA system were interpreted in post-processing mode. Therefore, a complete signal line was sampled for a preselected time of 5s, providing approximately 15000 samples in regions of higher intensity. The minimum particle number considered for sample acquisition is 1000 samples.

4. Boundary conditions

For analysis of the gas-solid flow in a two-phase particle-laden jet, a mixture of different particle diameters between 10µm and 200µm was used. The physical properties of the gas and particulate phase used in the experiments were particle density of 2500Kg/m^3, a gas density of 1.014Kg/m^3 and a gas viscosity of 1.81x10^{-5}Kg/m.s. The mean particle diameter of the particles measured was obtained for all experiments by the granular distribution analysis expressed in terms of Sauter mean particle diameter.

An overview of the initial velocities analized and their respective positions are shown in Table 1.

Table 1 – Initial velocities in different jet nozzles.

Case	U_0 (m/s) - Jet 1	U_0 (m/s) - Jet 2	U_0 (m/s) - Jet 3
1	0	11.5	0
2	8	8.5	8
3	10	9.5	10

5. Results and Discussion

The results obtained for three different cases are presented in terms of mean velocity, rms velocity, turbulence intensity and LSCS in terms of Chi^2 and number of deviations. These results can provide an overview of the behavior of the gas-solid flow in a confined jet at different flows, as shown in Table 1. Measurements were taken at two

different axial distances from the jet nozzle, 210mm and 240mm, in a region where the flow is developed and interaction with the flow from the adjacent nozzles already exists.

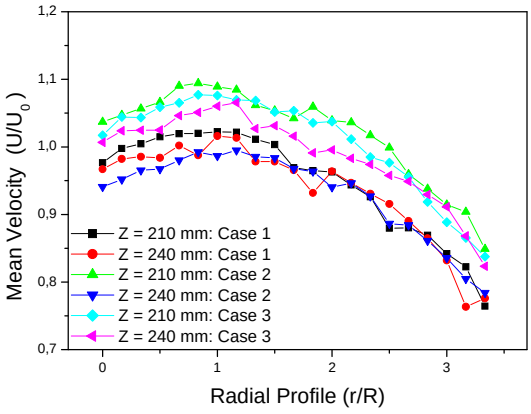

Figure 2 – Mean velocity profiles.

In Figure 2 the radial mean velocity profiles for the above mentioned axial positions are presented for the three cases under analysis. It is interesting to observe that with the increment in the adjacent velocities in jets 1 and 3, the radial profiles with particles loaded in jet 2 tend to be more uniform. For instance, the differences between maximal and minimal velocity in the same profile for cases 1 and 3 are respectively 3m/s and 2.2m/s. These differences are not huge, but show the tendency toward a flat profile. This flat profile is not seen in other studies, such as for the study developed by Decker et al. (2007) where a free jet flow with the same operational and geometrical characteristics was studied.

In that situation the authors found a difference between velocities around 8m/s in the same profile with flow characteristics similar to those found in this study. This shows that the walls and the adjacent flows have a strong effect on jet behavior and consequently on the homogeneity of the flow.

In Figure 3 it is possible to observe the rms velocity for the same conditions at those analyzed in Figure 2. It is interesting to observe a radial region for both profiles in case 1, where there are more interactions between particle. This region between 0.007m and 0.012m indicates the presence of strong flow structures (coherent or incoherent ones) and indicates the shared region of the jet, where the main flow interacts with a region of small velocities. This happens because in case 1 there is no adjacent velocity in nozzles 1 and 3 and the flow interactions are strongly affected by the chamber wall. This increment in rms velocity in the shared region is also observed for free jet flows.

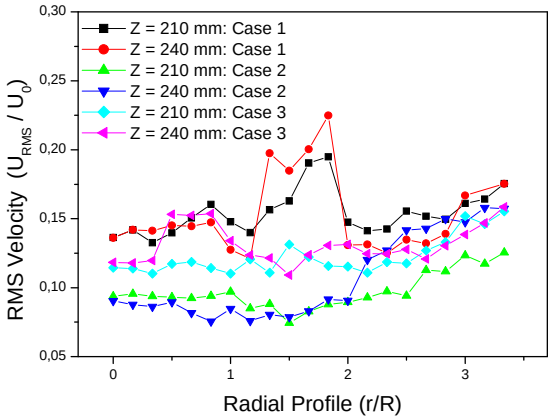

Figure 3 – Rms velocity profiles.

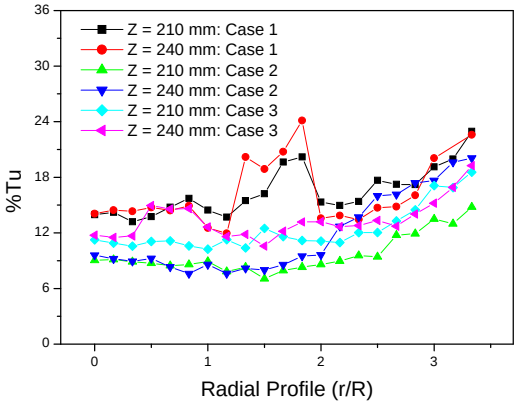

Figure 4 – Turbulence intensity profiles.

The presence of adjacent velocities provided by jets 1 and 3 produces the uniform behavior in the rms velocity profile, which is in agreement with the observations obtained for the mean velocity. In other words, the presence of adjacent flows affects the flow into the chamber in such away that the flow structures tend to become uniform in all radial positions. However such structures are still strong due to the high level of turbulence in the flow.

In Figure 4 the turbulence intensity profile is shown. It is important to observe that the turbulence intensity values are obtained from mean velocity and rms velocity values. As the mean velocity has almost the same profile for all the radial positions, the turbulence intensity profiles become similar to the rms velocity profiles. Furthermore, these results show a uniform behavior in the jet when there are adjacent flows, as previously mentioned.

The large-scale structures may be understood by the statistical study of multiple points, as reported by Heinlein and Fritsching (2006). This technique is based on time distribution between successive arrival particles, known in the literature as interparticle arrival time (IAT). This analysis can be expressed in terms of Chi^2 and number of deviations, which provide data about the flow structures and instabilities in two-phase flows. By definition, steady flows are those whose IAT distribution obeys inhomogeneous Poisson statistics and unsteady flows are those that the IAT distribuition does not obey. Are LSCS in two-phase flows examples of unsteadiness.

It is important to mention that alone the Chi^2 analysis does not guarantee confidence regarding the existence and location of LSCS. This is because the Chi^2 values may be obtained due to random fluctuation and no conclusion can be obtained. Based on this necessity, a parallel analysis of number of deviations must also be developed so the steadiness and unsteadiness of the flow can be assessed.

In Figures 5 and 6 the Chi^2 and the number of deviations analysis, respectively, are presented for the cases and axial positions in Figure 2. It is interesting to observe in Figure 5 that large values for Chi^2 are obtained at position Z = 210mm for case 2. Furthermore, in Figure 6, a larger number of deviations can also be observed for the same case, but at Z = 240mm. However, neither of the cases is able to identify LSCS, because they are not in agreement with the Chi^2 and number of deviations criteria. In other words, no LSCS exist under these conditions. In these cases, the values of Chi^2 observed in Figure 5 are due to random fluctuation since the majority of the values in Figure 6 are under the zero line.

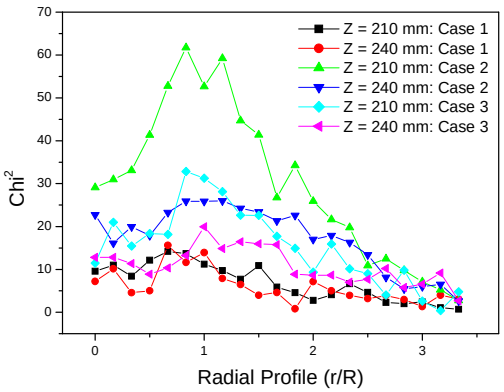

Figure 5 – Chi^2 profiles.

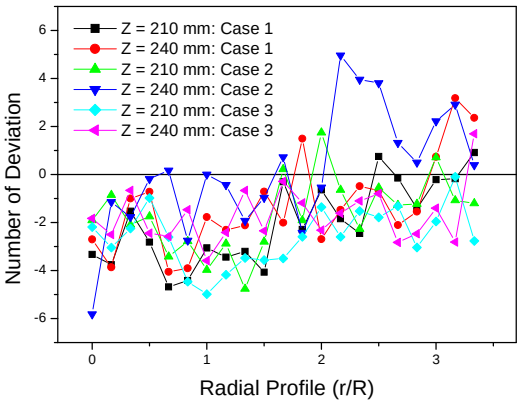

Figure 6 – Number of deviations profiles.

6. Conclusions

In this study flow structure and particle interaction are analyzed for a confined two-phase jet flow with three different nozzles: one main nozzle where particles are loaded together with the gas phase and two adjacent ones without particles. Three different cases are analyzed for two different axial positions of the jet nozzle: 210 and 240mm. The results are presented in terms of mean velocity, rms velocity, turbulence intensity, Chi^2 and number of deviations radial profiles. In all these analyse the confined jet had similar characteristics, such as flat radial profiles with the increment in adjacent velocities in the adjacent nozzles. Another behavior observed is in relation to LSCS. In all cases presented in this study, no such flow structures are observed and incoherent structures dominate the flow field. This happens due to two different characteristics of this study: high velocities in the jets and the presence of the wall. Under these conditions, a high level of flow structures exists, mainly due to the direction and redirection of the main flow and the presence of secondary flows, which produce the dissipation and suppression of these coherent structures.

Abstract

The main objective of this investigation was to experimentally study, in the free board of a bubbling fluidized bed of sand, the heat transfer towards a water cooled confining membrane wall. New results were obtained on the heat transfer mechanisms occurring in the membrane walls placed above a bubbling fluidized bed heated by an electrical resistance of 2 kW. Two kinds of experiments were performed: in the first part, the bed was fluidized with air and the temperature in the bed reached values in the range of 400 – 700 ºC, and in the second set of experiments, propane was injected and mixed with the fluidizing air and combustion took place in and above the bubbling bed. For the latter situation, the temperature in the bed reached values above 700ºC. An empirical correlation was developed to determine overall heat transfer coefficients.

1. Introduction

The temperature of fluidized bed boilers and furnaces is controlled by the heat transfer rate towards non-refractory walls, either membrane walls or heat transfer bundles placed in the gas flow path. The understanding and explanation of heat transfer mechanisms among the bed or particles and confining walls, like membrane walls, is of great importance. Published data concerning the heat transfer in this region are scarce, and are essentially concerned with the heat transfer towards tube bundles placed in the free board region, while data on heat transfer towards membrane walls are almost non-existent. Wen–Ching (2003) refers to numerous works using laboratory scale fluidized bed reactors and confirms that the information available on the transport region of bubbling beds is quite limited.

Several heat transfer studies were carried out in fluidized beds for operating conditions different than those considered in the present work. Al-Busoul (2002) used bed immersed surfaces while several other studies consider the membrane wall, but only in the bubbling bed region. Pagliuso and Lombardi (2000) presented results for an experimental set-up quite similar to that considered in this investigation and so their work was used for a preliminary analysis. However, these authors refer to a circulating fluidized bed operating at around 150 ºC, while the present study covers a higher range of temperatures.

The literature search carried out also reveals no information about studies of heat transfer in fluidized beds with the combustion of propane. Some authors (Gayan et al, 2004; Dounit et al,

* Corresponding author. Tel + 351-228340500. E-mail:asr@isep.ipp.pt

2001 and Ribeiro and Pinho 2004) experimentally studied combustion reactions in fluidized beds, but only to characterize reaction kinetics and not the heat transfer phenomena involved.

The current investigation presents new results on the heat transfer mechanisms occurring in the membrane walls placed above a bubbling fluidized bed. Based on the experimental data obtained, a new empirical correlation was developed to determine overall heat transfer coefficients.

2. Experimental

2.1 Experimental apparatus

The fluidized bed reactor used in the present study was able to work in either bubbling or circulating bed conditions. A full description of the apparatus is found in Neto (2008). The system was built in stainless steel and was thermally insulated with Kaowool ceramic fibre. The riser portion of the reactor was formed by two vertical sections with water jacket membrane walls. The first part of the reactor, from the distributor to the flange separating it from the first membrane wall section, was 420 mm long, whereas each membrane wall section was 1000 mm long. The internal diameter of the reactor, made in stainless steel AISI 316, was 54.5 mm.

The fluidized bed reactor was heated by means of a 2 kW electrical resistance wrapped around the bubbling bed region of the reactor. Alternatively, propane could be injected and mixed with the fluidizing air, with combustion taking place in and above the bubbling bed, according to the bed particle size.

Heat from the gas solid suspension was transferred to these regions and the corresponding rate of transfer was determined through the energy balance of the cooling water flow. Temperatures were measured with K-type thermocouples, with a precision of 0.4% of the measured value, and were linked to a data acquisition system operating with Labview software. The thermocouple measuring the bed temperature was also connected to a PID temperature controller, which acted upon the bed heating electrical resistance.

To evaluate the pressure drop in the bubbling bed and in the riser section of the reactor, Omega PX 142 pressure transducers were used. These were also connected to the same data acquisition system as the thermocouples.

The fluidizing air flow was measured using a calibrated orifice plate equipped with a differential pressure transducer connected to a data acquisition system. The uncertainties associated with the air flow rates were in the range from 6 to 10 %. The water flow sent to the water jackets was measured by a calibrated rotameter and the uncertainties associated with these flow rates varied between 5 and 10 %.

Throughout the experiments, the bed was formed by silica sand with the following average diameters: 107.5 μm, 142.5 μm, 180 μm, 282.5 μm and 357.5 μm (all belonging to type *B* of the Geldart classification). For all the experiments, the sand was introduced into the bed until a fluidizing pressure drop of 10-15 cm H_2O was obtained.

2.2 Experiments without combustion

During normal operating conditions, in the 400 to 700 ºC bed temperature range and at 1 atm, the air mass flow rate was varied from 0.82 to 1.5 kg/h. Three cooling water flows through the membrane walls were used (35, 73 and 140 kg/h), always in laminar regime. Their values had no influence on the heat transfer rate because the overall resistance to the energy transfer was in the bed side wall.

The experimental work took place above the minimum fluidization velocity and below the terminal settling velocity of the bed particles, with the exception of the smaller bed particles where the fluidizing air superficial velocity was above this value. However no bed pressure drop reduction was found, which meant that no carry over of bed sand particles took place during these runs. All tested situations were therefore for bubbling bed fluidization, and the objective was to find out the importance of the projection of bed particles high above the bed surface on the heat transfer rate towards the water cooled membrane wall of the riser portion of the reactor.

2.3 Experiments with combustion

For these experiments, the electrical resistance was used to reach a bed temperature of 700 - 720ºC, this being the minimum temperature necessary to ignite the propane. The air was fed to the reactor below the distributor plate at flow rates between 0.85 -1.2 kg/h, enabling a bubbling fluidized bed to be obtained. Following this, the propane gas was fed to a point below the reactor at flow rates in the range of $0.095 < \dot{m}_{pro}$ (kg/h) < 0.12, in order to obtain an air to fuel ratio in the range of 8 to 10, so that the mixture equivalence ratio, *r*, was always above one.

The operating conditions which were adopted lead to a bubbling fluidized bed for all air and propane mass flow rates that were used. One of the objectives of this work was to compare the influence of particle size, so the operating conditions were similar in all the experiments made with combustion.

3. Results and Discussion

3.1 Experiments without combustion

In the experiments carried out in the bubbling bed fluidized with air, the following parameters were studied for each particle size: cooling water mass flow rate, bed temperature and fluidized bed air flow rate. Although two sections of water cooled membrane walls were used, there was only significant heat transfer in the region close to the bubbling bed.

From the results obtained it may be concluded that the water mass flow had no influence on the heat transfer rate towards the confining membrane walls. The experiments showed that an increase in the air flow rate increases the temperature difference of the cooling water as heat transfer rate increases, not only by convection of the gas solid flow, but also through radiation effects and, more importantly, due to the augmentation of particle projection towards the membrane walls. This increase in the cooling water outlet temperature is stronger for the smaller bed particle size when the projection of particles from the bed surface is strongest. Higher bed temperatures also means that bed hydrodynamic conditions enhance particle projection and thus the increase in the heat transfer rate.

3.2 Experiments with combustion

These experiments allowed the study of the heat transfer mechanisms in the presence of combustion reactions taking place simultaneously in the bed and immediately above it. They allowed the correlation of bed particle size with combustion, and evaluation of the importance of this interaction on the global heat transfer rate.

The experiments carried out showed that the beds exhibited two different behaviours, depending on the bed particle size. For the three smaller particles (107.5 μm, 142.5 μm, 180 μm) the combustion reaction took place both inside and at the surface of the bed. In addition, as the experiment was occurring, a decrease in the mass of the particles in the bed was observed. The

cause of this decrease was the carryover of particles due to the explosions occurring during the combustion reaction.

For the larger particle sizes (282.5 μm and 357.5 μm), the combustion reaction started inside the bed but rapidly moved towards the transport zone. For these experiments, and in the determination of the global heat transfer coefficient, only the data corresponding to combustion inside the bed was considered. This procedure was assumed in order to ensure that the combustion conditions were similar for all of the particle sizes under study.

The experiments with combustion showed, for all bed particle sizes tested, an increase in the enthalpy of the water when compared with the results obtained without combustion. This increase in the enthalpy of the water was more pronounced for the particle sizes of 107.5 μm, 142.5 μm, 180 μm, and decreased as the particle size was increased.

3.3 Correlation to calculate global heat transfer coefficients with and without combustion

The results obtained indicated that the heating of the cooling water was due to three mechanisms of heat transfer: convection due to the gas flow; radiation between the fluidized bed and the wall, and radiation due to the flame (in the experiments carried out with combustion); convection heat transfer due to particle splashing and projection away from the bed surface. The importance of these mechanisms is enhanced by the combustion reaction.

To calculate the importance of the heat transfer rate towards the confining membrane walls, the enthalpy increase of the cooling water flow was determined and compared with the air convection, the bed, and with the flame radiation components. The difference was attributed to the heat transferred through the particles' movement as they were expelled from the bed by the bursting bubbles reaching the free surface of the bed. The heat transfer area is the membrane wall area and the temperature difference adopted was given by:

$$\Delta T_{ln_{b-w}} = \frac{T_b - T_{go}}{ln\left(\frac{T_b - T_w}{T_{go} - T_w}\right)} \quad (1)$$

where T_b is the bed temperature, T_{go} is the temperature of the gas flow at the end of the first membrane wall heat exchanger, and T_w is the membrane wall temperature determined through the heat transfer balance of the membrane wall heat exchanger.

On the other hand, the cooling water enthalpy increase, $\dot{Q}_w$, was calculated through:

$$\dot{Q}_w = \dot{m}_w c_w \left(T_{wto} - T_{wti}\right) \quad (2)$$

where T_{wi} and T_{wo} are, respectively, the inlet and outlet water temperature, $\dot{m}_w$ is the water mass flow rate, and c_w is the specific heat of the water. From this the overall heat transfer coefficient, h_{glo}, based upon the internal area of the bed riser, or membrane heat exchanger pipe, A_p, and on $\Delta T_{ln_{b-w}}$, was determined according to:

$$Q_w = h_{glo}\, A_p\, \Delta T_{ln_{b-w}} \quad (3)$$

The area of the heat transfer surface was calculated by: $A_p = \pi\, d_i\, L_p$, where L_p is the height of each membrane wall section and d_i is the bed internal diameter.

A simple correlation was determined by means of a dimensional analysis, taking into account the main physical parameters characterizing the experimental conditions, both with and without combustion. The adjustment of this correlation to the experimental data through adequate fitting parameters leads to:

$$Nu = 17{,}3\, Re^{-0.24} Pr \left(\frac{U_0}{U_{mf}}\right)^{-0.024} \left(\frac{d_p}{d_i}\right)^{-0.30} \left(\ln\left(\frac{T_b - T_w}{T_b - T_{go}}\right)\right)^{0.17} r^{0.78} \qquad (4)$$

where U_o and U_{mf} are, respectively, the superficial gas velocity and the minimum fluidization velocity. Re is the Reynolds number $\left(Re = \rho_g U_o d_i / \mu_g\right)$, Pr is the Prandtl number, and r is the mixture equivalence ratio. The fluidizing air properties were determined at the film temperature.

Equation (4) is valid for a bed of sand with an ID of 54.5 mm, either fluidized with air or with combustion of propane, at atmospheric pressure in the region above the bed free surface and according to the following operating limits:

- 107.5 < d_p (µm) < 357.5
- 0.85 < $\dot{m}_a$ (kg/h) < 1.2
- 0.09 < $\dot{m}_{pro}$ (kg/h) < 0.12
- 1.4 < r < 1.9 (r = 1 for the experiments without combustion)
- 400 < T_b (ºC) < 820
- 200 < Re < 400
- 2 < U_o / U_{mf} < 40

An average deviation of 17 % was determined between the calculated and the experimental Nusselt numbers $\left(Nu = h_{glo} d_i / k_g\right)$. Figure 1 validates the Nu calculated from equation (4) against the experimental data.

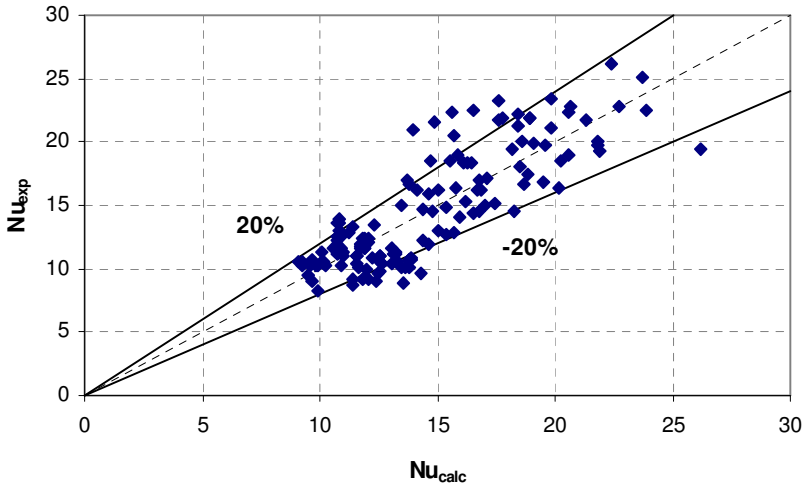

Figure 1 – Validation of equation (4).

4. Conclusions

In these experiments heat transfer was quantified in terms of a global heat transfer coefficient, taking into account the following mechanisms: convection due to the gas solid flow, radiation from the bed surface, and convection heat transfer due to particle projection away from the bed. The importance of these mechanisms is enhanced by the combustion reaction, especially the latter, due to the action of bursting bubbles that appear during the combustion. A correlation for the global heat transfer coefficient was proposed with an average deviation of 17%.

Abstract

Displacement encoding Pulsed Field Gradient Nuclear Magnetic Resonance (PFG-NMR) complements traditional elution measurements of axial dispersivities in packed beds by measuring the variance of the displacement distribution of inert tracers as they move down the packed column. It is clear, however, that NMR derived dispersivities in packed beds of monodisperse solid spheres, the fundamental random porous system for which there exist canonical (1; 2; 3) but incompatible theoretical predictions with few or no adjustable parameters, can be affected by the same experimental complications which have substantially contributed to the puzzling scatter in published dispersion results based on elution experiments. Notable among these are macroscopic flow heterogeneities near walls (4), and inhomogeneous flow injection. Analyzing PFG-NMR results we delineate a transition from a pre-asymptotic to a quasi-asymptotic dispersion regime and extract the true dispersivity of the ideal (unbounded) random pack of solid monodisperse spheres with perfectly homogeneous flow injection.

1 Introduction

In an idealized traditional tracer elution experiment with creeping and constant uni-axial flow of velocity v_o through a random pack of identical spheres a narrow pulse of inert tracers is injected uniformly in a plane perpendicular to the mean flow, at time $t = 0$. Moving through the sample the tracer cloud spreads by a combination of random processes, diffusion and mechanical mixing, and asymptotically a tracer band with Gaussian concentration profile is expected to develop, centered around the mean displacement $\langle\zeta\rangle = v_0 t$. The variance σ^2 of the tracer concentration is proportional to time or to the distance traveled. This proportionality defines the Péclet number dependent dispersion coefficient $D = \sigma^2/2t$ or equivalently the dispersivity $l_d = D/v_0 = \sigma^2/2v_0 t$. The shape of the tracer distribution and its variance σ^2 can then be determined from time series measurements of tracer concentration in the eluent, and from the known flow velocity. With repeat experiments at different flow velocities one determines the Péclet number dependence of the dispersion coefficient, at a fixed degree of mechanical mixing set by the porespace geometry and the length of the sample. In real samples of packed particles complications arise due the presence of macroscopic stagnation zones, which are not the subject of this paper, or due to non-uniformity of flow on the scale of the sample. The latter may be caused for example by uneven flow injection into the sample, by faster flow near containing walls (4), by filtration effects in the sample, or due to sample preparation. One then observes non-Gaussian tracer distributions whose variance grows super-linearly with time or mean displacement as the tracers traverse the sample. The measured dispersion coefficient (or dispersivity) is "effective", meaning sample dependent, and hence the consistency of nominally comparable dispersion data is not what one might hope for (5), as can been seen for example in Fig.1a reproduced from reference (6). It plots measured dispersion coefficients normalized by the molecular diffusion coefficient of the fluid. Many similar canonical plots exist in the literature and

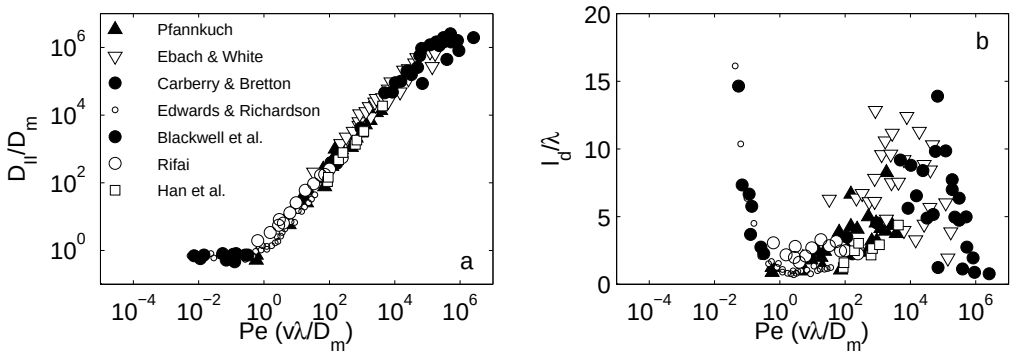

Figure 1: (a) A reproduction of fig. 11 in ref. (6), plotting longitudinal dispersion coefficients for a number of experiments, normalized by the molecular diffusion coefficients, against Péclet number, D/D_m vs. Pe. (b) The same data now replotted as dispersivity normalized by the length scale used to define the Peclet number, $l_d/\lambda = 1/Pe \times D/D_m$, with $\lambda = d\epsilon/(1-\epsilon)$. The porosity of the pack is ϵ, and the diameter of constituent solid spheres is d.

in text books. The two logarithmic axes of Fig.1a are useful in plots of dispersion coefficients spanning several decades, and not coincidentally the Pe-dependence of the dispersion coefficient is frequently discussed in terms of an effective power law coefficient $\delta \ll 1$, $D \propto Pe^{1+\delta}$. It is worth noting, however, that a value of $\delta = 0$ corresponds trivially to pure mechanical mixing, while the interesting physics of the mixing process is buried in the small parameter δ. After dividing the normalized dispersion coefficients by the associated Péclet numbers and replotting the resulting normalized dispersivity on a semi-logarithmic plot in Fig.1b, one appreciates the amount of scatter and uncertainty associated with typical measurements of longitudinal dispersion. The expedient power law description of the data in Fig.1a is considerably less compelling when the data are viewed, closely, on the semi-logarithmic axes in Fig.1b. We also note that Fig.1b contains valuable information which is not readily apparent in the double logarithmic plot of Fig.1a. First, there appears to be a lower bound on the dispersivity approximately where $l_d/\lambda = 0.4$. Second, the data for the largest Pe appear to recover the low dispersivities seen near $Pe = 1$, suggesting that turbulent mixing at high Pe has the same effect on the mixing process as diffusive mixing does near $Pe = 1$.

2 NMR experiments

Many displacement encoding PFG-NMR measurements (7) have been conducted on Stokes flows through randomly packed beds of identical spheres, in order to elucidate a wide range of dispersion phenomena accessible to PFG-NMR investigation (8; 9; 10; 11; 12; 13; 14; 15; 16; 17; 18; 19; 20; 21; 22). The particular case of longitudinal dispersion in packed beds of identical solid spheres is widely studied both because of its theoretical (1; 2; 3) and practical importance, generally using PFG-sequences compensating for internal gradients (23). In our displacement encoding PFG-NMR measurement with flowing water all protons act as tracers. The NMR-signal is is a complex number $S(q) = \langle e^{iq\zeta_j} \rangle = \int P(\zeta) e^{iq\zeta} d\zeta$ where q is the magnitude of the magnetization wave vector $\vec{q}$ set up by the pulsed field gradients, ζ_j is the displacement of the spin o tracer molecule j during an evolution period Δ, typically ranging up to a few seconds, and $P(\zeta)$ is the probability distribution of molecular displacements along the direction of the pulsed field gradients. The PFG-NMR analogue of a traditional tracer elution experiment is one where the degree of mechanical mixing is kept constant by adjusting the evolution time Δ to keep the mean displacement ζ_0 constant, $\Delta = \zeta_0/v_0$. Then the fixed mean displacement ζ_0 takes the role of the sample length in the elution experiment. In contrast to the elution experiment, where mechanical mixing is fixed and the tracer distribution is observed at the end of the sample alone, the NMR experiment can track the displacement of all tracers as they sweep through different mean displacements ζ_0; the degree of mechanical mixing is thus variable continuously. We make use of this property to analyze measurements conducted at fixed velocities v_0 for variable evolution times Δ and correponding mean displace-

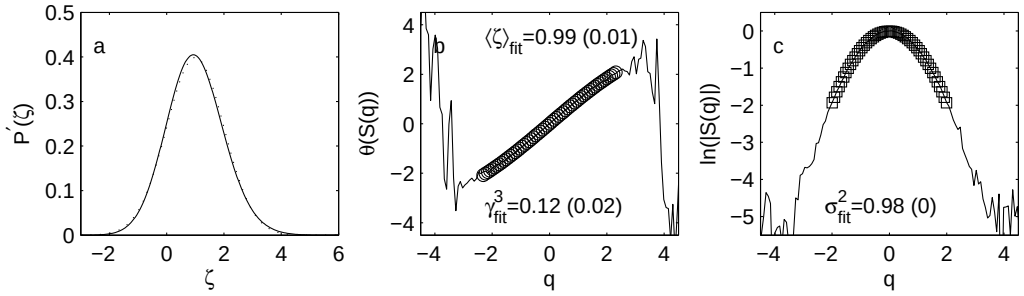

Figure 2: (a) Synthetic skewed displacement distribution P' (solid) with $\langle\zeta\rangle = \sigma^2 = 1$ and skewness factor $\gamma^3/\sigma^3 = 0.15$. Gaussian distribution (dots) with $\langle\zeta\rangle = \sigma^2 = 1$ and $\gamma^3/\sigma^3 = 0$ for comparison. Odd (b) and even (c) cumulant fits (symbols) to synthetic noisy NMR data (solid) calculated from P'. Fit ranges set by self consistent cumulant analysis (20).

ments $\zeta_0 = \Delta v_0$. We find and discuss a transition from a pre-asymptotic (16) to a "quasi-asymptotic" regime (22) in which the intrinsic dispersivity of the random pack of spheres can be determined.

We established creeping water flow through three different packs made of monodisperse borosilicate glass beads of diameter $100\mu m$. They were filled into a plexiglass tube with inner diameter $37.5mm$, to a pack length of $70mm$. Flow distributors placed at the inlet and outlet of the packs assured reasonably homogeneous but presumably imperfect flow injection. The tube was placed into an $85MHz$ imaging system fitted with an imaging gradient set whose maximal gradient strength was a modest $10g/cm$. Axial water flow was established using pulse free ISCO piston pumps. We employed (22) the 13-interval APGSTE sequence (23). All results reported here refer to displacements along the direction of mean flow. The first three terms of a cumulant (16; 24) analysis of the NMR signal $S(q)$, $\ln(S(q)) = \ln(|S(q)|) + i\theta(S(q)) = \sum_{j=1}^{\infty} \frac{(iq)^j}{j!} X_j$ sampled at low q yield the mean $\langle\zeta\rangle = X_1$, the variance $\sigma^2 = X_2$ and the skewness $\gamma^3 = X_3$. These are the first moment and the second and third central moments of $P(\zeta)$, respectively. Evidently odd cumulants appear in the phase θ of the signal, while even cumulants appear in the logarithm of its magnitude. One obtains the effective dispersivity $l_{eff} = \sigma^2/2\langle\zeta\rangle$ and skewness factor γ^3/σ^3 which is a useful non-dimensional measure of the symmetry of a nearly Gaussian distribution. We employed a self consistent cumulant analysis (SCA) (20) to verify that our data was not fitted over excessive fitting ranges in q-space, and to extract the first three cumulants and error bars. The analysis is illustrated in Fig. 2, using synthetic near gaussian displacement distribution constructed to have a realistic skewness factor of $\gamma^3/\sigma^3 = 0.15$, with fit results indicated in the figures. Below we discuss and analyze comparable experimental cumulant results.

3 Results and Discussion

Figure 3 shows SCA-derived flow velocities (a), effective dispersivities (b) and the skewness factors (c) versus mean displacement, obtained in three nominally identical packs labelled P1, P2, P3, using the same volumetric flowrate $\dot{V} = 44ml/min$ and sampling times Δ. The inset shows three full probability distributions obtained in packs P1, P2 and P3 respectively, of displacements at a mean displacement of approximately 37 bead diameters; to the eye they do resemble the skewed distribution of figure 2a. The velocities v_0 of figure 3a are obtained by dividing the phase-derived mean displacement by the corresponding evolution time Δ. First we observe that for displacements larger than some 10 bead diameters d the measured velocity in all samples is constant to within 0.4%. Second, the mean velocity differs from one sample to the next, spanning a range of 5%, despite the fact that the samples were made with the same particles, contained in the same tube, and were prepared, nominally, in the same manner. This is indicative of different packing densities known to occur for random packs. Each sample's porosity can be calculated by $\epsilon = \dot{V}/Av$, where A is the cross section of the tube containing the pack. Third, the measured velocities for displacements of less than about 10 particles are enhanced above the asymptotic value, by up to 2%. This is attributed to surface relaxation which preferentially removes slow spins, near

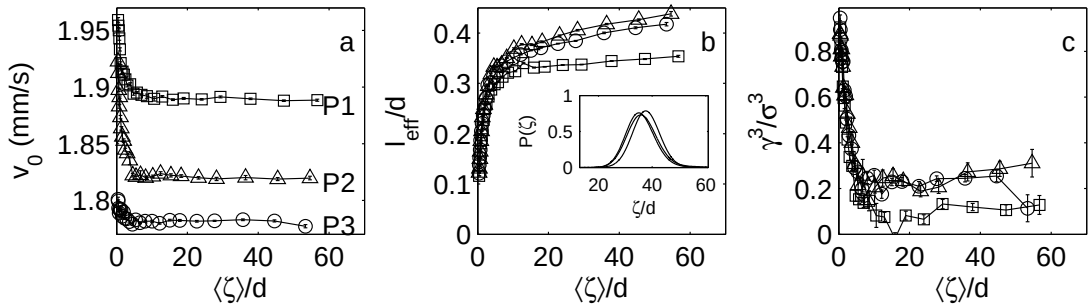

Figure 3: Cumulant derived velocities $v_0 = \langle\zeta\rangle/\Delta$, effective non-dimensional dispersivities $l_{eff} = \sigma^2/2\langle\zeta\rangle d$ and skewness factors γ^3/σ^3, in three nominally identical samples, at the volumetric flow rate 44ml/min. (a) Non-vanishing displacement-relaxation correlations result in enhanced NMR derived velocity readings in the pre-asymptotic regime $\langle\zeta\rangle/d \lesssim 10$. Final velocity readings reflect different packing densities. (b) Effective dispersivities grow approximately linearly with mean displacements, in the quasi-asymptotic regime $\langle\zeta\rangle/d \gtrsim 10$. (c) Decreasing skewness factor in the pre-asymptotic regime, but constant skewness factor in the quasi-asymptotic regime.

the walls, from the measurement. This relaxation-induced bias, also seen in earlier NMR measurements with flow through microporous beads (19), is transient because mechanical mixing ensures that all surviving spins have seen all relaxation environments equally, for mean displacements above about 10 bead diameters. One might therefore suppose that for $\langle\zeta\rangle/d \gtrsim 10$, where the relaxation becomes asymptotic, the dispersion would be asymptotic as well. This, however, is not the case. Figure 3b reveals that the effective dispersivity continues to grow approximately linearly with increasing mean displacement rather than tending towards an asymptotic value. Furthermore figure 3c reveals that after a steep initial drop in the skewness factor occurring roughly where $\langle\zeta\rangle/d < 10$ the displacement distributions remain skewed with approximately constant skewness factor. The linear growth of the effective dispersivity and the roughly constant skewness can be understood quantitatively using a simple model allowing for spatial variations in the drift velocity within the sample. When variations of drift velocities occur on scales larger than the mean displacements attained in the experiments, then variations of the mean velocity are not averaged out by the experiment. We call this regime "quasi-asymptotic" because it is locally asymptotic after about a mean displacement of 10 to 15 sphere diameters, as indicated by the asymptotic relaxation behavior, but globally pre-asymptotic, because all tracers have not yet seen all mean velocities which are present in the sample. In a recent paper(22) we have therefore written the "quasi-asymptotic" displacement distribution as a convolution of a dispersive Gaussian displacement distribution - governed by a single dispersivity l_d which depends on the geometry of the pore space and the Péclet number - with a distribution of mean displacements governed by a reasonably narrow distribution of mean velocities defined over an experimental coarse graining volume given by the longitudinal ($\approx \langle\zeta\rangle$) and transverse ($\approx \sqrt{\langle\zeta\rangle d}$) tracer displacements. One obtains

$$l_{eff} = \sigma^2/2\langle\zeta\rangle = l_d + \frac{1}{2}\langle\beta^2\rangle\langle\zeta\rangle \tag{1}$$

for the measured effective dispersivity l_{eff}. It is equal to the intrinsic dispersivity l_d plus a term proportional to mean displacement and the variance of the distribution of mean velocities divided by the squared mean velocity, $\langle\beta^2\rangle \equiv \langle(v - v_0)^2/v_0^2\rangle$. $\langle\beta^2\rangle$ is approximately constant when the dominant variations of the mean velocity occur on scales larger than the ones set by the experimental coarse graining volume. The observed growth of effective dispersivity is thus linear in $\langle\zeta\rangle$ in figure 3b. The skewness factor is

$$\gamma^3/\sigma^3 = \frac{6l_d\zeta_0^2\langle\beta^2\rangle + \langle\beta^3\rangle\zeta_0^3}{(2l_d\zeta_0 + \langle\beta^2\rangle\zeta_0^2)^{3/2}} \Rightarrow \frac{\langle\beta^3\rangle}{\langle\beta^2\rangle^{3/2}} \tag{2}$$

and it asymptotically approaches the constant and finite skewness factor of the velocity distribution $\langle\beta^3\rangle \equiv \langle(v - v_0)^3\rangle/\langle(v - v_0)^2\rangle^{1.5}$. Using expression (1) we could determine intrinsic dispersivities l_d for different values of the Péclet number $Pe = v\lambda/D_m$ in all three samples, where D_m is the molecular

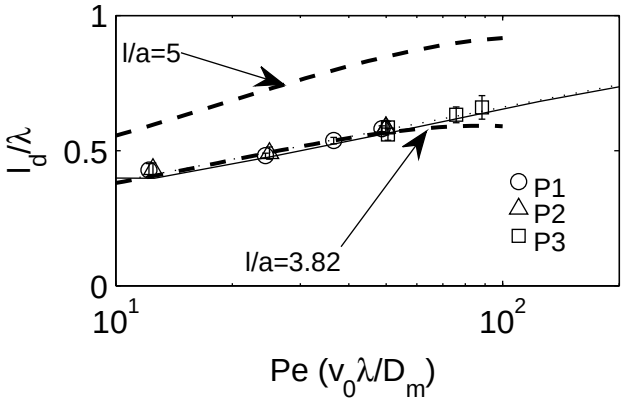

Figure 4: Adapted from ref. (22): Dispersivity vs. Péclet number, scaled by the hydrodynamic length $\lambda = 6r_h$. The dotted line is a linear fit to our data, the solid line from simulations (25), and dashed lines are Saffman's prediction for random networks of identical capillaries having length l and radius a.

diffusion coefficient. When scaled by the hydrodynamic length $\lambda = d \times \epsilon/(1-\epsilon)$ of the pore space all values of l_d/λ collapse onto a straight line in Fig. 4, to within the errors which we carried through the entire analysis. The numerical results by Maier(25) et al. are shown in a thin solid line and agree with our findings, as do Saffman's (1; 2) theoretical results for the dispersivity in a random network of identical capillaries with length l and radius a, shown with a dashed line for the best fit $l/a = 3.82$. The agreement of experiments, simulations and theory are remarkable. For reference we also show Saffman's original estimate $l/a = 5$ which to date has often served for comparisons between theory and experimental results.

4 Conclusion

Large random packs of identical solid spheres are a special case among porous samples where displacement encoding NMR measurements can distinguish dispersion regimes associated with two widely separated length scales: a pre-asymptotic regime, where the relevant dispersive length scale is on the order of a few particle diameters, and a quasi-asymptotic regime, where the relevant macroscopic dispersion length scale is larger than the experimental coarse graining length. The measurements are sensitive to displacement-relaxation correlations which give rise to enhanced measured velocities where the local mixing process is incomplete. The disappearance of enhanced velocity readings signals the end of the pre-asymptotic dispersion regime and the beginning of the quasi asymptotic regime, where measurement and analysis of effective dispersion coefficients yield Péclet-number dependent intrinsic dispersivities of the random pack of spheres, and the variance $\langle \beta^2 \rangle$ particular to the sample. This variance is a measure of macroscopic hydrodynamic sample heterogeneity and is perhaps not irrelevant for a linkage of dispersion and permeability data in other more heterogeneous samples.

Topic: Advancing the chemical engineering fundamentals (Particulate systems)

Introduction

The treatment of the nonuniform particulate solids mixtures with high inclination to segregation is a widespread technological problem. First of all, this problem is the consequence of the necessity to provide the distribution homogeneity of particles differing in size or density in the apparatus working volume. The ignorance of this condition leads to the different residence time of nonuniform particles in the apparatus working volume and reduces the product quality.

On the other hand, the high segregating components make difficult their mixture production and place exacting technological standards upon the mixing equipment. In consequence of high nonuniformity of the mixture particles their segregated flows arise. These flows are situated in dominate areas of the working volume and differ from each other by structural and kinematical characteristics. Traditionally these flows are destructed by means of several special methods.

In the present paper the principle of operating segregated flows is suggested in order to solve the technological problems during the treatment of nonuniform particulate solids. The basic advantage of this principle consists in its realization possibility for many technological applications. These applications may be as follows:

a) differentiation of technological conditions for different particles by means of operation of their residence time in the apparatus working volume;
b) increasing the mixture quality of particulate solids inclined to segregation due to the intensification of longitudinal and transversal mixing segregated flows;
c) separation process organization of traditionally hard separated mixtures by means of intensification of segregated flows of mixtures.

In the present paper a version of practical realization of the above mentioned principle is discussed.

A version of segregated flow operation in apparatus with rotating drum.

The segregated flows especially occur in the course of granular materials treatment when there are steady or cyclic repeated shear flows in apparatus working volumes. That is why the segregated flows are revealed brightly during particulate solids treatment in apparatus having rotating drums. It is well known [1] that the segregated flows formation in a rotating bed of granular materials is very active. The rotating bed process takes place in a rotating drum which has not any nozzles in its working volume.

However our investigation has shown that there are significant segregated flows not only in a nozzleless drum but also in drums provided with peripheral lifting blades (Fig.1.) It is explained by necessity to provide the conditions of blade filling for all the drum length.

* Corresponding author. E-mail: ioo_c4@rambler.ru

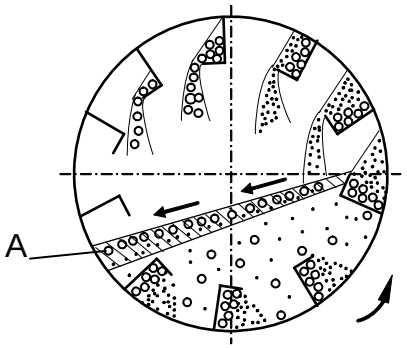

Fig.1. Schematic of segregated flow formation in a cross section of a rotating drum apparatus with peripheral blades: A – is the area of segregated flows formation

In order to carry out this condition it is necessary that the material heap in the lower drum part must be sufficiently big. Then it is evidently that the heap height must be grater than the blade height. In this case a shear gravity flow of particles arises near the free surface of the heap. Because of that the segregated flows of granular materials take place in the upper part of the heap. These flows are characterized by the movement of big or light particles over small or dense ones.

Since the blades are filled at the contact with the above mentioned segregated flow (Fig.1) then initially the blade takes big or light particles from the free surface of the heap. The further filling the blade is fulfilled by small or dense particles from segregated flow depth.

On the other hand as it is shown on Fig.1 when the blade rises from the heap initially small and dense particles are falling from the blade. When the blade goes down towards the heap big and light particles are falling from the blade.

Thus the effect of segregated flows arising in the drum heap is extended to the bed of falling particles in the cross drum section. Taking into consideration that the apparatus with rotating drums widespread are used for heat and mass transfer as well as for hydromechanical process organization we developed a realization version of the principle of operating the segregated flows of granular materials on the basis of the above discussed physical effect.

This version uses the traditional construction of apparatus which consists of horizontal rotating drum with peripheral lifting blades. Basing on the investigation results in terms of segregated flows in the apparatus of the traditional construction we suggested a device allowing the operation by named flows.

The device operating the segregated flows realize the principle of the multistage counter current flows of nonuniform particles [2] and additionally provides the possibility to change their value and direction along and across of the drum axis. The addition of the traditional apparatus by the suggested device allows to set the different treatment time for particles differing in size and density. If the main technological aim is the qualitative mixture production then the residence time of nonuniform components is equalized and longitudinal and transversal mixing segregated flows is organized in the working volume.

Moreover this equipment may be used for separation of particles differing in size and density. In this case the longitudinal countercurrent flows of segregated particles are intensified in the apparatus.

Experimental and analytical research on the efficiency and dynamic characteristics of a multifunctional apparatus

The paper presents the results of experimental and analytical investigations of technological efficiency and dynamic characteristics for multifunctional apparatus at various versions of its technological application.

The basic application versions are the periodic and continuously working mixers also the separator for hard separated materials. Thereby it is noteworthy, that the apparatus construction is rather suitable simultaneously to organize heat-mass transfer processes, because of existence of the falling particles bed in the apparatus working volume.

The experiments on the mixing and separation carried out with the use of hard mixed and hard separated materials respectively. In order to prepare these materials we have used glass beads and polyethylene granules differing in size and density (see Table 1). The particle sizes were choused to complicate the mixing and separation processes.

Table 1 Characteristics of modeling particulate mixtures

Process	Mixture materials	Fraction size $d \cdot 10^{-3}$, m; and its concentration, kg kg^{-1}	Density ρ, kg·m^{-3}
Separation	glass beads	+3,0–3,5; 0,7	2500
	polyethylene granules	+2,5–4,0; 0,3	920
Mixing (periodic)	glass beads	+3,0–3,5; 0,7	2500
	polyethylene granules	+4,0–5,0; 0,3	920
Mixing (continuous)	glass beads	+2,5–3,5; 0,6	2500
	polyethylene granules	+4,0–5,0; 0,4	920

In order to forecast the effect of the segregated flow operation an analytical approach is developed in the paper. This approach is based on an adaptation of the general mass transfer equation for conditions of segregating particulate media.

The dynamics of test component distribution along the drum length *z* is described in the following way

$$S(z)\cdot\frac{\partial(\rho_b\cdot c(z,\tau))}{\partial\tau}=-\frac{\partial(c(z,\tau)\cdot G(z))}{\partial z}+ \\ +D_{dif}\cdot\frac{\partial}{\partial z}\left(S(z)\cdot\rho_b\cdot\frac{\partial c(z,\tau)}{\partial z}\right)+I_l\cdot c_0+S(z)\cdot\rho_b\cdot\left(I_v^+ + I_v^-\right) \quad (1)$$

where *G(z)* is the mixture flux in the drum heap along the drum length, *kg·s*$^{-1}$; $I_v^-(z)=\omega\cdot n\cdot F\cdot c(\tau,z)/(2\pi S(z))$ is the function, describing the exhausting action of the lifting blades; $I_v^+(z)$ is the function modeling the effect of operation of the segregated flows in the falling bed of particles in the drum.

Equation (1) was integrated numerically at the boundary conditions

$$\left.\frac{\partial c}{\partial z}\right|_{z=0,L}=0$$

and initial conditions:

$c(z,0)=c_0$ for separation process,

$c(z,0)=\begin{cases}1, & 0<z<0.42L\\ 0, & 0.42L<z<L\end{cases}$ for periodic mixing process.

The mixture non homogeneity was estimated by means of the variation coefficient determination. This coefficient is calculated as the ration of the standard concentration deviation of the test component to its mean concentration in the mixture expressed as the percentage.

The investigation results for different technological application versions of apparatus are presented on Figs. 2-5. Thereat Figs. 2 and 4 show the mixing and separation dynamics respectively, as the comparison of experimental and calculated data. The authors explain particularly the observed deviation of these data from each other by technical difficulties arising during mixture concentration measuring along the drum length for high segregating materials.

The investigation results reveal that the suggested apparatus is rather effective especially when it is important to process the high segregating materials without sieves and separating gas-liquid flows.

Conclusions

The principle of operation of segregated flows is suggested in order to solve the technological problems during the treatment of nonuniform particulate solids. The basic advantage of this principle consists in its realization possibility for many technological applications. These application versions are determined as follows:

a) differentiation of technological conditions for different particles by means of operation of their residence time in the apparatus working volume;
b) increasing the mixture quality of particulate solids inclined to segregation due to the intensification of longitudinal and transversal mixing segregated flows;
c) separation process organization of traditionally hard separated mixtures by means of intensification of segregated flows of mixtures.

Variant of practical realization of the above mentioned principle on the bases of a rotary apparatus, having rotating drum with peripheral lifting blades is suggested.

The results of experimental and analytical investigations of technological efficiency and dynamic characteristics for multifunctional apparatus at its basic application versions are presented. These basic versions are the periodic and continuously working mixers also the separator for hard separated.

In order to forecast the effect of the segregated flows operation an analytical approach is developed.

The investigation results reveal that the suggested apparatus is rather effective especially when it is important to process the high segregating materials without sieves and separating gas-liquid flows.

List of symbols

c – test component concentration, $kg \cdot kg^{-1}$

c_0 – nominal mixture concentration, $kg \cdot kg^{-1}$

D – drum diameter, m

D_{dif} – quasi-diffusion coefficient, $m^2 s^{-1}$

F – cross section area of a heap on a blade, m^2

$I_l(z)$ – function of the test component distribution in the charging part of apparatus, $kg \cdot s^{-1} m^{-1}$

L – drum length, m

n – lifting blade number

$S(z)$ – cross section area of a heap in the drum, m^2

z – longitudinal coordinate, m

Greek letters

ρ_b – bulk density, $kg \cdot m^{-3}$

τ – time, s

ω – angular velocity, s^{-1}

Keywords: Hindered diffusion, Porous media, Fractal, Simulation
Topic: Advancing the chemical and biological engineering fundamentals.

Abstract

Two-dimensional simulation of porous media using a pore fractal dimension D was performed. Obtained results can be outlined as follows: 1). Starting from large pores with aspect ratio of micro-particle size to pore size λ > 0.001, molecules (or test object) recognise the pore volume as a partially restricted space with reduced fractal dimension. 2). The restriction effect on a molecule depends on pore topology (in the present case on the type of packing). 3). Dramatic reduction of D is observed when λ overcomes 0.01 and approaches λ ~ 0.1 in a 2-D approach, meaning that the test object recognises the pore as one dimensional rather than a 2-D space; in turn, a 3-D system will be recognised by the the test object as a 2-D system. 4). Concerning the hydrodynamic chromatography (HDC) the simulation explains why micro-objects become significantly retarded even at λ ~ 0.01, that is, even when the ratio between the Stokes-Einstein diameter of the diffusing micro-object to the equivalent pore diameter is very small. The developed approach confirms that even for micro-object with a very simple geometry (a square test box) a molecule might be much more sensitive to pore topology than what could be expected by a steric effect. It is possible to expect a more pronounced effect for asymmetric micro-objects in tortuous channels. These results show that the problem of molecular sensitivity towards pore topology may be understood using fractal analysis. Further work will apply this fractal approach to diffusivity behaviour in gel-like and fibre-like or foam structures.

1. Introduction

The quest for higher resolution in macromolecules bio-separation, nano-particles, viruses and micro-organisms, together with the requirement to keep their full bioactivity by preserving their shape and conformation is calling for new approaches in the bio-separation field. A hydrodynamic theory developed for the diffusion and convection of micro-objects in porous media for the case of hindered motion was presented in a previous work of Mota et al. (2006) and can be briefly summarised as follows.

The pore topology plays an important role in the separation of micro-particles of different shapes when the aspect ratio (micro-particle size)/(pore size) approaches λ = 0.1. The complexity of the observed retardation phenomenon needs further investigation to clarify the interaction particle-pore topology mechanism. The obtained results may open interesting applications for bio-separation, for deep bed filtration, and to understand the motion of micro-objects (for instance viruses and nano-particles) in porous media.

2. Hindered diffusion

The effective diffusion coefficient D_e of a solute in a channel is composed of two correction functions, $F_1(\lambda)$ and $F_2(\lambda)$: $D_e = D_0 F_1(\lambda) F_2(\lambda)$, where D_0 is the bulk diffusion coefficient and λ is the ratio of Stokes-Einstein diameter of the diffusing

* Corresponding author. Tel + 351-25360-1191. E-mail: mmota@reitoria.uminho.pt

micro-object d_m to the equivalent pore diameter d_{por}, $\lambda = d_m / d_{por}$. The parameter $F_1(\lambda)$ is the steric partition coefficient, which is defined as the cross-sectional area of the pore available to the solute molecule divided by the total cross-sectional area of the pore

$$F_1(\lambda) = (1-\lambda)^2 \tag{1}$$

The correction factor $F_2(\lambda)$ accounts for the effect of the pore wall on the solvent properties (an increase in the local solvent viscosity near the pore wall) and is often represented by a polynomial series, as displayed in equation (2), or by an exponential function, as displayed in (3). Other model functions are particular cases of (2) or (3)

$$D_e / D_0 = (1-\lambda)^2\left[1 - 2.1044\lambda + 2.089\lambda^3 - 0.948\lambda^5\right],\ \lambda \le 0.5 \tag{2}$$

$$D_e / D_0 = (1 - 1.83\lambda + 4.18\lambda^2)\exp(-6.52\lambda) \tag{3}$$

Numerous experimental results show that hindered diffusion and convection depend not only on equivalent micro-object and pore sizes, but on the pore topology as well, (Mota et al., 2006). Havsteen (1993) analysed non-classical flow through narrow-pored membranes and concluded that when the passages through the membrane become small enough in comparison with the size of the percolating molecules, fractal properties of the pore must be accounted for. Giona et al. (1996) admit that the topology complexity of a fractal pore network modifies the scaling properties of diffusion.

Using a 2-D model, when pore size is significantly larger than a molecule, fractal dimension tends to the topological value of 2. When the pore scale gets close to the size of a molecule, the fractal values become close to the topological dimension of unity. For better understanding transport phenomena in porous materials it is interesting to know how a molecule will behave in the porous space geometry between the aforementioned boundaries.

To consolidate the experimental observations, a two-dimension porous media simulation was made with a disc packing.

3. Simulation conditions

Pore area fractal analysis was performed by a test-box counting method

$$\log\left[N(r)\right] = \log(k) - D_{pa}\log(r) \tag{4}$$

where D_{pa} is the porous area fractal dimension; $N(r)$ is the number of boxes of side length r needed to cover a porous medium image. The test-box simulates a compact micro-object inside the pore space formed by discs packing.

The fractal dimension was measured by means of the commercial software *Fractal Vision* 2.5, Oliver (1992). This software was successfully applied to quantify the surface roughness of flocs and granules and gave a quite reasonable estimation of the fractal dimension, as reported by Bellouti et al. (1997). The *Fractal Vision* algorithm allows determining the fractal dimension of an image tested by three types of box size r = 2, 4 and 6 pixels, Oliver (1992). The molecule size in simulation was assumed to be equal to the test box size r.

Image in pixel's representation has rough bounds with a minimal size resolution of 1 pixel. This roughness simulation imitates the rough channel surface. The ratio of roughness scale to the discs size, that builds the porous medium skeleton, will be variable. The ratio increases when disc size decreases. Such behaviour means that, for a fixed molecule size, decreasing the porous medium scale results in a more active role of roughness. This fact does not contradict known reports. For instance, Douglas, (1989) during simulation of fractal surface adsorption observed a great probability of polymer-surface interaction with increasing roughness.

All images of porous media are considered as cross-sections that are perpendicular to the direction of the molecule diffusion and the measured parameter was the fractal dimension of pore area D_{pa}. The following two-dimensional models of porous media have been used: 1) binary and ternary mixtures of different size and fraction of discs; 2) regular uniform disc square and hexagonal packings.

4. Results and discussion

4.1. Binary and ternary packings

Binary and ternary mixtures of different size and fraction content of discs were built by the algorithm described by Mota et al. (1999). The mixture model was used in the cited research for investigation of porous media geometry: porosity, tortuosity, etc. Procedure of the binary porous medium building was based on randomly packing and compacting of discs in order to obtain high-density packing. The ternary mixture model is built by filling the void space of a binary mixture with smaller discs. In simulation the following model of porous media were used: binary packing of discs with disc size ratio (1) : (1.9), (1) : (3.8), and (1) : (15.7); ternary packing, obtained from binary (1) : (1.9) and (1) : (3.8) packings, disc size ratio (1) : (4.5) : (8.6) and (1) : (3.36) : (12.8).

Fractal dimension of pores cross-section area D_{pa} is shown in Fig. 1 for two types of ternary (data sets 1 and 2) and three types of binary (data sets 3 – 5) systems as a function of fraction of large disc (x_D) in the packing. Discs size ratio is shown in Fig. 1 in brackets. Test disc boundary roughness was 1 pixel.

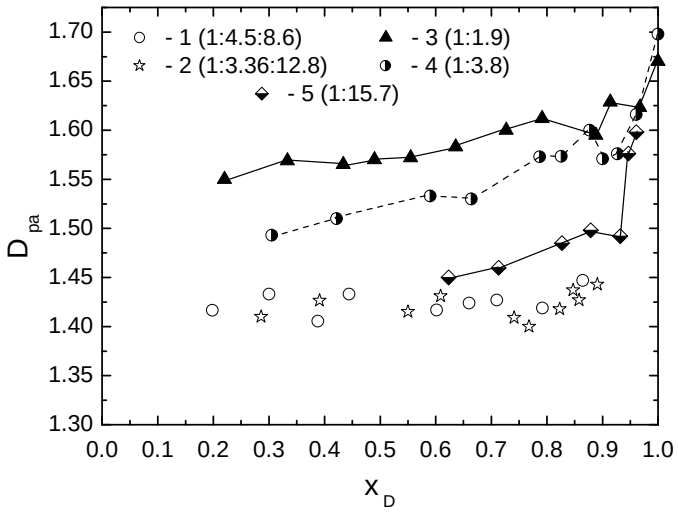

Figure 1. Fractal dimension of the porous area, D_{pa}, vs. fraction of largest discs in the mixture, x_D.

In binary packing, at the same fractional content x_D, increasing discs size ratio significantly reduced the fractal dimension that also depends on the large particle fraction in the mixture, x_D. The most dramatic D_{pa} decrease in mixtures with minimum porosity, occurs for x_D ~ 0.85 – 0.9 (Mota et al., 1999). Ternary mixtures built by filling the appropriate binary mixture free area by smallest discs have lower D_{pa} but are less sensitive to x_D.

For all binary mixtures the fraction of smallest discs which was possible to insert in free space, to get the ternary packing, was less than 10%. This observation leads to the conclusion that even a small amount of fine particles present in the binary packing can significantly affect on macromolecule diffusion because of the change in pores network topology.

Decreasing D_{pa} in binary packings for x_D below 0.8 is related with pore size

distribution when smallest pores have greater impact of the fractal dimension (Mota et al., 2004).

Concerning application to hydrodynamic (HDC) and slalom chromatography, we may assume that the process resolution may be improved by transition from monosize to the binary packing, at the same time saving the number of small size particles, usually more expensive. Binary packing is a well controlled system and the molecule's sensitivity can be controlled by particle fraction content and size ratio.

4.2. Fractality and diffusivity (fractal and steric approach)

To evaluate fractal and diffusive behaviour of porous media regular uniform square and hexagonal disc packings were investigated. The measured parameter was D_{pa} at different disc size versus the aspect ratio r/d_{por}: the ratio between the test-box size (r) and the equivalent pore size was determined based on disc size.

To compare the measured 2-D fractal dimension and 3-D diffusivity D_e/D_0 models (1-3), a re-normalisation procedure was performed based on the assumption that the equivalent pore diameter is $d_{por} = (2/3)[\varepsilon/(1-\varepsilon)]d$, where d is the sphere diameter; ε is the sphere packing porosity, ε = 0.476 for cube packing and 0.26 for hexagonal packing. Hence, the equivalent pore diameter is for cube packing $d_{por} \approx 0.6d$ and for hexagonal packing $d_{por} \approx 0.234d$, consequently, for other packing structures $d_{por} \approx a \cdot d$, a < 1, where d is the diameter of sphere equal to the diameter of disc. Finally, normalised pore size becomes $\lambda = d_m/d_{por} \sim r/d_{por} = r/(a \cdot d)$. Obtained results are shown in Figure 2.

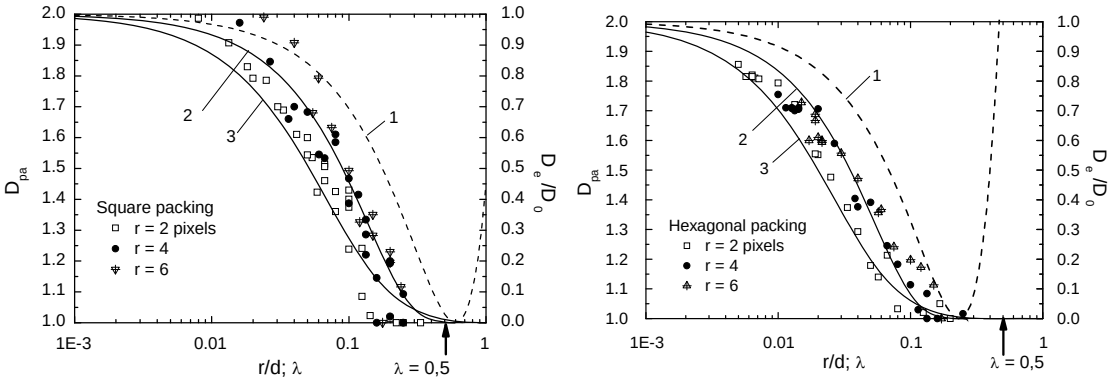

Figure 2. Dependence of D_{pa} on r/d and diffusivity D_e/D_0 on λ for square packing (a) and hexagonal packing (b) of uniform discs. 1 – Equation (1); 2 – Equation (2); and 3 – Equation (3).

The most important simulation result is the following: the range of molecule's "sensitivity" to the pore network cross-section area coincides to the hindered diffusion range. The main measured values of D_{pa} occupy an area between curve 1, equation (1) for steric partition coefficient, (cylindrical pore and spherical molecule) and curve 3, equation (3) for hindered diffusion of a macromolecule, whereas Renkin equation (2) is close to the scattering zone of the determined fractal dimension.

Concerning three dimension porous media, obtained results can be treated as follows: 1). Starting from large pores with λ > 0.001, molecules recognise the pore volume as a partially restricted space with reduced fractal dimension. 2). The restriction effect on a molecule depends on the pore topology (in present case on the type of packing). 3). Dramatic reduction of D_{pa} is observed when λ overcomes values around 0.01 and

approaches λ ~ 0.1 in 2-D approach meaning that the test object recognises the pore as one dimensional rather than a 2-D space; in a 3-D system the test object will recognise the pore with a behaviour closer to a 2-D system. 4). Concerning the hydrodynamic chromatography (Mota et al., 2006) the simulation explains why micro-objects become significantly retarded even at λ ~ 0.01, that is, even when the ratio between the Stokes-Einstein diameter of the diffusing micro-object d_s to the equivalent pore diameter is very low.

The developed approach confirms the fact that even for simple micro-object geometry (= test box) a molecule might be much more sensitive to pore topology than the predicted by the steric effect. It is possible to expect an even more pronounced effect for asymmetric micro-objects in tortuous channels, for example, branched and long macromolecules.

These results show that the problem of molecular sensitivity to pore topology may be satisfactorily solved using fractal analysis. Further work will apply this kind of approach to molecular diffusion inside gel-like, fibre-like or foam structures.

4.3. Molecule – pore size scale estimation

Based on fractal analysis let us estimate the pore diameter and disc (particle) size of uniform hexagonal packing model and the Tyn and Gusek (1990) list of protein sizes, assuming also that the test molecular size is equal to the protein size.

Calculations will be made 1) for hexagonal uniform sphere packing at two cases, namely, when test object recognises pore cross-section area with two fractal dimensions D_{pa} = 1.5 and 1.77.

Noting that $\lambda = r/(a \cdot d)$, for a hexagonal uniform sphere packing when D_{pa} ~ 1.5, the ratio $r/(0.234d)$ is around 0.03, and for D_{pa} ~ 1.3, $r/(0.234d)$ ~ 0.059, therefore, $d = r/(0.234\lambda)$. Assuming that twice the molecular gyration radius r_g is equal to the test box size ($r = 2r_g$), for the above defined D_{pa} we have the particle diameter $d = 2r_g/0.03/0.234$ or $d = 2r_g/0.059/0.234$. Obtained results are given in Table 1.

Table 1

Estimated packing particle size d for hexagonal uniform sphere packing recognised by test-box molecule as fractal medium with fractal dimension D_{pa} = 1.3 and 1.5.

Protein	Molecular weight	r_g, nm	D_{pa} = 1.5		D_{pa} = 1.3	
			d, μm	d_{por}, μm	d, μm	d_{por}, μm
Myoglobin	17,500	1.63	0.46	0.11	0.24	0.055
Ovalbumin	44,000	2.03	0.56	0.14	0.29	0.069
Catalase	225,000	3.98	1.13	0.27	0.58	0.13
Fibrinogen	340,000	14.2	4.05	0.95	2.06	0.48
Collagen	345,000	87.0	24.8	5.8	12.6	2.95
Myosin	493,000	46.8	13.3	3.12	6.78	1.59
DNA	4,000,000	117.0	33.3	7.8	16.9	3.97

Obtained data in Table 1 show that for a spherical particle we may expect a system's molecule-porous medium fractal behaviour in the submicron and micron range close to chromatographic column and micro-column packings for macromolecules such as fibrinogen. Moreover, the obtained particle size falls in the range of HDC and slalom chromatography modes (Hirabayashi and Kasai, 1996). Nevertheless, for proteins such as myoglobin, or ovalbumin, the determined particle/pore size is smaller and locates in nano-scale where data on chromatography are still scarce.

The carried out analysis considers the molecule as a square (2-D), but real

macromolecules are shaped, therefore, such type of macromolecules would be sensitive to pore topology even for r/d_{por} << 0.01 if the pore channel is rough and tortuous.

The drawback to porous media model analysis by the rectangular test box (molecule) is that such approach cannot be considered as a pure fractal analysis because of spatial scales dependence. Nevertheless, it seems interesting to get some “pseudo-fractal” dimension measurements for investigation of linear macromolecule interaction with porous media channel topology.

5. Conclusion

Images of 2-D porous media cross-section area generated on the simplest level of rough disc were analysed by test count method. The range of molecule’s sensitivity to the pore network cross-section area includes the range where hindered diffusion is observed. Renkin equation for hindered diffusivity is close to centreline of fractal dimension measured values.

The results confirm the idea that hindered diffusion effect may be described in fractality terms when pore wall is rough. It is possible to expect a more pronounced effect for asymmetric macromolecules in tortuous channel which can be subject of further investigation.

It was shown that hindered diffusion might be partially described in fractal dimension terms for porous media. Estimation based on bio-molecules size shows that the calculated by D_{pa} particle size is in the submicron and micron ranges close to chromatographic column packings.

It can be concluded that the problem of molecule sensitivity to the pore topology may be satisfactorily solved using fractal features but future work must validate obtained results. Other important point is to study the molecule sensitivity to roughness and tortuosity of pore channels. The present results can contribute theoretically and practically to the development of the hydrodynamic separation methodology and to determine the effective range of HDC method.

Maxwell-Stefan based model for ion exchange in microporous materials

Patrícia F. Lito, Carlos M. Silva[1]
University of Aveiro, Department of Chemistry, CICECO, 3810-193 Aveiro, Portugal

Keywords: Ion Exchange, Titanosilicates, Maxwell-Stefan Equations, Nernst-Planck Equations
Topic: Advancing the chemical and biological engineering fundamentals.

Abstract

The aim of this work is to describe a batch ion exchange process with microporous zeolites using a model based on the generalized Maxwell-Stefan equations and to establish a comparison with the results obtained using the Nernst-Plank equations. Model capability to represent and predict experimental data is analyzed using data available in literature concerning batch experiments on mercury (II) removal from aqueous solution using ETS-4 microporous titanosilicate. Results reveal both models provide good and similar representations as well as fine predictive capability. Therefore, under the particular conditions investigated here, both models can be successfully applied to describe intraparticle ionic transport.

1. Introduction

The use of microporous zeolites as decontaminating agents has gaining considerably attention, mainly due to their interesting adsorption properties and ion exchange capability (Rocha and Anderson, 2000).

Beyond experimental measurements, modelling and simulation are unquestionably valuable tools to study and design a chemical plant. It is fundamental to be able to predict the dynamic behavior of any unit, optimize their operating conditions, and scale up from laboratory to large scale. The objective of this work is to present a theoretical model comprising external and intraparticle mass transport resistances to describe and predict the concentration profiles of a batch ion exchange process in a microporous solid.

Mass transport in dilute ionic systems can be described by the Nernst-Planck (NP) equations (Helfferich, 1995; Rodrigues et al. 1998). In an electrolyte solution, the electrical field induced by the different mobility of counter ions produces an additional force responsible for transference of ions; NP Equations accounts for both concentration and electric potential gradients. However, in this approach the interdiffusion coefficients of counter ions are composition-dependent and the ionic interactions are lumped into effective diffusivities, Furthermore, NP Equations do not take non-ideality effects into account. An alternative approach concerns the application of the Maxwell-Stefan (MS) equations. In the MS based model presented here, the exchanger solid pellets are considered to be pseudo component in the ionic mixture, in a way similar to the Dusty Gas Model approach (Jackson, 1977), and both ion-ion and ion-solid interactions are considered and distinguished (Graham and Dranoff, 1982a,b; Wesselingh et al., 1995). In this treatment one diffusivity coefficient is defined for each pair of components, being dependent on their properties only. In addition, surface diffusion of adsorbed species is taken as the transport mechanism occurring in zeolite micropores, since ions never escape from the force field of the matrix co-ions, due to their small diameters.

In this work a batch ion exchange process in a microporous material is described using a model based on the generalized MS equations. Model capability to represent and predict experimental data is analyzed using data available in literature concerning batch experiments on mercury (II) removal from aqueous solution using ETS-4 microporous titanosilicate. Model results are compared with results obtained using the NP equations.

2. Modelling

The models presented here to describe batch ion exchange were derived assuming the following hypothesis: i) there exist film and intraparticle mass transfer resistances; ii) spherical solid particles; iii) perfectly stirred tank; iv) isothermal and isobaric operation; v) liquid and solid volume changes are neglected; (vi) co-ions are excluded from the zeolite particles (Donnan exclusion); (vii) effect of competitive ions (e.g. H^+) is neglected and (viii) ideal solution.

Maxwell-Stefan Equations. Intraparticle resistance to ion exchange in microporous materials can be described by the generalised MS equations (Krishna and Wesselingh, 1997):

$$-\nabla\mu_i - Fz_i\nabla\phi = \sum_{j=1}^{N}\frac{y_j\Re T(u_i-u_j)}{Đ_{ij}} \tag{1}$$

where $\nabla\mu_i$ is the surface chemical potential gradient of i, F is the Faraday constant, z_i is the charge of component i, $\nabla\phi$ is the electrostatic potential gradient, $Đ_{ij}$ is the MS surface diffusivity of pair i - j, u_i and u_j are the velocities of i and j, $\Re$ is the gas constant, and T is the absolute temperature. The derivation of our MS based model has been presented elsewhere (Silva and Lito, 2007), and considers the following assumptions: i) Surface diffusion is the unique transport mechanism, since due to the very small pore diameters ions never escape from the force field of the matrix co-ions; ii) The solid matrix is considered to be a uniform distribution of fixed charges corresponding to the $(N+1)^{th}$ component. Therefore, $u_{N+1}=0$, as in the well known Dusty Gas Model (Jackson, 1977). Besides, conditions of electroneutrality and nonexistent electric current are assumed:

$$\sum_i q_i z_i = 0 \qquad \text{and} \qquad \sum_i z_i N_i = 0, \qquad i = 1,...,N+1 \tag{2}$$

where q_i is molar concentration of i and N_i is its molar flux. The resulting multicomponent Maxwell-Stefan equations are, in matrix notation:

$$(N) = -q_t[B]^{-1}(\nabla y) - q_t[B]^{-1}(z.y)\varphi \tag{3}$$

where

$$y_i = \frac{q_i}{q_t},\ q_t = \sum_{1=1}^{N+1} q_i,\ B_{ii} = \frac{y_s}{Đ_{is}} + \sum_{\substack{j=1\\ j\neq i}}^{N}\frac{y_j}{Đ_{ij}},\ B_{ij} = -\frac{y_i}{Đ_{ij}},\ \varphi = \frac{-\sum_{i=1}^{N} z_i\left(\sum_{j=1}^{N} L_{ij}\nabla y_j\right)}{\sum_{i=1}^{n} y_i z_i\left(\sum_{i=1}^{n} z_j L_{ji}\right)},\ [L] = [B]^{-1} \tag{4}$$

Nernst-Plank Equations. In dilute ionic solutions, intraparticle flux of each counter ion can be described by the Nernst-Planck equations (Helfferich, 1995):

$$J_i = -D_i\nabla q_i - D_i z_i q_i\frac{F}{RT}\nabla\phi \tag{5}$$

where D_i is the self-diffusion coefficient of species i, q_i is the molar concentration of counter ion i in the particle, z_i is the electrochemical valence of i, F is Faraday constant, $\Re$ is gas constant, T is absolute temperature, ϕ is the electrostatic potential and r is the radial position. NP equations presented here are recast as a special form of Fick's first law, in nondimensional form, with concentrations expressed in equivalents:

$$N_i^* = -D_{ij}^*\left(\frac{\partial y_i}{\partial \xi}\right), \text{ with } \quad D_{ij}^* = \frac{\delta\left(z_i y_i + z_j y_j\right)}{z_i y_i + \delta z_j y_j}, \tag{6}$$

Nondimensional variables are defined as follows:

$$\delta = \frac{D_j}{D_i}\ y_i = \frac{z_i q_i}{Q},\ \xi = \frac{r}{R},\ N_i^* = \frac{z_i R}{Q D_i} N_i \tag{7}$$

where Q is the ion exchanger capacity and R is the particle radius. The above equations were developed assuming conditions of electroneutrality and nonexistent electric current.

Material balances, initial and boundary conditions, and equilibrium isotherm. Concerning diffusing components, we deal with counter ions A and B: A is the pollutant we want to remove from solution $\left(\mathrm{Hg}^{2+}\right)$, using an ion exchanger initially in B– form $\left(\mathrm{Na}^{+}\right)$. Therefore, the material balances in the particle and in the reservoir are, respectively:

$$\left(\frac{\partial q_A}{\partial t}\right) = -\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2 N_A\right) \tag{8}$$

$$\frac{\partial C_A}{\partial t} = -\frac{V_s}{V_L}\frac{\partial \bar{q}_A}{\partial t} \tag{9}$$

where C_A is the concentration of A in bulk solution, and V_s and V_L are the solid and fluid phase volumes, respectively. The average loading per unit particle is given by:

$$\bar{q}_A = \frac{3}{R_p^3}\int_0^R r^2 q_A dr \tag{10}$$

The above differential equations are subjected to the following initial and boundary conditions:

$$t = 0, \qquad \begin{cases} q_A = \bar{q}_A = 0 \\ C_A = C_{A,0} \end{cases} \tag{11}$$

$$r = R, \qquad q_A = q_{A,R} \tag{12}$$

$$r = 0, \qquad \left(\frac{\partial q_A}{\partial r}\right) = 0 \tag{13}$$

The concentration at the interface is determined by the equality of internal and external fluxes, i.e.,

$$N_A A\big|_{r=R} = A k_c\left(C_A - C_{A,R}\right) \tag{14}$$

where k_c is the convective mass transfer coefficient and A is the particle surface area.

In this work, the equilibrium between bulk solution and ion exchanger is represented by the Freundlich equation, given the good equilibrium representation obtained in the experimental conditions studied. Thus

$$q_A = K_F C_A^{1/n} \tag{15}$$

where K_F and n are the Freundlich parameters.

Solution Approach. The simultaneous solution of that set of differential and algebraic equations gives the concentration of counter ions in the fluid, and their concentration profiles in the solid phase as function of position and time. The models have been solved numerically using the Method of Lines (Schiesser, 1991) and integrated by the Finite-Difference approach. For that purpose, two programs in Matlab has been written to solve the resulting Ordinary Differential Equations (ODEs) with finite-difference approach. Ode15s has been used to integrate these set of ODEs of the initial-value type. Maxwell-Stefan diffusivities, self-diffusion coefficients and film mass transfer coefficient were obtained by optimization.

Data Source. The case studied is this work is mercury (II) removal from aqueous solution using ETS-4 microporous titanosilicate. Experimental data and physical properties of ETS-4 may be found elsewhere (Lopes et al., 2007). Experimental conditions are listed in Table 1.

Table 1 – Experimental conditions of data used in calculations (Lopes et al., 2007).

Exp. Conditions	Exp. 1	Exp. 2	Exp. 3
Temperature, K	295 ± 1		
Solution volume, 10^{-3} m^3	2		
Initial Hg^{2+} conc., $10^{-6}\ kg/m^3$	50		
Mass of ETS-4, $10^{-6}\ kg$	1.63	5.06	12.2

3. Results and Discussion

Figure 2 shows experimental data and results obtained with both MS and NP based models, plotted in $C_A(t)/C_{A0}$ *versus* time form. Calculated results, namely MS diffusivities and NP self-diffusion coefficients, the mass transfer coefficients for each model, and average absolute deviations (AAD) found are listed in Table 2. Figure 1 points out the good representations achieved for the experimental data, corresponding to $AAD_{\mathrm{MS}} = 5.37\%$ and $AAD_{\mathrm{NP}} = 5.27\%$; an accurate correlation is accomplished even in the transition from steep descent to the horizontal branch, where kinetic curves are most difficult to fit. Furthermore, the comparison of results shows their similar fitting capability to represent such data.

The diffusion coefficients optimized with both models (Table 2) have the same order of magnitude, i.e., $10^{-20} - 10^{-18}$ m^{2}s^{-1}. These values are consistent with the small pore diameters of ETS-4 (0.3-0.4 nm) and follows others found in literature (Barrer and Rees, 1959; Coker and Rees, 2005). It should be noted, however, that MS and NP diffusivities do not have to be identical because of their distinct intrinsic physical meaning; MS diffusivities characterize the interaction between each pair of species in the mixture, including the solid fixed ionic charges, whereas NP self diffusion coefficients represent the mobility with which counter ions diffuse in the ion exchanger. Moreover, the calculated convective mass transfer coefficients are almost the same (4.748×10^{-3} m.s^{-1} and 4.740×10^{-3} m.s^{-1}, respectively).

The predictive capability of both models may be assessed from Figure 3, where simulations of Exp. 1 and 2 obtained with parameters optimized from Exp.3 alone are graphed. It may be observed that both models perform similarly, as NP and MS predictive curves practically overlap. The $AADs$ of the correlations and predictions are compiled in Table 3, and prove that both models offer good predictions with modest global deviations increments over those corresponding to correlation. With respect to the individual $AADs$, they are equally ordered, i.e. $AAA_3 < AAA_2 < AAA_1$. Furthermore, passing from correlation to prediction both $AADs$ for Exp.2 diminish and both $AADs$ for Exp.1 increase. Nonetheless, Nernst-Planck based model results are still slightly better. Therefore, under the conditions investigated, both approaches can be applied successfully to describe intraparticle ionic transport.

Table 2 – Calculated results with the MS and NP based models of this work.

Maxwell-Stefan				
$Đ_{As}\,[m^2 s^{-1}]$	$Đ_{Bs}\,[m^2 s^{-1}]$	$Đ_{AB}\,[m^2 s^{-1}]$	$k_c\,[m\,s^{-1}]$	AAD [%]

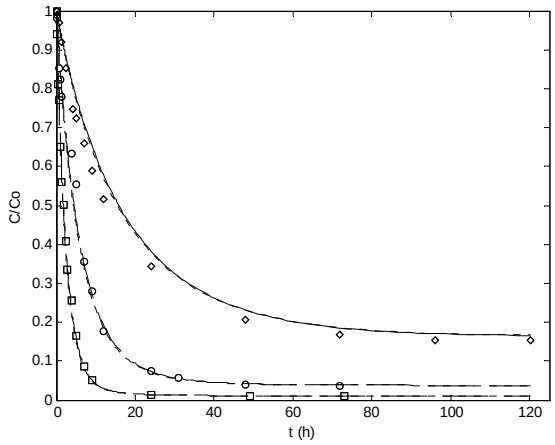

Figure 2 – Normalized concentration of bulk solution *versus* time: modelling and experimental data. Full and dashed lines are representations achieved optimising all data with NP and MS based models, respectively; Symbols: ◊ Exp.1; ○Exp.2 and □ Exp.3 (see Table1).

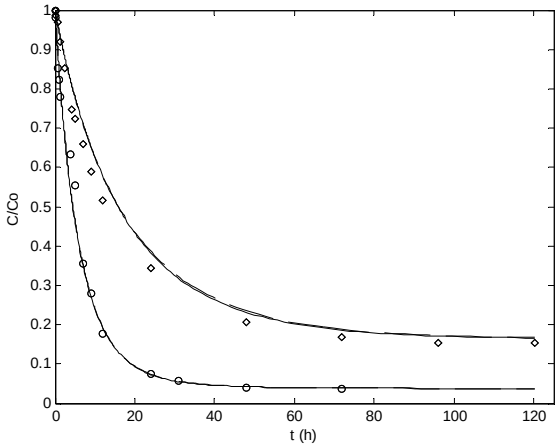

Figure 3 – Prediction ability of MS and NP based models. Full and dashed lines are predictions obtained with parameters independently fitted to the third set of data (not represented here, for simplicity), with NP and MS based models, respectively. Symbols: same as Figure 2.

4. Conclusions

A comparison between MS and NP based models to describe ion exchange in microporous materials has been accomplished, using experimental data from literature. Results reveal both models provide good data representation, as well as exhibit fine predictive capability. The advantageous of the MS description, which arise particularly from taking into account ion-ion and ion-solid interactions, are not highlighted here. Such result can be ascribed to the experimental conditions used, namely dilute ionic solutions and binary exchange. However, it is expected theoretically that these models will behave differently in concentrated solutions and in multicomponent systems; NP equations lump ionic interactions into effective diffusivities and are not able to take non-ideality effects into account. In the whole, under the conditions studied here both models can be successfully applied to describe ion exchange process in microporous crystalline solids.

Topic: Advancing the chemical and biological engineering fundamentals

Abstract

This paper discusses the application of a new transient simulation method, called the sequencing method, to solve a model representing a fixed bed adsorption column. In each time step, convection and mass transfer are applied successively on the column's mesh. Numerical simulations are given for linear adsorption isotherms. These results are compared with the traditional finite difference method. The results show that the sequencing method yields excellent fluid and solid concentration profiles along the column's length and a more accurate prediction of breakthrough time than the finite difference method.

1. Introduction

Most separation and purification processes based on sorption technology use continuous flow columns. Starting at the inlet, the saturated solid sorbent zone gradually extends throughout the column, the sorbate eventually breaking through the column. The breakthrough time represents the duration of ongoing sorption until a predefined exit threshold sorbate concentration is reached. Any optimized column system is based on the accurate prediction of breakthrough time under given specific operating conditions.

Several common numerical methods have been used to approximate partial differential equations (PDEs) to ordinary differential equations (ODEs) for numerical simulation: finite difference methods (FDM), finite element methods (FEM) and orthogonal collocation methods (OCM) (Santacesaria, *et al.* 1982; Srivastava and Joseph, 1984; Gu *et al*., 1990; Gu *et al*., 1992; Gu *et al*., 1993; Altenhöner *et al*., 1997; Strube *et al*., 1997; Kaczmarski *et al*., 1997). When treating a method without diffusion, most methods introduce some form of diffusion called numerical diffusion (Finlayson, 1992). A numerical method called the Sequencing Method (SM) for solving convection-dispersion-reaction equations of homogeneous tubular reactor was recently proposed by Renou et al. (2003). The SM is based on the separation of the various phenomena. At each time step, convection, dispersion and reaction are applied successively on the reactor mesh. This method exhibits excellent shock capturing features for weakly dispersive reactors, and accurate simulations are also obtained for highly dispersive reactors. In the latter case, the only minor drawback is the fact that the SM has some problems to capture the inlet gradient correctly

The aim of this work was to investigate the sequencing method for solving the mathematical model depicting a fixed bed adsorption column, including the column's hydrodynamics and mass transfer on the fluid and solid phases. In the solution of the mathematical model, an extension of the sequencing method is proposed for solving heterogeneous column systems consisting of convection and transport equations. These are compared with the traditional numerical method of finite differences.

2. Mathematical modeling

The effect of axial dispersion is neglected because in real chromatographic systems, which are dominated by convection rather than by diffusion, this simplification can be applied without loss of accuracy (Zhong &Guiochon 1996, Dünnebier *et al*., 1998; Dünnebier & Klatt, 2000). The differential equations governing linear adsorption are given by two equations, the first a mass balance in the fluid phase and the second a mass balance in the stationary phase (Finlayson, 2006).

$$\phi\frac{\partial c}{\partial t'}+\phi V\frac{\partial c}{\partial x'}+(1-\phi)\frac{\partial n}{\partial t'}=0 \tag{1}$$

$$\frac{\partial n}{\partial t'}=k(\gamma c-n) \tag{2}$$

where c is the fluid concentration (moles per fluid volume), n is the concentration on the solid adsorbent (moles per solid volume), ϕ is the void fraction in the bed, V is the fluid velocity, t' is time, x' is distance down the bed, k is a mass transfer coefficient, and γ is the slope of the equilibrium line, n vs. c. The initial conditions give the concentration in the fluid phase and adsorbed phase at time zero, which, in this example, is no concentration at all.

$$c(x,0)=0 \tag{3}$$

$$n(x,0)=0 \tag{4}$$

The only boundary condition is the inlet concentration, here taken as 1.0.

$$c(0,t)=1 \tag{5}$$

The equations are written nondimensionally using the following variables:

$$x=\frac{x'k}{V}\qquad t=kt' \tag{6}$$

Equation (1) is

$$\frac{\partial c}{\partial t}+\frac{\partial c}{\partial x}+\frac{1-\phi}{\phi}(\gamma c-n)=0 \tag{7}$$

$$\frac{\partial n}{\partial t}=\gamma c-n \tag{8}$$

3. Simulation results

The model proposed here consists of a system of partial differential equations (Equations 7 and 8), whose solution is required for the transient simulations. Two approximation methods were used: the sequencing method and the finite difference method.

3.1. Sequencing method

At each time step, convection and mass transfer between the fluid and solid phases are applied successively on the column's phase mesh. The solution for each subsystem becomes the initial condition of the next subsystem. This can be described mathematically by the following algorithm. For a given column, let the initial condition be the profile of the fluid phase and the profile of solid phase. The initial profile of the fluid phase is used as an initial condition for the following convective subsystem, which is solved for one time step Δt

$$\frac{\partial c^*(x,t)}{\partial t}=-\frac{\partial c^*(x,t)}{\partial x} \tag{9}$$

$$c^*(x,0)=c_0(x) \tag{10}$$

$$c^*(0,t) = c_{in}(t) \tag{11}$$

where $c^*(z,t)$ represents the variable state associated with the convection part of the simulated problem. Next, the result of the solution for the fluid phase convection profile is passed through the following transfer subsystem, where it serves as the initial condition such that $c^*_{\Delta t}(x) = c^*(x,\Delta t)$ for a time step Δt

$$\frac{\partial c(x,t)}{\partial t} = -\gamma \frac{1-\phi}{\phi} c(x,t) + \frac{1-\phi}{\phi} n(x,t) \tag{16}$$

$$c(x,0) = c^*_{\Delta t}(x) \tag{17}$$

and the solid phase

$$\frac{\partial n(x,t)}{\partial t} = \gamma c(x,t) - n(x,t) \tag{18}$$

with an initial condition of $n(x,0)$.

For a time step Δt, N elements of dimension Δx are used to define the reactor mesh. The following values are used:

$$\Delta x = \frac{L}{N} \tag{19}$$

$$\Delta t = \frac{\Delta x}{V} \tag{20}$$

Therefore, the choice of the mesh's dimensions determines the time and space discretization. The resolution of the convection subsystem can be treated as a delay system from an input-output standpoint. Thus, at each time step, the data are moved one step forward in the mesh, the column's output concentration is removed and the concentration at the column inlet is placed at position one in the mesh. The mass transfer subsystem (Equations 16 and 18) is a linear system:

$$\begin{bmatrix} \dot{c}_1 \\ \vdots \\ \dot{c}_N \\ \\ \dot{n}_1 \\ \vdots \\ \dot{n}_N \end{bmatrix} = \begin{bmatrix} -\gamma\frac{1-\phi}{\phi} & \cdots & 0 & \frac{1-\phi}{\phi} & \cdots & 0 \\ & \vdots & & & \vdots & \\ 0 & \cdots & -\gamma\frac{1-\phi}{\phi} & 0 & \cdots & \frac{1-\phi}{\phi} \\ & \cdots & & & \cdots & \\ \gamma & \cdots & 0 & -1 & \cdots & 0 \\ & \vdots & & & \vdots & \\ 0 & \cdots & \gamma & 0 & \cdots & -1 \end{bmatrix} \begin{bmatrix} c_1 \\ \vdots \\ c_N \\ \\ n_1 \\ \vdots \\ n_N \end{bmatrix} \tag{21}$$

Since this system is linear, it can be solved for a given Δt using a transition matrix formulation:

$$\frac{d\mathbf{y}}{dt} = \mathbf{A}\mathbf{y} + \mathbf{b} \qquad \mathbf{y}(0) = \mathbf{y}_0 \tag{22}$$

The solution of this equation is the solution to the general Equations (7) and (8) for a time step Δt and is given by:

$$\mathbf{y} = \exp(\mathbf{A}\Delta t)\mathrm{y}_0 \tag{23}$$

Two different values are considered for the slope of the equilibrium line: 2 and 0.1. A value of 2 represents a high adsorption capacity while 0.1 indicates low adsorption capacity. The numerical values adopted for the process parameters are taken from Finlayson (2006). Figures 1-3 show the results for $\gamma = 2$ and were obtained using only 101 nodes. The solution is plotted at $t = 0.2$, $t = 0.4$, $t = 0.6$, $t = 0.8$, and at $t = 1.0$. Figure 1 shows the solution for c, using the sequencing method, while Figure 2 shows the corresponding solution for n. Figure 3 shows the breakthrough curve found with the sequencing method. The c profiles are steep while the n profiles are not.

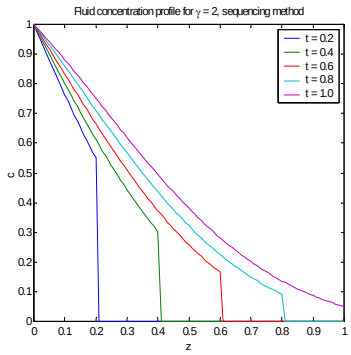

Figure 1. Fluid concentration for $\gamma = 2$ by the sequencing method

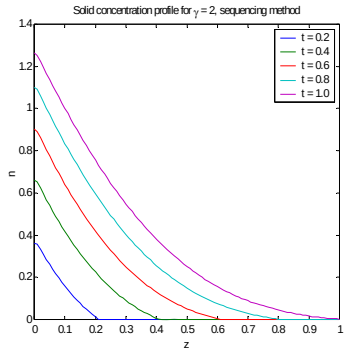

Figure 2. Solid concentration for $\gamma = 2$ by the sequencing method

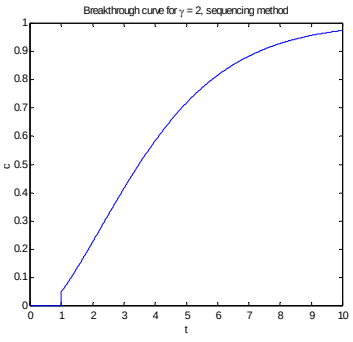

Figure 3. Breakthrough curve for $\gamma = 2$ by the sequencing method

At equilibrium, the value of n is $\gamma c = 2$. This indicates that the adsorption capacity of the bed is very large, resulting in a rapid reduction of c with distance; all the material is adsorbed.

3.2. Finite difference method

Simulation by the FDM is done using the explicit, upstream finite difference method, i.e., upstream difference for the first order partial derivative, and the explicit method is applied to the time derivative to obtain the working equations (Finlayson, 2006).

$$\frac{c_i^{k+1} - c_i^k}{\Delta t} = -\frac{c_i^k - c_{i-1}^k}{\Delta x} - \frac{1-\phi}{\phi}\left(\gamma c_i^k - n_i^k\right) \tag{24}$$

$$\frac{n_i^{k+1} - n_i^k}{\Delta t} = \gamma c_i^k - n_i^k \tag{25}$$

The solution obtained with this method when the inlet condition undergoes a step change is shown in Figures 4-6. This solution was obtained using only 101 nodes; the sharp front is steady over quite a large region. Keep in mind that the exact solution is a vertical line at the position $x = t$.

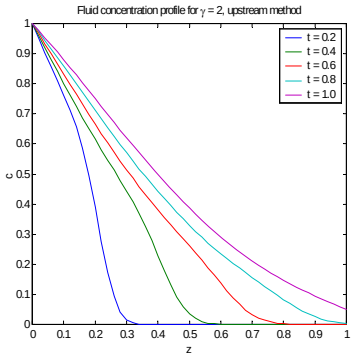

Figure 4. Fluid concentration for $\gamma = 2$ by the upstream method

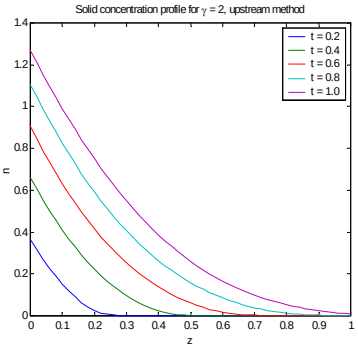

Figure 5. Solid concentration for $\gamma = 2$ by the upstream method

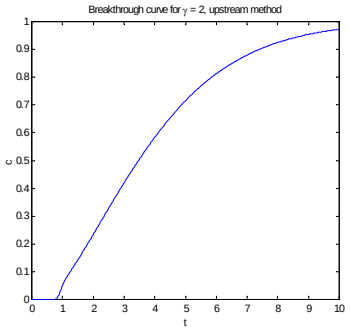

Figure 6. Breakthrough curve for $\gamma = 2$ by the upstream method

Next, the value of γ is changed to 0.1. The bed's adsorptive capacity is lower, so the problem resembles the advection equation. The liquid and solid concentration profiles and the breakthrough curve are shown in Figures 7-12, which also indicate that the results are evened out by the upstream explicit method.

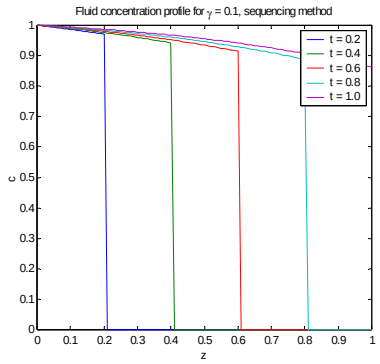

Figure 7. Fluid concentration for $\gamma = 0.1$ by the sequencing method

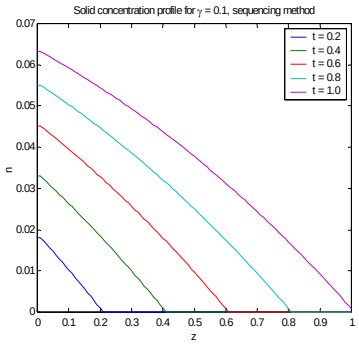

Figure 8. Solid concentration for $\gamma = 0.1$ by the sequencing method

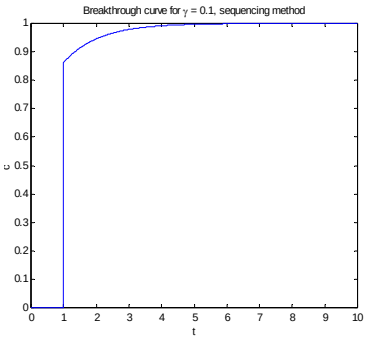

Figure 9. Breakthrough curve for $\gamma = 0.1$ by the sequencing method

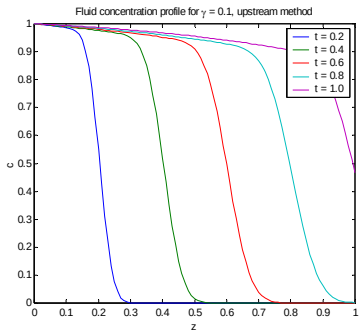

Figure 10. Fluid concentration for $\gamma = 0.1$ by the upstream method

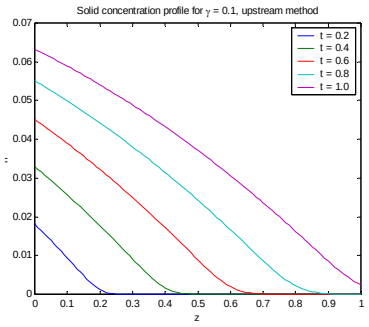

Figure 11. Solid concentration for $\gamma = 0.1$ by the upstream method

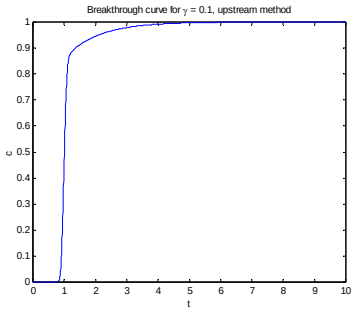

Figure 12. Breakthrough curve for $\gamma = 0.1$ by the upstream method

An analysis of the results confirms that, overall, both the numerical approaches capture the behavior of the column. Although the FDM method yields good results, the profile for c is not as steep as that obtained with the sequencing method. In Table 1 indicates the computation times (on a 800 MHz PC with 256 Mb RAM) for the transient profiles displayed in Figures 1-12. As can be seen, the sequencing method is generally faster.

Table 1. Computation time for transient profiles.

	$\gamma = 2$	$\gamma = 0.1$
SM	2.47 s	2.31 s
FDM	12.47 s	12.52 s

Conclusions

A new algorithm was proposed for simulating adsorption columns, based on a time solution approach of the PDE model, and was validated by phenomenological arguments. This approach implies the successive solution of a specific sub-problem describing each phenomenon. The column simulations showed that the SM method yields adequate transient responses to step inputs. The FDM method also provided good results, but the concentration profile was steady and considerably less steep than the sequencing method solution. Because the SM method can account for sharp inputs, it can more accurately predict breakthrough time. Finally, a comparison was made of the computational efficiency of two numerical methods for solving the transient

problem, i.e., the sequencing method and the finite difference method used in this work.

Keywords: adsorption, methanol, water, SAPO-18
Topic: Advancing the chemical and biological engineering fundamentals

Abstract

This work deals with the adsorption process of both water and methanol over SAPO-18, studied by means of pulse techniques. The values of the kinetic and equilibrium constants have been calculated by fitting the experimental response of the injections. Runs have been performed in an Autochem II equipment coupled to a mass spectrometer. It is concluded that the capacity of water vapour to be adsorbed on acid sites effectively hinders the transformation of methanol into dimethyl ether, since the equilibrium values are similar for both systems, while the adsorption rate of water is one order of magnitude higher.

1. Introduction

Dimethyl ether (DME) has aroused great interest, as it can be used directly as a diesel fuel for automobiles with a high cetane number, lower NO_x emission, near-zero exhaust production and reduced engine noise compared to conventional diesel fuel (Bo et al., 2006). The use of this new fuel is a way of promoting the utilization of diesel engine cars, since these engines are more efficient in reducing CO_2 emissions than those of gasoline (Fei et al., 2006a,b). Moreover, DME is a substitute for LPG in geographic areas with no oil supplies, and it is suitable for the generation of the H_2 required for fuell cells, especially in automotion.

The synthesis of DME from methanol leads to a high amount of water in the reaction medium, which has a considerable unfavourable effect, as it causes a decrease in the equilibrium values of DME yield and selectivity. Moreover, it may attenuate the activity of the acid function, due to the adsorption on active sites. In a previous work, Aguayo et al. (2005) reported the poor hydrothermal stability of γ-Al_2O_3, an acidic function commonly used in the synthesis of DME.

The possibility of using an alternative acidic function has been investigated. The selected catalyst for this paper is a SAPO-18 silicoaluminophosphate. Several authors have suggested that water in the reaction medium may attenuate the deactivation of the catalyst, as it might shift the coke formed over its active sites (Morán, 2002).

2. Experimental

The catalyst has been prepared in the laboratory following the method proposed by Chen et al. (1994). Runs have been performed by using pulse techniques, in a mass spectrometer (Omnistar from Pfeiffer) coupled to a catalyst characterization equipment (Autochem II 2920), provided with a TCD detector.

The experimental procedure is as follows. The first step is a sweeping stage with an inert gas (helium) at 400 ºC, in order to remove the physically adsorbed impurities. Subsequently, the temperature required for the adsorption process is established. Runs have been performed using different temperatures, in the range 200-400 ºC for water vapour-SAPO system, and 150-250 ºC for methanol-SAPO system. The adsorption of methanol has been carried out at

lower temperature in order to limit the methanol dehydration reaction, which takes place at temperatures above 250 ºC. In each run five pulses of helium saturated with water or methanol have been injected, in order to saturate the catalyst sample.

The modelling of the experimental response (signal of water or methanol collected in the mass spectrometer) allows for calculating the mass transfer coefficients, diffusivities and kinetic constants of the adsorption process. In order to simplify the model, the following assumptions have been made: (i) there is no radial temperature or concentration gradient, (ii) there is no axial heat or mass dispersion in the gas phase, (iii) the physical properties of both gas and solid phase are constant, (iv) pressure drop is negligible, (v) mass transfer rate is expressed by means of an equation including a linear gradient, (vi) the mass transfer resistances in both gas and solid phase are included in an overall mass transfer coefficient, k.

The mass balance for the catalyst is:

$$\frac{\partial x}{\partial t} = \frac{k}{(1-\varepsilon)\rho_{solid}}\left[(K_{eq}\, y) - x\right] \quad (1)$$

where x is the adsorbate (water or methanol) concentration in the solid phase, y is the concentration of the adsorbate in the gas phase, ε the porosity, k the kinetic constant and K_{eq} the equilibrium constant of the adsorption process. On the other hand, the mass balance for the gas phase is:

$$\frac{\partial y}{\partial t} = -\frac{Q}{S\varepsilon}\frac{\partial y}{\partial l} - \frac{RT}{\varepsilon}k\left[(K_{eq}\, y) - x\right] \quad (2)$$

where Q is the gas flow and S the cross section of the catalyst bed.

The Langmuir model has been used to describe the adsorption equilibrium:

$$\frac{1}{k_{eq}} = \frac{1}{k_L x_m} + \frac{y}{x_m} \quad (3)$$

where k_L is the Langmuir equilibrium constant (ratio between the adsorption and desorption rates) and x_m the maximum amount of adsorbate in the solid phase.

The system of partial differential equations has been solved by means of a programme written in MATLAB. The differential equations have been approximated using the line method, which is a numerical method based on finite differences. The parameters to optimize are the kinetic and equilibrium constants of adsorption. The objective function used for kinetic parameter optimization is the sum of square residuals:

$$\Phi = \sum \left(y_{cal} - y_{exp}\right)^2 \quad (4)$$

where Φ is the objective function, and y_{cal} and y_{exp}, respectively, the calculated and experimental values of the response (partial pressure of the adsorbate, obtained from the data collected in the mass spectrometer).

Figure 1 displays, as an example, the fitting between the experimental values and those calculated of partial pressure of methanol for a pulse injected at 200 ºC. It is concluded that the chosen methodology is suitable to describe the adsorption process over SAPO-18 catalyst.

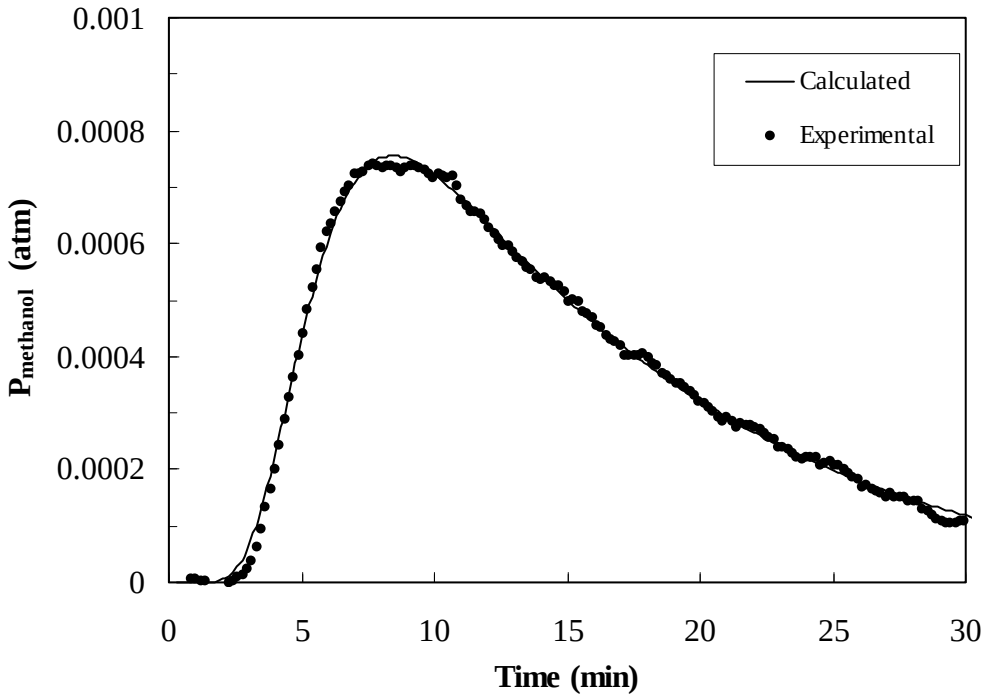

Figure 1. Fitting of the experimental response of an injection of methanol over SAPO-18 at 200 ºC.

3. Results and discussion

Adsorption of water over SAPO-18

First of all, the adsorption process of water vapour over SAPO-18 has been studied, using four different temperatures: 200, 250, 275 and 300 ºC. Figures 2 and 3 display the TCD signal obtained for two experiments performed at 200 ºC and 300 ºC, respectively. It is observed that in the experiment performed at 200 ºC, the signal corresponding to the first peak is lower than the signal of subsequent peaks. This means that part of the volume injected in the first pulse is retained in the surface of SAPO-18 catalyst (irreversibly adsorbed or chemisorbed). The fraction of the injected volume which is not chemisorbed, generates a signal of lower area than that of the last peaks of the experiment, corresponding to a process of physical adsorption, in which all the injected volume is desorbed.

When the adsorption process takes place at temperatures higher than 250 ºC (Figure 3 shows, as an example, the signal obtained at 300 ºC), on the contrary, the adsorption of water is a reversible process (there is only physical adsorption). It is observed that the peaks of the experimental response have a similar area, which means that there is no chemical adsorption at this temperature. The sharp peaks detected in the TCD correspond to a very fast kinetics, with high values of the kinetic constant.

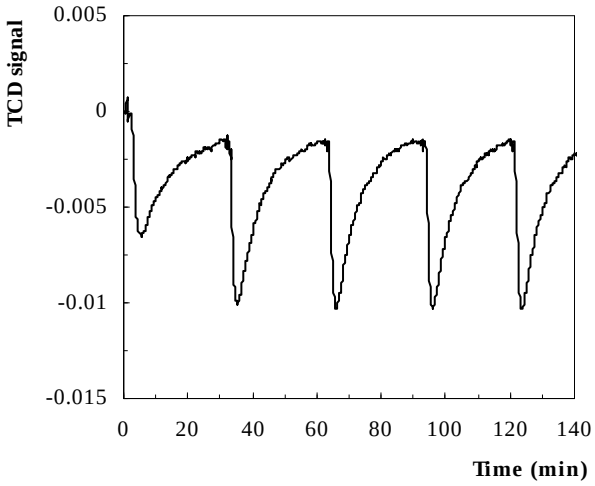

Figure 2. TCD signal of the adsorption process of water vapour over SAPO-18 at 200 ºC.

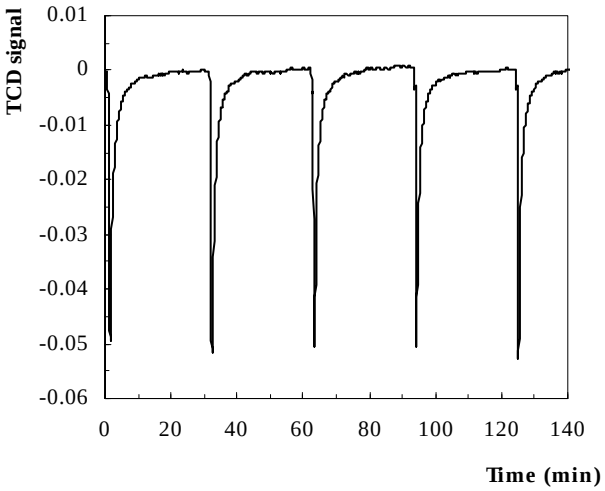

Figure 3. TCD signal of the adsorption process of water vapour over SAPO-18 at 300 ºC.

Figure 4 displays the effect of the partial pressure of water on the equilibrium constant. It is clear that an increase in the partial pressure of adsorbate leads to a decrease in the equilibrium constant of adsorption. Consequently, the equilibrium of water-SAPO system cannot be described using Henry's Law. The experimental data have been fitted to the Langmuir isotherm. The following values of the parameters have been obtained: x_m= 1.66 mol (kg of catalyst)$^{-1}$, k_L= 17 atm^{-1}.

Finally, the infuence of temperature on the adsorption process of water over SAPO-18 has been studied. Figure 5 shows that the equilibrium is severely affected by temperature. The explanation is that the level of chemical adsorption is higher at low temperatures, which results in a higher equilibrium constant.

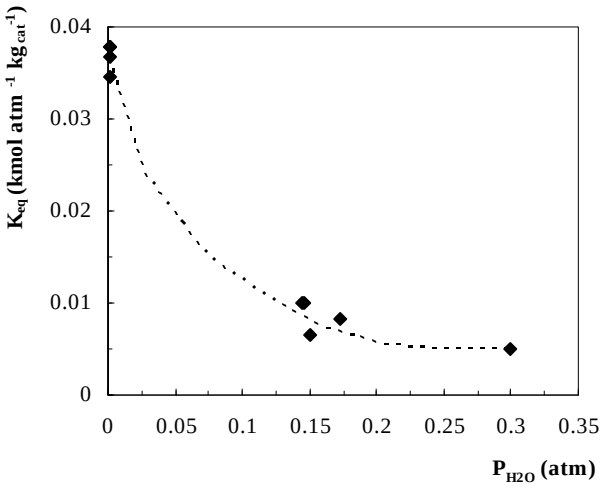

Figure 4. Influence of the partial pressure of the adsorbate on the equilibrium for water-SAPO system.

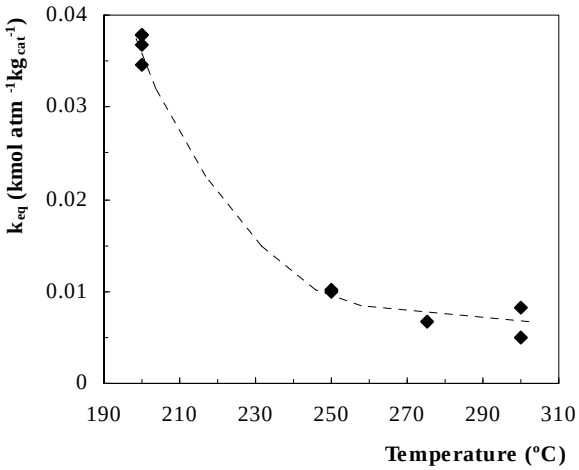

Figure 5. Influence of the adsorption temperature on the equilibrium for water-SAPO system.

Adsorption of methanol over SAPO-18

The adsorption process of methanol over SAPO-18 has been carried out at three different temperatures: 150, 200 and 250 ºC. The data of the TCD signal show that the adsorption is fundamentally physical at temperatures above 250 ºC, while for lower temperatures there is also chemical adsorption. The equilibrium constant decreases as the partial pressure of methanol increases (Figure 6). The equilibrium of the methanol-SAPO system can be described using the Langmuir isotherm. The following parameters have been calculated: x_m=0.12 mol (kg of catalyst)$^{-1}$; k_L=400 atm^{-1}.

Finally, the effect of temperature on the equilibrium for methanol-SAPO system has been studied (Figure 7). The results show that the adsorption equilibrium is severely affected by temperature. It is observed that the equilibrium constant is higher for the first pulses, as a consequence of the chemical adsorption. This process is more evident at low temperatures, due to the higher level of chemisorption. At temperatures above 250 ºC, the equilibrium value is constant for the different pulses, as the adsorption process is basically physical.

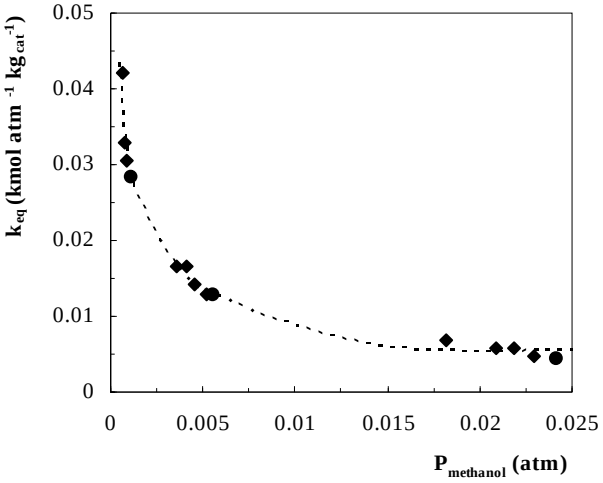

Figure 6. Influence of the partial pressure of the adsorbate on the equilibrium for methanol-SAPO system.

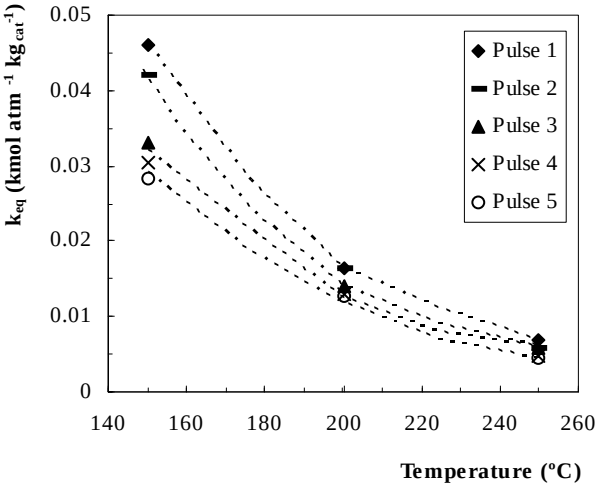

Figure 7. Influence of the adsorption temperature on the equilibrium for methanol-SAPO system.

Comparison of the adsorption process for both adsorbates

Table 1 shows the values of the kinetic and equilibrium constants of adsorption for both systems. These values have been calculated from the modelling of the experimental response collected in the mass spectrometer.

It is observed that the equilibrium constant is similar in both cases (water-SAPO and methanol-SAPO systems). Nevertheless, the adsorption process of water vapour is much faster than that of methanol, since the kinetic constant is one order of magnitude higher. Thus, water in the reaction medium competes with methanol for the acid sites of the catalyst, leading to a decrease in the activity of the catalyst to carry out the dehydration of methanol.

Consequently, the low hydrothermal stability of SAPO-18 catalyst must be considered in reactions in which water concentration is high, such as the MTO process (methanol to olefins) and the dehydration of methanol to DME.

Table 1. Values of the kinetic and equilibrium constants for the adsorption of water and methanol over SAPO-18.

System	Kinetic constant (min^{-1} m^{-3} kg_{cat}^{-1})	Equilibrium constant (mol atm^{-1} kg_{cat}^{-1})
water-SAPO	$>$ 500	5-40
methanol-SAPO	50-75	5-45

4. Conclusions

The adsorption process of methanol and water over SAPO-18 has been studied. The aim of this work is to investigate the suitability of this catalyst in the dehydration of methanol to DME, without being affected by the high amount of water produced.

It is concluded that the chosen methodology (modelling of the experimental response of several injections of helium saturated with the adsorbate) is suitable to describe the adsorption process, and calculate the parameters (kinetic and equilibrium constants).

The results reveal that water in the reaction medium effectively hinders the methanol dehydration reaction, as it competes with methanol for the acid sites of SAPO-18 catalyst. The equilibrium values are similar for both adsorbates, while the kinetics of the adsorption process is one order of magnitude faster for water-SAPO system. Therefore, the acidic sites of the SAPO-18 catalyst are partially deactivated when the concentration of water in the reaction medium is high (for example, during the dehydration of methanol to DME).

Topic: Advancing the chemical engineering fundamentals.

Abstract

In this paper it will be presented and discussed the experimental and simulation results obtained for the preparative separation of ketoprofen and flurbiprofen enantiomers by chiral liquid chromatography. Experimental results include solubility studies, elution and frontal chromatographic experiments and the measurement of competitive adsorption isotherms, using different mobile phase compositions. Modeling and simulation tools are used to predict the behavior and the performance of fixed bed and simulated moving bed processes. These prediction tools are used to select the proper mobile phase composition for the enantiomers separation in a preparative and production-scale point of view.

1 Introduction

Ketoprofen (R,S)-2-(3-benzoylphenylpropionic acid) and Flurbiprofen (R,S)-2-(2-fluoro-4-biphenylpropionic acid) are both examples of profens, the actual most relevant subclass of the Non-Steroidal Anti-Inflammatory Drugs (NSAIDs). These drugs are frequently prescribed worldwide in relieve of pain and in the treatment of several forms of inflammation and in the treatment of main articular diseases such as rheumatoid arthritis, osteoarthritis, ankylosing spondylitis (Burian and Geisslinger, 2005). The recent literature presents several studies concluding for different pharmacological proprieties for R and S profen enantiomers. Following these findings, chiral resolution of profen enantiomers can contribute to the development of new drugs with distinct therapeutic applications and/or safer pharmacological actions (Panico ***et al.***, 2006).

The optimization of preparative chiral liquid chromatography and Simulated Moving Bed (SMB) processes is a complex task that requires a careful selection of mobile phase composition. In this selection, high resolution (or high selectivity) is not the only aspect, since other parameters, such as high solubility and low retention times, are crucial aspects that must also be considered (Ribeiro ***et al.***, 2008).

In this work, experimental results obtained for the ketoprofen and flurbiprofen enantiomers will be shown, including solubility and adsorption measurements, and pulse and breakthrough experiments. Additionally, simulation results, based on the experimental adsorption isotherms measured, will be presented to compare the performance of fixed-bed and SMB processes.

2 Experimental tools, modeling and simulation

The experimental tools, modeling and simulation procedures for the optimization of mobile phase composition are described in a recent published work (Ribeiro ***et al.***, 2008). This includes experimental methods for solubility and adsorption isotherms measurements, and simulation tools to predict the operation of fixed-bed and simulated moving bed processes.

3 Results and Discussion

3.1 Solubility of profen racemic mixtures

Firstly, the solubility of ketoprofen and flurbiprofen enantiomers was measured in three pure solvents, all with a composition of 0.01%TFA: 100%n-hexane, 100%ethanol and 100%methanol. These solubility measurements were performed in duplicate and at a temperature of 23ºC (room temperature). Obtained results (not shown) indicate that profens solubility increases when the solvent is changed from 100%n-hexane to 100% ethanol and from this to 100% methanol. On a second stage, the dependency of solubility with the alcoholic composition in an ethanol/n-hexane mixture was investigated. Results were consistent with the previous ones. Ketoprofen and flurbiprofen enantiomers have high solubility values in solvents with a high polar composition. On the other hand, a mobile phase with an increased polar content is referred as an advantage in preparative chromatography due, not only because it allows higher racemate solubility, but also because presents lower retention times (Lynam and Stringham, 2006).

3.2 Elution chromatography

Several experiments of elution chromatography (pulses) were performed on different solvent mixtures of ethanol/n-hexane and methanol/n-hexane, in order to characterize the system selectivity at preparative conditions. A preparative column (Chiralpak AD, Daicel, Japan), with a particle size of 20 μm, was used on these experiments. Six level concentrations were prepared in the range between 0.05 and 4.0 g/L, and injected using two different loops: 100 μL and 1 mL. Obtained results are presented in Figure 1, for ketoprofen, and in Figure 2, for flurbiprofen.

For ketoprofen enantiomers, results show that the 20%ethanol/80%n-hexane mobile phase presents considerable higher retention times than the pure mobile phases (ethanol and methanol). The hydrocarbon mobile phase also leads to important chromatographic tails, which is an indication of strong non-linear behavior and not welcome for preparative separations. Comparing the results obtained for the two pure alcohol mobile phases it can be clearly concluded that, despite higher ketoprofen solubility, pure methanol does not allows acceptable selectivity values and, consequently, ketoprofen enantioseparation.

For the flurbiprofen enantiomers, high selectivity values can be obtained for mobile phase compositions lower than 10%ethanol/90%h-hexane (results not shown). However, this mobile phase composition exhibits retention times substantially higher and very low solubility values, which means a clear disadvantage for high productivities. For an ethanol/n-hexane-based mobile phase, a 10/90 composition represents a reasonable compromise between selectivity, retention time and solubility. For methanol/n-hexane-based mobile phase, due to the immiscibility range between 6% and 60% methanol, its use is not possible. Taking into account the very low solubility values, experiments with less than 6% of methanol in n-hexane were also not carried out, since they are not attractive under preparative point of view. On the other side, and despite high solubility, the use of a mobile phase with higher methanol content (more than 60%) does not allow selectivity values as the ones obtained with ethanol/n-hexane mixtures.

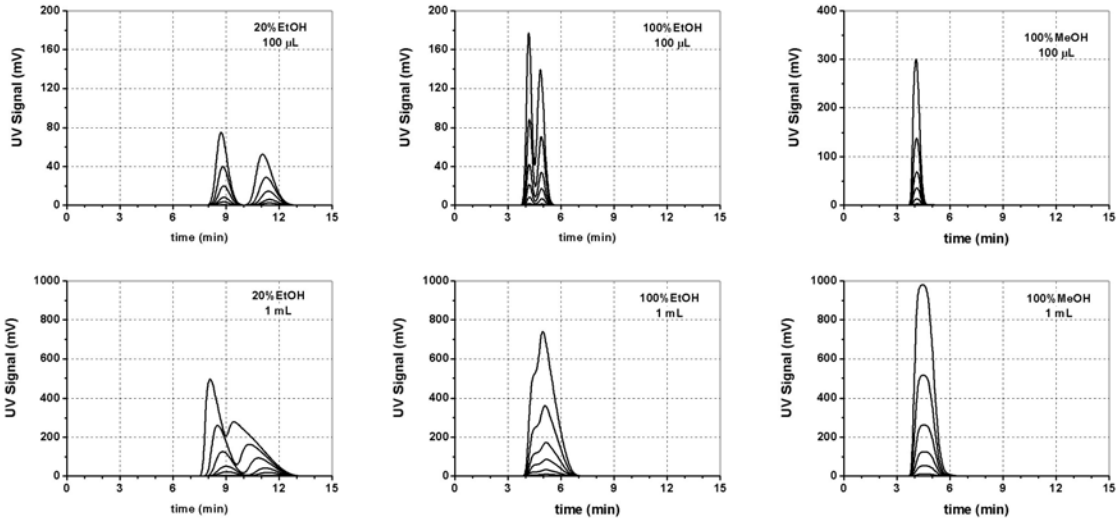

Figure 1. Experimental elution profiles of ketoprofen enantiomers in different mobile phase compositions: 20%ethanol/80%n-hexane, 100%ethanol and 100%methanol. Racemic ketoprofen concentrations in six different levels: 0.05, 0.2, 0.5, 1.0, 2.0 and 4.0 g/L; preparative column (particle diameter of 20 µm); UV detection at 260 nm; flow rate of 1 mL/min; temperature of 23ºC; injection volumes of 100 µL and 1 mL.

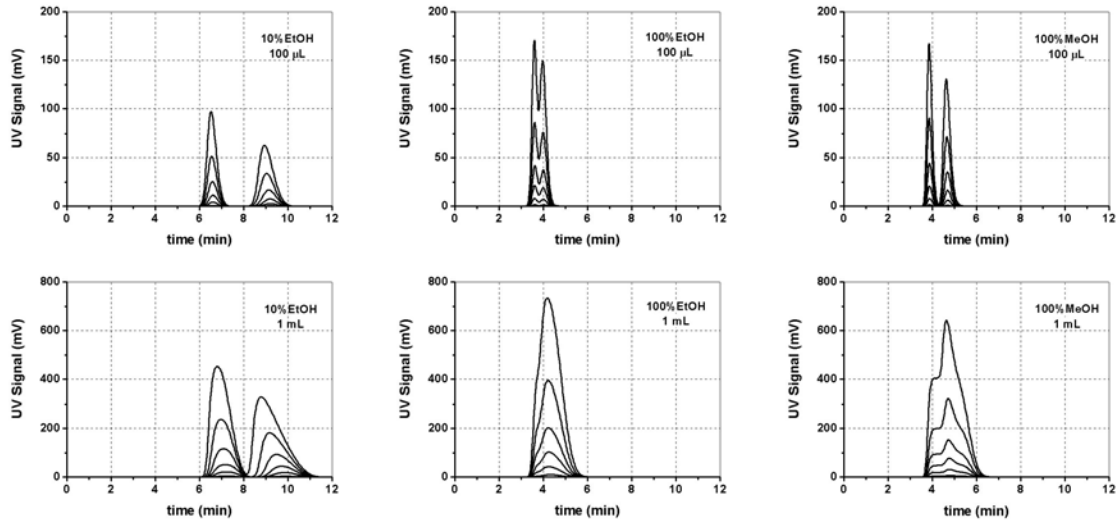

Figure 2. Experimental elution profiles of flurbiprofen enantiomers in different mobile phase compositions: 10%ethanol/90%n-hexane, 100%ethanol and 100%methanol. Racemic flurbiprofen concentrations in six different levels: 0.05, 0.2, 0.5, 1.0, 2.0 and 4.0 g/L; preparative column (particle diameter of 20 µm); UV detection at 260 nm; flow rate of 1 mL/min; temperature of 23ºC; injection volumes of 100 µL and 1 mL.

3.3 Multicomponent adsorption isotherm experiments and modeling

Figure 3 (for ketoprofen) and Figure 4 (for flurbiprofen enantiomers) present the experimental results obtained for the adsorption isotherms measurements in different mobile phase compositions, showing a good agreement with model predictions. In these figures, the prediction of the selectivity factor and its concentration dependency is also represented.

Ketoprofen results clearly show three different situations: for 100%methanol, selectivity is low and constant, which means that the separation of ketoprofen enantiomers hardly can be achieved using pure methanol as mobile phase. Despite its high selectivity for low concentrations, the common 20%ethanol/80%n-hexane mobile phase presents a strong decrease in selectivity with the increase of enantiomers concentrations. The better situation

is obtained for 100%ethanol, where selectivity maintains high values even for high enantiomer concentrations.

Results obtained for flurbiprofen enantiomers confirm a decrease in selectivity with the increase of the alcoholic content. High selectivity values can be observed for high hydrocarbon content. However, this mobile phase composition exhibits retention times substantially higher and very low solubility values. As stated before, for the separation of the flurbiprofen enantiomers, a 10%ethanol/90%n-hexane mobile phase composition is a reasonable compromise between selectivity, retention time and solubility.

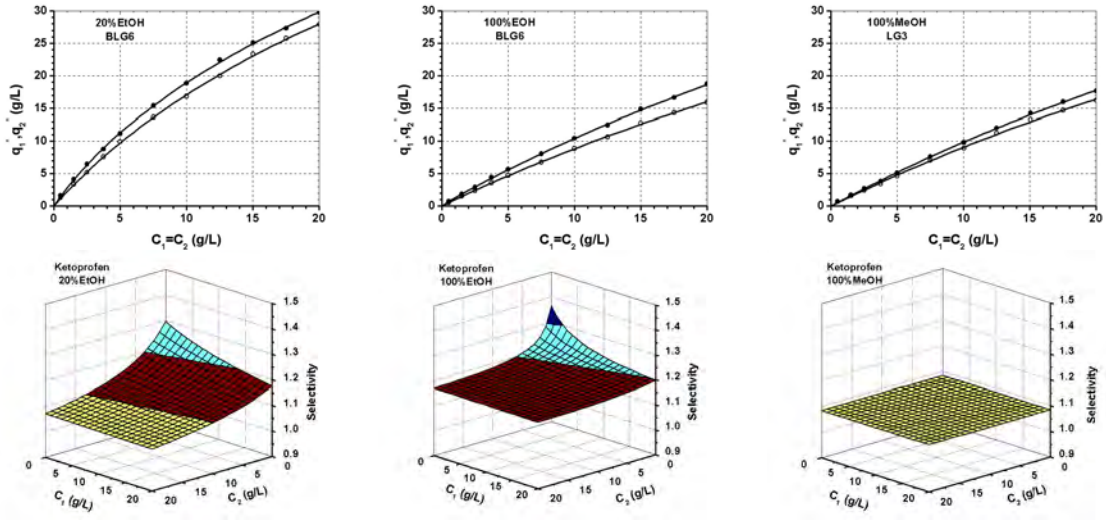

Figure 3. Comparison between model and experimental results for the equilibrium adsorption isotherms of ketoprofen enantiomers using the bi-Langmuir model (BLG6) in 20%ethanol/80%n-hexane and 100%ethanol and using the Langmuir model (LG3) in 100%methanol. Open and closed circles for the experimental concentration of the less and the more retained enantiomer, respectively; solid lines for the adsorption isotherm model. Temperature: 23ºC. The second line presents the prediction of the selectivity factor as a function of both enantiomers concentration.

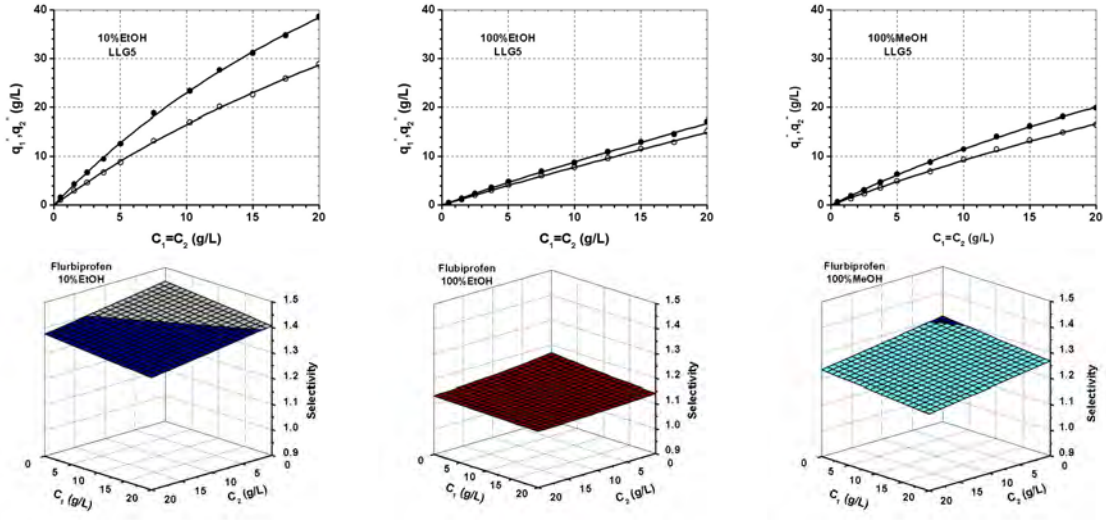

Figure 4. Comparison between model and experimental results for the equilibrium adsorption isotherms of flurbiprofen enantiomers using the modified linear+Langmuir model (LLG5) in 10%ethanol/90%n-hexane, 100%ethanol and 100%methanol. Open and closed circles for the experimental concentration of the less and the more retained enantiomer, respectively; solid lines for the adsorption isotherm model. Temperature: 23ºC. The second line presents the prediction of the selectivity factor as a function of both enantiomers concentration.

3.4 Frontal chromatography experiments and simulation

Breakthroughs experiments were carried out with the purpose of testing the selected adsorption isotherm models. In the present work it is shown experiments using a racemic feed solution of 40 g/L and the selected mobile phase composition: 100%ethanol for the ketoprofen and 10%ethanol/90%n-hexane for flurbiprofen enantiomers. It can be clearly observed from Figure 5 that both the selected models describe very well the experimental data behaviour in the whole concentration range.

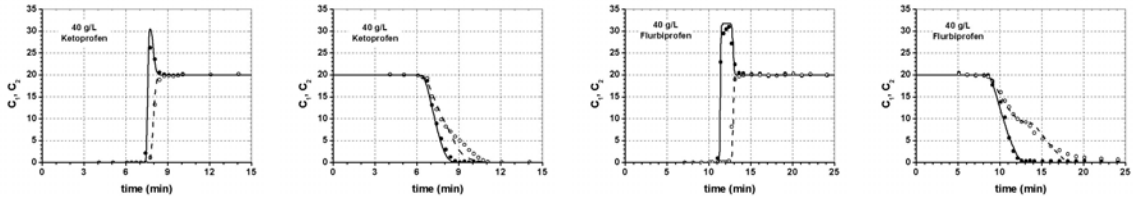

Figure 5. Saturation (adsorption) and regeneration (desorption) curves for a racemic feed concentration of 40 g/L. Comparison between experimental (points) and simulation (lines) results. Closed and open circles for the less and the more retained enantiomer, respectively. Temperature: 23ºC. Flow rate: 0.5 mL/min. Ketoprofen: 100%ethanol and bi-Langmuir model (BLG6); Flurbiprofen: 10%ethanol/90%n-hexane and modified linear+Langmuir model (LLG5). Model parameters: ε=0.4, ***Pe***=3500, ***St***=$k\tau$=1000 (see Ribeiro ***et al.***, 2008)***.***

3.5 Performance of SMB operation

The performance of the ketoprofen enantiomers separation by SMB technology is compared in Figure 6 for different mobile phase compositions using the Equilibrium Theory model. The separation region (see plot $\gamma_3 x \gamma_2$) for 20%ethanol/80%n-hexane has operating conditions considerable different from the ones obtained for the pure alcohol mobile phases (pure ethanol and pure methanol) due to the higher retention times. Comparing the separation regions for the three mobile phases, it can be concluded that, for the 20/80 composition, the separation region becomes quickly smaller with the increase of feed concentration. This is a sign of stronger non-linear behavior of the adsorption process and a reason for lower productivities.

The comparison of the SMB performance for the two pure alcohol mobile phases is clear: both have similar operating conditions due to similar retention times, but pure ethanol presents considerable better performances due to higher selectivity. Figure 6 also presents the productivity and the solvent consumption obtained for the different mobile phase compositions, as a function of feed concentration. These simulation results also clearly show that pure ethanol is the better choice for the separation of ketoprofen enantiomers through SMB operation: at high feed concentrations, the productivity using pure ethanol is three times the ones obtained with the other two solvents, and solvent consumption is only 75% and 25% of the one needed with pure methanol and 20%ethanol/80%n-hexane, respectively.

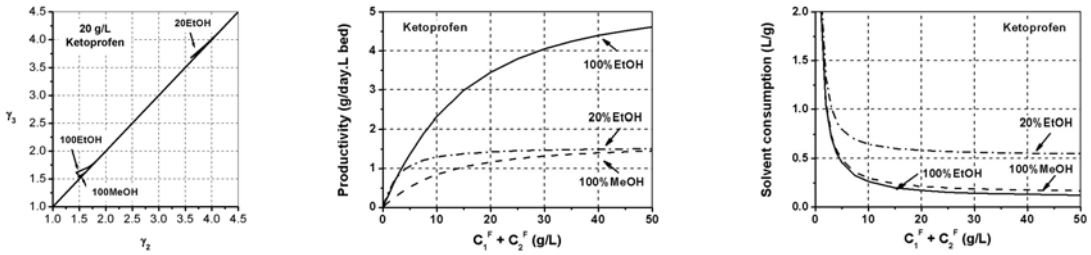

Figure 6. SMB separation regions and prediction of the performance of SMB operation for ketoprofen enantiomers: productivity and solvent consumption as a function of feed concentration for the different mobile phase compositions.

For flurbiprofen enantiomers (see Figure 7) it can be observed high retention time values in mobile phases with high hydrocarbon contents (the separation regions are progressively located at higher values of γ_2 and γ_3 with an increase of the n-hexane content). On the other side, these results are very different from the ones obtained for the separation of the ketoprofen enantiomers. The dimension of the separation regions progressively decrease with the decrease of the n-hexane content (increase of the ethanol content). Therefore, the best performance (bigger separation region) is obtained with a 10%ethanol/90%n-hexane composition through all feed concentration range. The performance parameters predictions also support the previous conclusions. Under preparative conditions, maximum productivity is achieved with the 10/90 composition, while solvent consumption does not significantly differ for all mobile phase compositions.

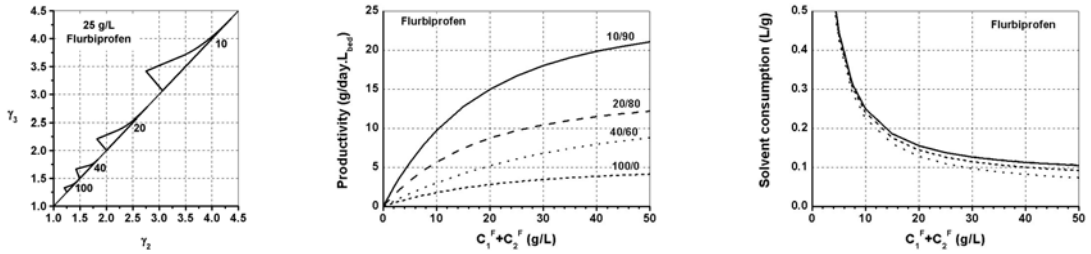

Figure 7. SMB separation regions and prediction of the performance of SMB operation for flurbiprofen enantiomers: productivity and solvent consumption as a function of feed concentration for the different mobile phase compositions.

4 Conclusions

For the separation of ketoprofen enantiomers, best situation is achieved using pure ethanol as mobile phase. For flurbiprofen enantiomers, the experimental results obtained lead to different conclusions: a 10%ethanol/90%n-hexane composition is the better choice since it represents a good compromise between selectivity, retention time and solubility. The present work shows that the choice of the proper mobile phase composition is a topic of utmost importance for the optimization of preparative liquid chromatographic separations. This choice will affect the throughput of the separation process since solubility, retention time, and selectivity are all parameters very sensitive to changes in mobile phase composition.

Topic: Advancing the chemical and biological engineering fundamentals.

Abstract

The growing consumption of natural gas and the stringency of environmental legislation have created a greater demand for knowledge of the behavior of diverse means of filtration that can be used under high pressure. To remedy this need, we sought to develop a research project to present a preliminary investigation of cellulose filters which are commonly employed, but also of acrylic, treated and untreated polyester that can be reutilized and avoid the accumulation of residue on disposable filters. A battery of trials at pressures varying from 98 to 900 kPa and air leaks of 0.00028 to 0.0019 m^3/s, were used to determine the permability coefficient and the porosity of the filters media. At the end of the trials, Darcian and non-Darcian permeability coefficient (k_1 and k_2) increased with the increase in system pressure. Small alterations in porosity and no variation in the shape of the filter media fibers over time occurred when submitted to high pressure.

1 Introduction

The utilization of natural gas has risen in recent years due to its diverse applications and has substituted conventional forms of energy (petroleum derivatives, electricity and coal). While these energy sources have specific areas of utilization, natural gas has no captive market and easily adapts to the energy needs of many sectors. Aside from this, as a combustible that is less polluting due to its simple chemical structure, its use has grown more rapidly than petroleum derivatives. This advantage has made natural gas a more appropriate product for use in urban centers with pollution problems.

Natural gas has a substantial participation in industry, as it is utilized by the principal equipment in this segment: vapor generators (steam generator), hot air ovens (drying ovens), Fluid heaters, melting ovens, refrigeration systems, etc. It is also a viable alternative for improving environmental problems associated with automotive vehicles, because it burns more completely than gasoline, alcohol or diesel. For this reason, natural gas powered vehicles emit less of pollutants such as nitrate oxides, carbon dioxide (CO_2) and principally carbon monoxide (CO) – gases responsible for global warming (Alonso, 1999). Another advantage of natural gas is that it does not require stockage which eliminates the need for logistic control, delivery vehicles at the factory, and other costs and risks associated with the storage and handling of combustible liquids. In addition, use of natural gas also lowers operational costs in industry by eliminating the expenses with maintenance, cleaning and purchasing antipollution equipment.

* Corresponding author. Tel + 55-16-33518443. E-mail: mlaguiar@ufscar.br

One inconvenient factor, however, is the residue that accumulates on the inside of pipelines that transport natural gas, called black powder. This particulate material may originate from contamination during the construction or maintenance of the gas pipeline from lamination, soil or electrodes. Black powder may also originate from silica and inorganic salts from petroleum wells, or jointly as the erosion residue from solid residues traveling at high velocity and the corrosion residue from carbon steel pipes with no interior covering.

These residues can damage equipment and shorten its usable lifetime and are generally eliminated by filtration at high pressure.

Filtration is an important operation utilized for the separation of solid gas by fluid flowing through a permeable porous filter (Dickenson, 1994). This filtration initially captures solid particles or liquid on the inside of the filter media, known as internal filtering, where the filter media becomes impregnated and then forms a layer of particulate material called cake.

Given the notable of natural gas use, innumerous advances are being proposed for the study of the filtration process of this gas to improve operational conditions. Very few researchers have studied the filtration process in the field of natural gas, a combustible that is considered to be extremely important today in the concretization of sustainable development, due to the inherent difficulties in working with high pressure systems.

For good filter media performance, it is desirable that this presents high permeability and porosity generating a low pressure drop and keeping maximum efficiency.

Porosity is a structural parameter of filter media which corresponds to the amount of empty space (pores) present in the sample that can be determined by picnometry.

Permeability is the property that indicates the greater or lesser facility a liquid has passing through a porous media. Fluid flow generates a loss of energy reflected in pressure drop along the filter surface. Permiability can be determined by Equation 1, known as the Forchheimer equation for compressible fluids, where the pressure drop through the porous media describes the non-linear dependence on fluid velocity (Innocentini, 2008):

$$\frac{P_e^2 - P_s^2}{2P_eL} = \frac{\mu}{k_1} v_s + \frac{\rho}{k_2} v_s^2 \quad (1)$$

where P_e and P_s, are the absolute pressures before and after filtering, μ and e ρ, are the viscosity and density of the fluid, L, the thickness of the filter media and v_s, the superficial velocity of the gas, given by the relation of the volumetric leak and the area of the transversal section area, perpendicular to fluid flow. The k_1 and k_2 parameters are the Darcian and non-Darcian permeability, respectively. The first term of the Equation (1) represents the contribution of the viscous forces on pressure drop, caused by friction between the fluid molecules and the filter media. The following term represents the inertial forces, caused by the turbulence of the fluid flow and or the cake of the filter media.

For this reason, the objective of this study was to determine the parameters for permiability and porosity, as well as identify the behavior of the filter media fibers when submitted to gas filtration at high pressure.

2 Materials and methods

This section presents the equipment used in gas filtration, as well as the characteristics of the filters media of cellulose, acrylic, treated and untreated polyester.

The experimental unit, illustrated in Figure 1, is basically constituted of powder aspersor (to simulate residues in the gas), a high pressure compressor connected to three air filters, an air dryer, absolute filter, rotating valves and manometers.

Previously dried and filtered air was used instead of natural gas for the experimental trials because it was safer and cheaper. The filters media were cut in 0.07 m circular sections for a

total filtering area of 0.0038 m^2.

For the permeability trials, the acrylic filter media was placed in the experimental unit (item 7 in Figure 1). System pressure was adjusted to 98 kPa (item 2 in Figure 1), varying the gas leak from 0.00028 to 0.0019 m^3/s and noting the pressure drop values obtained by the differential manometer (item 8 in Figure 1) for the filter media without the addition of powder. This procedure was repeated at pressures of 196, 294, 392, 490 and 588 kPa. The filter media was substituted by cellulose, treated and untreated polyester and the pressure drop was measured as previously described.

Figure 1 – Experimental Unit

From the data for pressure drop, air viscosity varied by system pressure and the characteristics defined in Table 1, the filter media permeability was obtained utilizing Equation 1.

Table 1 – Filter media characteristics

Filter Media	Thickness (m)	Grams (g/m^2)
Acrylic	0.0028	550
Treated Polyester	0.0025	550
Untreated Polyester	0.0032	550
Cellulose	0.0035	120

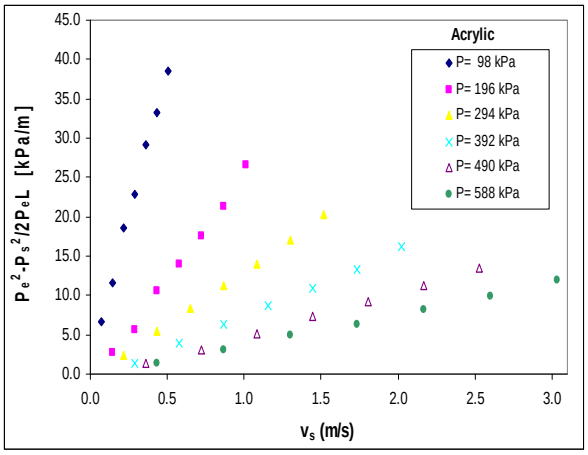
To determine porosity, the filters media (cellulose, acrylic, treated and untreated polyester) were submitted to maximum system pressure (900 kPa) and maximum leak (0.0019 m^3/s) for periods of 3,600 and 43,200 seconds. Following this, the solid volume was measured by Gás Micromeritics AccuPyc 1330 picnometer to calculate porosity.

For image analysis, these same filters media underwent the treatment technique developed by Coury and Aguiar (1995). This analysis was performed by an Image Pro-Plus analyzer, to visually verify the condition of the fibers and any possible wear.

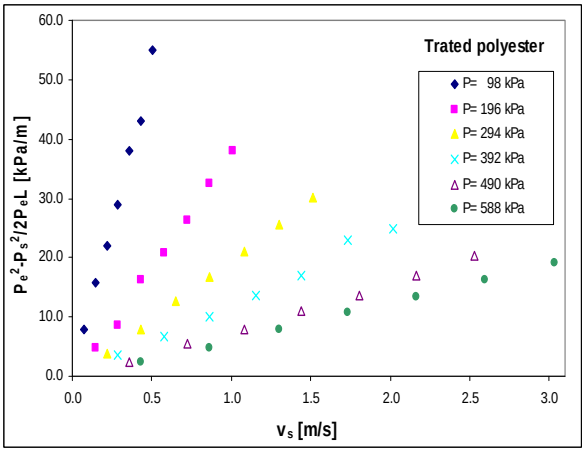
3 Results and discussions

This section presents the graphics obtained from the experimental data for pressure drop in function of superficial gas velocity and permeability in function of system pressure, as well as the porosity calculated for the filters media.

The fluid flow permeability trials were performed by varying the superficial velocity of the gas from 98 to 588 kPa band of system pressure. For each applied pressure, a graphic of pressure drop in function of the superficial gas velocity, utilizing the experimental system presented in Figure 1. The results are presented in Figures 2 and 3.



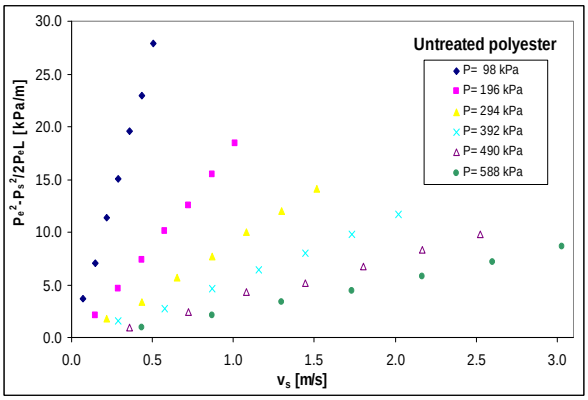
(a)



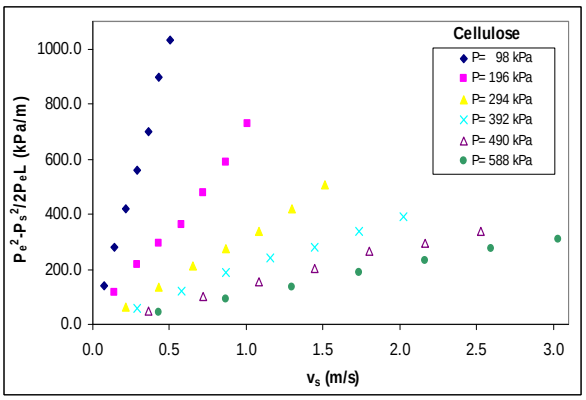
(b)

Figure 2 – Pressure drop in function of superficial velocity at different system pressures for: (a) acrylic filter media and (b) treated polyester filter media.

In Figure 2a, for acrylic filter media, the pressure drop values present a quadratic tendency with the superficial velocity of gas increase. This shows that the contribution of viscous and inertial terms were significant, as observed in the adjustments ($R^2 \approx 0.99$) of the curves seen in the graphs. It was also verified that an increase in system pressure lowered the filter pressure drop. This may have occurred due to the variation in system pressure that may have modified the position of the fibers by forcing air through the filter media and increasing the permeability. Similar behavior can be seen in the treated polyester (Fig. 2b), untreated polyester (Fig. 3a) and cellulose (Fig. 3b).



(a)



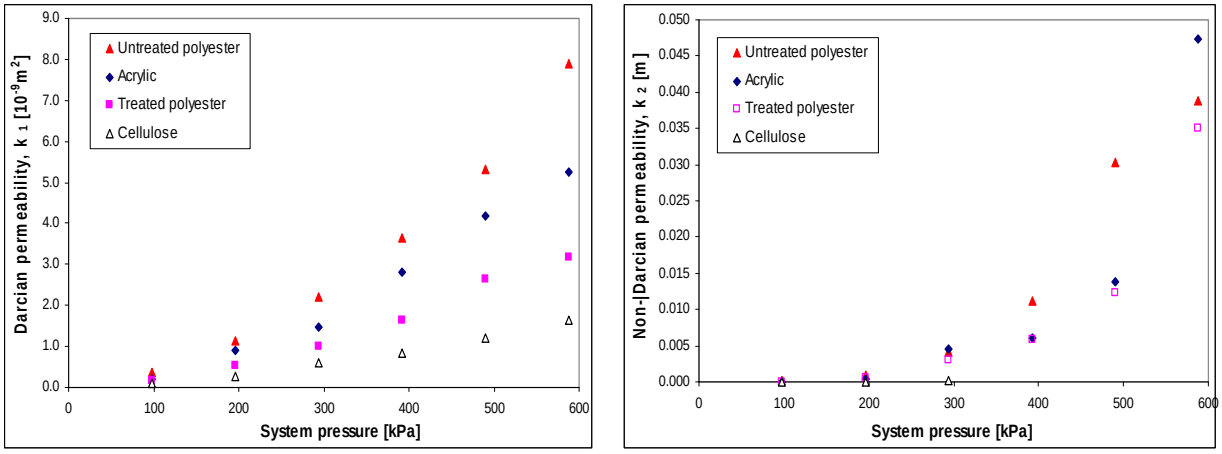
(b)

Figure 3 – Pressure drop in function of superficial velocity at different system pressures for: (a) untreated polyester filter media and (b) cellulose filter media.

Comparing Figures 2 and 3 of the filters media studied, greater pressure drops occurred for cellulose, followed by acrylic, untreated and treated polyester. This can be explained by the lower porosity of cellulose, as presented in Table 2 that increases resistance to fluid flow.

Figure 4 presents the behavior of Darcian and non-Darcian permeability (k_1 and k_2) for the different filters media in function of the pressure system. The constant was determined by the adjustment of Equation 1, which showed the significance for viscous and inertial effects as verified by the behavior of the Figures presented previously.

The analysis of Figure 4 shows the Darcian and non-Darcian permeability (k_1 and k_2) increased with the pressure system variations. This indicates that the permeability trials at elevated pressures contributed to alterations in the properties of the fluids, as well as the structure of the filter elements. Such changes may have occurred in the position of the fibers when gas was forced through at increased pressure.



(a) (b)

Figure 4 – Air permeability Darcian (a) and non-Darcian (b) in relation to system pressure for acrylic, cellulose, treated and untreated polyester filters media.

Untreated polyester presented the greatest permeability which showed that treatment confers greater stability to filter media fibers. This greater permeability would not be appropriate for performing filtration trials because the great accumulation of particles on the interior of the filter media would interfere with the filter cleaning and increase the residual system pressure drop as observed in the study by Tanabe (2008) in an ambient pressure system. The filters utilized in the removal of particulate matter should present high collection efficiency and a low residual pressure drop in order to minimize operation costs.

To investigate the possible changes in the structure of the filter media, results for porosity in function of exposure time were analyzed for filter media made from cellulose, acrylic, treated and untreated polyester submitted tor 900 kPa pressure for exposure periods of 3,600 and 43,200 seconds and are presented in Table 2. The porosity of the original filter media (not submitted to pressure) was also determined.

Table 2 – Porosity calculated by equation 1

Filter Media / Time (s)	Acrylic	Treated Polyester	Untreated Polyester	Cellulose
0	0.82	0.77	0.88	0.78
3600	0.74	0.72	0.84	0.77
43200	0.78	0.75	0.85	0.76

Note that in Table 2, after the application of system pressure, a small variation in porosity occurred with the increase in exposure time. The alteration in porosity values over time may occur due to the rearrangement of the fiber structure by increased pressure, which may cause the structure to become more or less permeable and further investigation of these results is warranted.

Transversal section images of filter media sample were used to verify any possible alteration in fiber morphology and microstructure and are presented in Figures 5 and 6.

The images presented show that the fibers did not result in any great changes in shape from pressure or periods of the exposure applied. A possible change may have occurred only in their position.

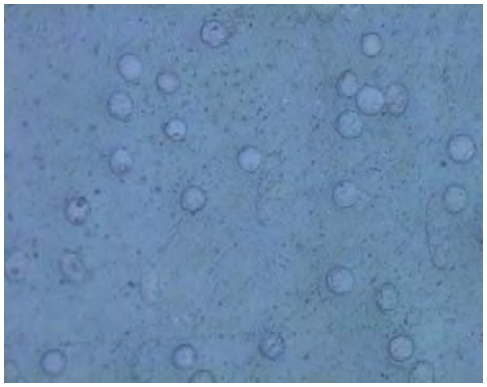


Figure 5 – Original transversal image of the untreated polyester filter media (200 X).

Figure 6 – Transversal imagem of untreated polyester filter media submitted to pressure for 43,200 seconds (200 X).

4 Conclusions

This section presents the principal conclusions obtained from the filtration trials performed for cellulose, acrylic, treated and untreated polyester.

The Darcian permeability coefficients (k_1) increased with the system pressure increase, due to the variations in the fluid properties and possibly, in the disposition of the fiber structure that facilitated the gas flow through the filter media.

The pressure versus velocity curves presented a linear behavior, greatly influenced by the system pressure.

The research performed showed that the filters media, when submitted to high pressure do not present any flattening of the fibers and only small alterations in porosity.

Topic: Advancing the chemical and biological engineering fundamentals

Abstract

Chemical reaction kinetics of carbon dioxide with aqueous solutions of piperidine has been studied using a stirred tank reactor with a planar interfacial area. The operational variables considered in this work have been the amine concentration and the reaction temperature. Specific absorption rates have been obtained and different correlations have been employed to estimate physicochemical properties of carbon dioxide in piperidine aqueous solutions. Results indicate that the absorption process occurs in a fast reaction regime with a first-order kinetic for amine and carbon dioxide. The reaction rate constant was calculated and correlated as a function of temperature.

1. Introduction

Carbon dioxide is a very important greenhouse gas that is emitted by several industrial processes. Carbon dioxide accompanying natural gas necessitates carrying out different cleaning operations for its later use. Recent methods for carbon dioxide capture, separation and sequestration, involve different options such as physical and chemical absorption (and adsorption), membranes separations, mineralization, etc.

The use of aqueous solutions of amines in gas-liquid reactors (stirred tanks, bubble and packed columns, air-lift, etc) for the capture of acid gases (mainly carbon dioxide) is a common procedure that is adopted in numerous industrial processes and has been the aim of a great number of research studies during the last decades [1].

Currently, aqueous alkanolamines solutions based on monoethanolamine, diethanolamine, 2-dipropanolamine and methyldiethanolamine are most commonly used in industry. These amines have shown fast regimes of absorption accompanied by a chemical reaction, which has a high importance as regards the aim of capturing higher quantities of carbon dioxide, as well as the scale-up of operation units. The most recent research studies are also related to the development and testing of new reagents and/or amines to capture carbon dioxide, as well as the use of blends of different amines [2] with the aim of achieving a certain enhancement in pollutant gas capture, due to their combined action. For these reasons, it is important to determine kinetic data for these kinds of reactions with the aim of understanding the behaviour of different amines or blends when reacting with the carbon dioxide present in a gas stream, so that we can calculate the capture efficiency or the geometrical characteristics [3] to design gas-liquid contactors.

2. Experimental section

Commercial grade CO_2 gas of 99.998% purity, supplied by Carburos Metálicos, (Spain) was used in this work. Piperidine of 99% purity was obtained from Fluka (USA). Aqueous solutions of piperidine were prepared with double distilled water.

The experiments were conducted in a stirred cell (1) having a planar interfacial area working in batches as regards both phases (see figure 1). Four baffles have been placed in its internal wall to improve the mixing and prevent vortex formation during stirring. The gas to be absorbed, carbon dioxide, was passed through two humidifiers (2) to prepare the gas phase. This procedure removed other resistance to mass transport and allowed only the evaluation of the liquid phase resistance to the gas transfer. Water was placed into the “humidifiers”. A soap flow-meter (3) was used to determine the absorption rate of carbon dioxide by the absorption accompanying the chemical reaction produced by the glucosamine present in the liquid phase. The absorption rate was measured by analysing the movement (produced by the consumption of carbon dioxide) of the soap film along the calibrated glass tube. The absorption processes have been carried out at different temperatures (7 to 55 ºC) by connection of humidifiers, stirred cell and flow-meter to a thermostat-cryostat (4).

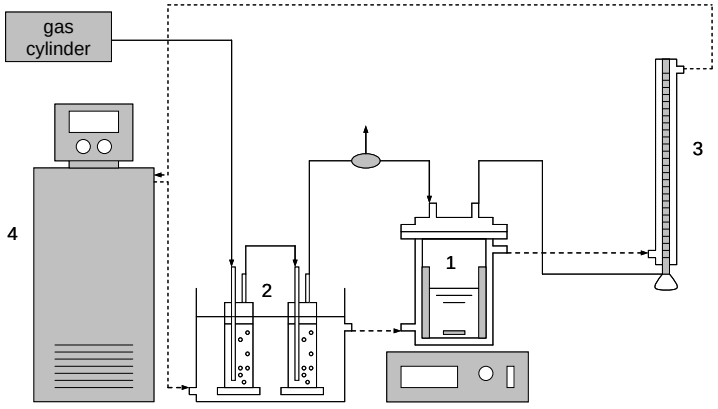

Figure 1. Experimental set-up for kinetic studies of gas-liquid systems.

3. Results and Discussion

The kinetics of reaction between carbon dioxide absorbed in water and piperidine were studied by employing gas phase absorption data. The flow densities were calculated assuming that the gas phase follows an ideal behaviour, taking previous studies into account [4].

Carbon dioxide flow density was calculated by means of experimental data corresponding to the absorbed quantity of carbon dioxide along the operation time. Figure 2 shows the experimental results which were obtained in relation to the flux density determined for the liquid phases employed in this work. Experimental data shows a linear trend in all cases in the studied operation time range, and this kind of behaviour allows the use of experimental data for kinetic studies. The slope of the linear plot shown in figure 2 allows the calculation of the absorption volumetric flux at different operation conditions. Similarly, results from figure 2 indicate that there is certain influence of initial piperidine concentration in the liquid phase upon the carbon dioxide absorption rate or upon the slope of linear fits. This observation confirms the existence of chemical reaction in the liquid phase of carbon dioxide with the amine.

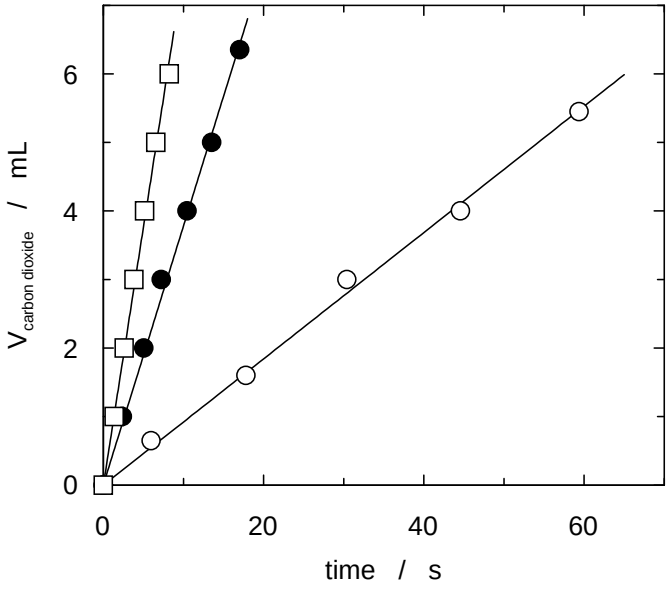

Figure 2. Influence of amine concentration on carbon dioxide absorption rate in gas-liquid kinetic studies. (○) [piperidine] = 0 M; (●) [piperidine] = 0.05 M; (□) [piperidine] = 0.1 M. T=25 ºC.

The reaction between carbon dioxide and amine involves different parallel chemical reactions, such as the reaction between this gas and hydroxyl ions (bicarbonate formation) and water (carbonic acid formation). However, the influence of these reactions under the conditions employed in the present work could be considered negligible. As regards the carbonic acid formation and reaction, it is very slow and it must be considered of no influence on the system studied. The other parallel reaction abovementioned between carbon dioxide and hydroxyl ions could be negligible due to the low hydroxyl ions concentration in the system, such as different studies have proved. Based on conclusions reached by different studies which indicate that carbamic reaction is the mechanism of reaction between carbon dioxide and amines when the carbonation relationship (moles of carbon dioxide/moles of amine) is lesser than 0.5, we could develop the analysis of our experimental results using this hypothesis, that is in agreement with results based on pH measurements (<11), previously commented.

A value of carbonation ratio lesser than 0.5 indicates that the reaction takes place by means of a second-order mechanism with three possible regimes: physical absorption, fast-reaction and instantaneous regime. Since the glucosamine concentration is high in the liquid phase and implies values of $C_{Bo}/C_{Ao} >> 1$, the physical absorption regime must be ruled out, so it is necessary to analyse the instantaneous and fast-reaction regimes.

An instantaneous regime relates carbon dioxide flow density (N_A) with initial glucosamine concentration with a linear trend. Figure 3 shows this relation, which indicates that this regime doesn't govern the reaction mechanism.

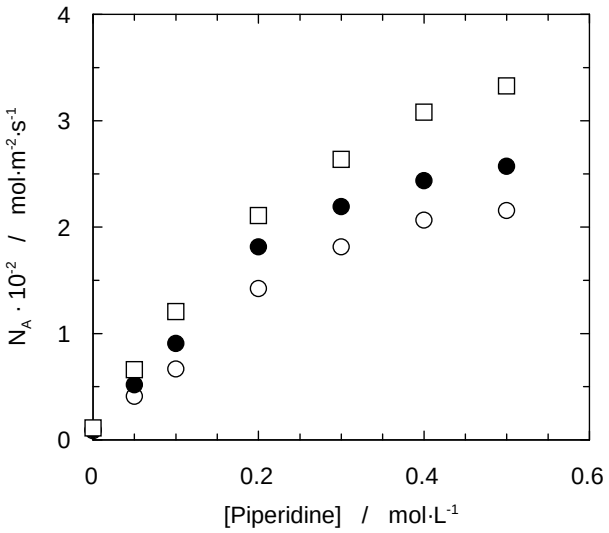

Figure 3. Influence of amine concentration and temperature on gas absorption rate with chemical reaction. (○) T = 15 ºC; (●) T = 35 ºC; (□) T = 55 ºC

The fast reaction regime allows the calculation of the carbon dioxide flow density by means of equation 1, taking into account that the reaction order, as regards the carbon dioxide when reacting with aqueous solutions of primary amines, is one.

$$N_A = C_{Ao}\sqrt{D_A \cdot k_{1,n} \cdot C_{Bo}^n} \qquad (1)$$

where C_{Ao} and C_{Bo} are the initial concentrations of carbon dioxide and piperidine in the liquid phase, D_A is the gas diffusivity in glucosamine aqueous solutions and $k_{1,n}$ is the overall reaction rate constant.

The diffusion coefficient corresponding to carbon dioxide in aqueous solutions of piperidine was calculated employing the expression shown in equation 2 [5].

$$D_A = D_{A,w} \cdot \left(\frac{\eta_w}{\eta}\right)^{0.8} \qquad (2)$$

where $D_{A,w}$ is the diffusivity of carbon dioxide in pure water, η_w and η are the viscosity of pure water and aqueous solutions of amine, respectively. The value of carbon dioxide diffusivity in pure water was determined employing the expressions proposed by different studies[12, 16]. On the other hand, the water viscosity and piperidine aqueous solutions have been obtained from literature [6].

The initial carbon dioxide concentration in the liquid phase must coincide with the concentration in equilibrium in gas phase. This parameter could be replaced in equation 1 employing Henry's law. These considerations allow us to obtain the linearized expression shown in equation 3 to fit experimental data as well as to calculate the reaction order corresponding to glucosamine:

$$\log\left(\frac{N_A^2 \cdot He^2}{P_A^2 \cdot D_A}\right) = \log\left(k_{1,n}\right) + n \cdot \log\left(C_{Bo}\right) \qquad (3)$$

where He is Henry's constant and P_A is the carbon dioxide partial pressure.

Figure 4 shows the results obtained after using equation 3 to fit the experimental results obtained in the present work. These results indicate a good agreement between the

experimental data and the linear fits of equation 3 under de operation conditions employed in this work.

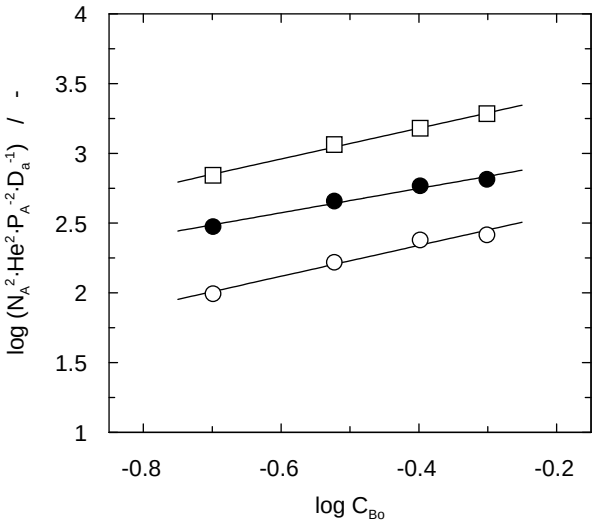

Figure 4. Linear fits according to equation 3 to obtain the reaction order and kinetic constant of the gas-liquid reaction. (○) T = 15 ºC; (●) T = 35 ºC; (□) T = 55 ºC.

Linear fits of the experimental data (i.e. in figure 4) have been used to calculate the reaction order regarding the piperidine, as well as the value of the kinetic constant employing the intercept with the origin. The slope of linear fits obtained at different temperatures contributes values close to 1. This is the reaction order corresponding to glucosamine, being in agreement with previous studies of chemical absorption of carbon dioxide with other primary amines [7].

Abstract

Present work analyzes the mass transfer process using N-methyldiethanolamine (MDEA) in the removal process of carbon dioxide using a bubble column reactor (BCR) as gas-liquid contactor. The use of this type of equipment requires the interfacial area determination for the following mass transfer coefficient calculation based on absorption kinetics. The effect of contactor, operation conditions, liquid phase nature and chemical reaction upon the mass transfer coefficient and interfacial areas have been analyzed.

1. Introduction

In general, the reaction between CO_2 and primary and secondary alkanolamines in aqueous solutions is described by the zwitterion mechanism reintroduced by Danckwerts [1]. According to this mechanism, the primary and secondary alkanolamines react directly and reversibly with CO_2 to form a zwitterion intermediate, which is deprotonated by the bases existing in solution including alkanolamines, OH^- ions, and water to produce a stable carbamate and a protonated base, except for the CO_2- MEA reaction, which is independent of the concentration of OH^- ions [2].

Certain authors revealed that the addition of tertiary amines with primary or secondary amines presents certain advantages to increase CO_2 absorption capacity [3]. In contrast to primary and secondary amines, the tertiary amines do not react directly with CO_2 to form stable carbamates. Specifically, MDEA (N-methyldiethanolamine) seems a very good amine to get the previously commented characteristics.

For the reaction of CO_2 with tertiary alkanolamines, Donaldson and Nguyen [4] proposed the following reaction mechanism. This reaction mechanism is essentially a base-catalyzed hydration of CO_2, and the mechanism implies that tertiary amines cannot react directly with CO_2. In most of the literature on CO_2 kinetics with tertiary amines in aqueous solutions, it is assumed that reaction of CO_2 with MDEA is a pseudo-first order reaction.

2. Experimental section

Aqueous solutions employed as liquid absorbent phases have been produced using different quantities of N-methyldiethanolamine (MDEA) supplied by Aldrich (CAS number 105-59-9). The solutions were prepared by mass using a balance with a precision of $\pm 10^{-7}$ kg. To prepare the absorbent phases (in the range 0-1 $mol \cdot L^{-1}$), bi-distilled water has been employed.

All experiments were performed at room temperature, operating in batches with respect to the liquid phase. The bubble column is made of methacrylate, 1.03 m height, and has a square cross-section (side length 6 cm). For the injection and uniform distribution of the gas phase, a gas sparger (three glass capillary sparger) is installed at the centre of the bottom plate. The simplicity of the gas sparger produces a small dead zone near to the gas inlet.

The absorption process has been carried out at 25 ºC using a similar experimental set-up employed by our research team in previous studies [5]. The gas to be absorbed, carbon dioxide, was passed through two bubbling flasks at 25 ºC to prepare the gas phase. This procedure removed other resistance to mass transport and allowed only the evaluation of the liquid phase resistance to the gas transfer. Pure water was placed into the bubbling flasks. The gas flow-rate fed to contactor was controlled with a mass flow controller (5850 Brooks Instruments) and measured with a soap flow-meter. The mass flow controller employed in the present study was calibrated by the supplier for the used gas flow-rates and pressures ranges. The gas flow-rates employed have been included into 15-30 $L \cdot h^{-1}$. The outlet gas flow-rate has been measured using a soap gas flow-meter and gas absorption rate was calculated as the difference between inflow and outflow rates.

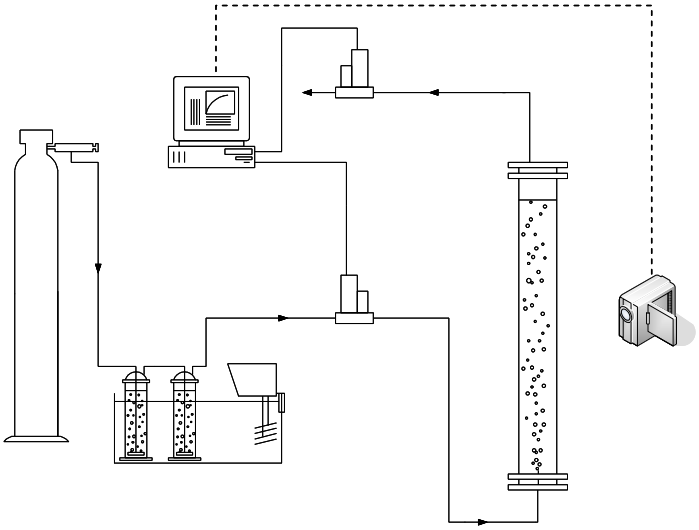

Figure 1. Experimental set-up employed in carbon dioxide absorption studies.

The use of a BCR to analyse carefully the experimental results implies the knowledge of the interface area employed in the gas/liquid mass transfer. For this reason the present paper includes the determination of the interfacial area to the operation conditions under which the mass transfer experiments have been carried out. The methodology employed implies the use of a rectangular bubble column.

The bubble diameter was measured using a photographic method based on taking images of the bubbles along the height of the column, from bottom to top. A Sony (DCR-PC330E) video camera was used to obtain the images. A minimum number of 80 well-defined bubbles along the bubble column were used to evaluate the size distribution of bubbles in the different liquid phases employed (different concentration of MDEA), and for each gas flow-rate which has

been used. We used the Image Tool v2.0 software to carry out the necessary measurements of the geometric characteristics of the bubbles. Photographs of different bubble column zones were analyzed, taking into account the possible influence of mass transfer accompanying of chemical reaction upon the bubble size along the liquid phase height.

3. Fundamentals

The interfacial area in gas-liquid contactors is commonly determined using physical or chemical methods. In relation to physical methods, the photographic one is the most employed methodology. In relation to the chemical method, it is based on absorption measurements of a chemical absorption process with a well known reaction kinetic. Due that the kinetic of the chemical absorption of carbon dioxide in aqueous solutions of MDEA has been determined in a previous paper, and in the basis of the equations previously commented, the interfacial area could be calculated. The knowledge of the interfacial area is necessary for the posterior mass transfer coefficient determination.

The images we obtained of the bubbles in the liquids employed show an ellipsoid shape. For this reason, major (*E*) and minor (*e*) axes of the projected ellipsoid (in two dimensions) were determined. The diameter of the equivalent sphere (equation 1) was taken as the representative bubble dimension.

$$d = \sqrt[3]{E^2 \cdot e} \tag{1}$$

Different authors recommend to use the Sauter mean diameter (d_{32}), which is possible to determine using the data calculated for the equivalent diameter.

$$d_{32} = \frac{\sum_i \left(n_i \cdot d_i^3\right)}{\sum_i \left(n_i \cdot d_i^2\right)} \tag{2}$$

where n_i is the number of bubbles which have an equivalent diameter (d_i).

The Sauter mean diameter and the gas hold-up values allow the calculation of the specific interfacial area using equation 3.

$$a = \frac{6 \cdot \varepsilon_G}{d_{32} \cdot \left(1 - \varepsilon_G\right)} \tag{3}$$

The overall gas hold-up, ε_G, was measured using the volume expansion method:

$$\varepsilon_G = \frac{\Delta V}{\Delta V + V_L} \tag{4}$$

where V_L is the ungassed liquid volume and ΔV is the volume expansion after gas dispersion, calculated from the liquid level change and the cross sectional area. The change in the volume in the bubble column was calculated based on the change observed in the liquid level and the increase in this value after gassing.

Due that the mass transfer process is the slowest step of the global process, is necessary to study the carbon dioxide transport to the liquid phase. The enhancement factor depends on the value of the mass transfer coefficient in absence of chemical reaction, the amine concentration, diffusivity of the reactants in the liquid phase and the values for the kinetic constants for the reactions evolved in the global process. Under certain conditions, the amine concentration at gas / liquid interface could be the same that in the liquid bulk and the reaction could be carried out completely at interface.

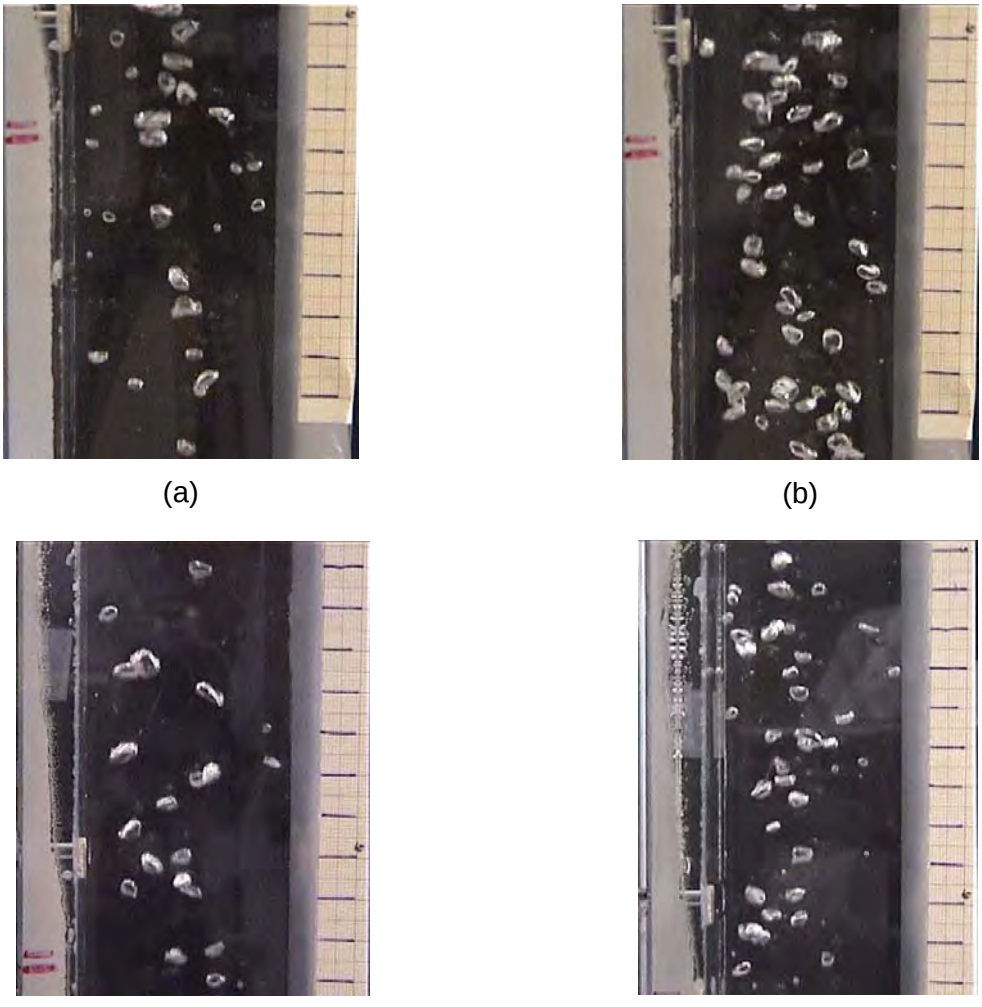
$$N = C_A^* \cdot a \cdot \sqrt{D_A \cdot k_2 \cdot C_B^{bulk}} \tag{5}$$

where *N*, is the absorption rate of carbon dioxide, C_A^* and D_A, the solubility and diffusivity of carbon dioxide in the aqueous phase, *a*, is the interface area, k_2, the rate constant for the reaction between carbon dioxide and hydroxyl ions and C_B^{bulk}, the MDEA concentration in the bulk of the aqueous phase.

The use of this expression (equation 5) needs that the concentration of amine remains constant practically along the time. If this condition is not satisfied implies that a part of the chemical reaction between carbon dioxide and hydroxyl ions is carried out at interface and the other part in the bulk of the liquid. The surface renewal theory developed by Dankwerts contributed the expression shown in equation 6.

$$N = C_{CO_2}^* \cdot a \cdot \sqrt{D_A \cdot k_2 \cdot C_B^{bulk} + k_L^2} \qquad (6)$$

4. Results and Discussion



(a) (b)

(c) (d)

Figure 2. Photographs from bubble column under different operation conditions (gas flow-rate and MDEA concentration). (a) [MDEA] = 0.5 M; Q_g = 14 L·h^{-1}; bottom section. (b) [MDEA] = 0.5 M; Q_g = 30 L·h^{-1}; bottom section. (c) [MDEA] = 0.1 M; Q_g = 20 L·h^{-1}; top section. (d) [MDEA] = 1 M; Q_g = 20 L·h^{-1}; top section.

An example of photographs obtained from the bubble column reactor under different conditions is shown in figure 2. The effect of gas flow-rate could be analysed in photographs (a) and (b) observing a higher number of bubbles in (b) photograph. This behaviour causes a direct effect on gas hold-up. Also, figures (c) and (d) allow analyse the effect of MDEA concentration. These photographs show that an increase in MDEA concentration in the liquid phase produces an increase in the number of bubbles and in their size. This kind of photographs have been employed to determine the bubbles size and it distribution and to obtain the reasons for these behaviours.

An example of the experimental results obtained in this analysis is shown in figure 3. In the experimental section, the method indicates that the bubble column must be analysed along the equipment height because bubble size distribution could vary significantly along the bubble column due to the absorption process that carry out into the contactor.

Figure 3 shows that this hypothesis must be taken into account because a clear difference in the bubble size distribution exists at the bottom and the top of the bubble column reactor. Smaller bubbles were detected at the top of the contactor respect the bubbles present at bottom zone. This size bubbles decrease is due principally to the transfer of gas carbon dioxide to the liquid phase.

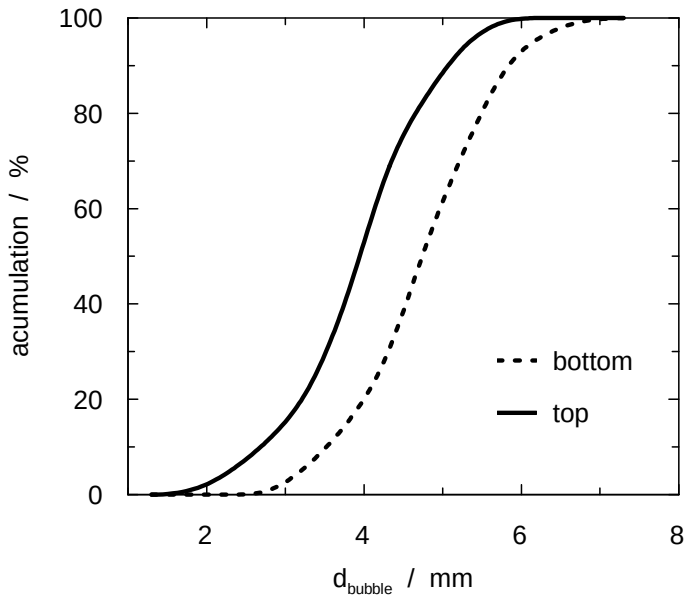


Figure 3. Bubbles size distribution obtained at different column zones. C_{Bo} = 0.5 mol·L^{-1}. Q_g = 30 L·h^{-1}.

Using equation 1-4 and experimental data of bubbles diameter is possible to determine the area between both phases (gas and liquid) and analyse the influence of amine initial concentration and gas flow-rate on the generated interfacial area in the bubble column reactor. Figure 4 shows the influence of both operational variables upon the value of interfacial area. An increase in the gas flow-rate produces a clear increase in the value of interfacial area. This behaviour is due to the increment in the gas hold-up because a higher volume of gas phase is introduced in the contactor. On the other hand, bubble diameter increases too but it has negative effect on the interfacial area value.

An increase in the initial amine concentration in the liquid phase produces also an increase in the value of the interfacial area. This behaviour is assigned to the influence of surface tension of liquid phase upon the diameter of bubbles generated in this liquid phase. Different authors have studied the influence of this physical property on the hydrodynamic of bubble

contactors [6, 7] and they have concluded that a decrease in the surface tension produces a reduction in the bubbles size and it inhibits the coalescence phenomenon.

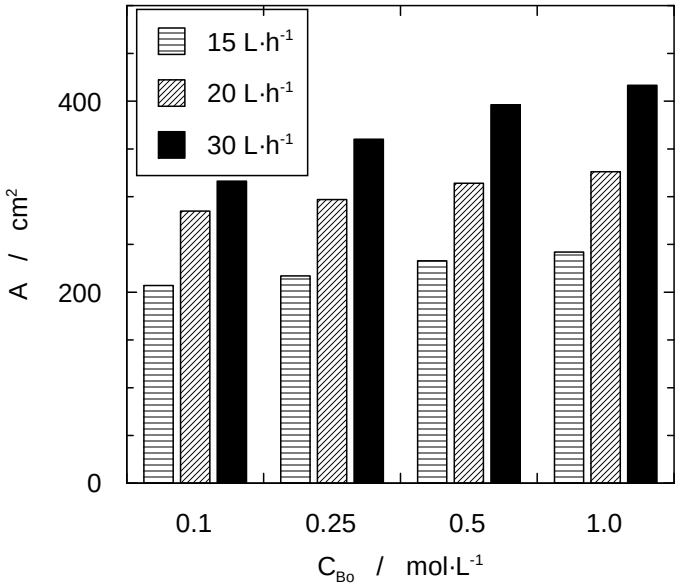

Figure 4. Effect of amine concentration and gas flow-rate upon the interfacial area.

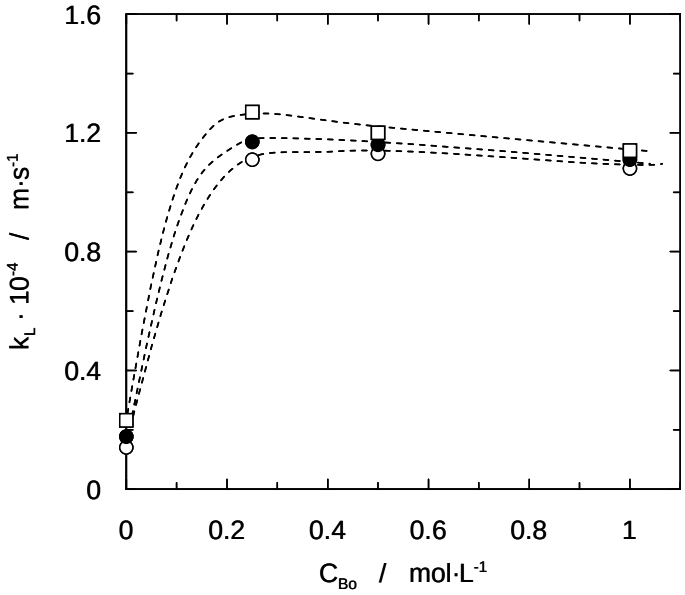

Figure 5. Influence of initial MDEA concentration and gas flow-rate on mass transfer coefficient. (○) Q_g = 15 L·h^{-1}; (●) Q_g = 20 L·h^{-1}; (□) Q_g = 30 L·h^{-1}.

The experimental data corresponding to interfacial area under the experimental conditions employed in present work is employed in the mass transfer coefficient using equation 6 by fitting absorption intensity and amine concentration data.

The calculated results obtained for the mass transfer coefficient and the influence of initial MDEA concentration and gas flow-rate, are shown in figure 5. This figure shows that a higher

initial concentration of amine produces an increase in the mass transfer coefficient until a maximum because higher values of amine concentration produce a slight decrease in this coefficient. The decrease in the value of mass transfer coefficient is due to the viscosity of the liquid phase that increases with the amine concentration. The influence of this physical property upon the mass transfer coefficient has been commented widely by [6, 7].

Topic: Advancing the chemical and biological engineering fundamentals – Membranes and membrane science

Abstract

A modified Maxwell-Stefan model, which considers both the concentration polarization and the transport through the membrane, is tested for the simulation of Dextran-98000 aqueous solutions filtration.

The model is able to successfully simulate experimental data in the high rejection/low flux region, but does replicate the observed rejection drop/pressure build-up which occurs for increased fluxes, which may be due to limitations of the model itself.

1 Introduction

The modeling of mass transfer phenomena in solute separations through inert membranes is essential for the efficient design and optimization of these operations, namely ultra-filtration processes, widely applied in an important range of industries, that include food and biotechnological industrial processes. In this work, a model is applied to simulate the ultra-filtration of aqueous solutions, based on a particular aproach to the Maxwell-Stefan general equations (Kerkhof, 1996). The ultra-filtration process simulation provides an analysis of the solute rejection phenomenon, which, in general, depends on the solution components properties (namely, their molecular sizes), the membrane characteristics and the process operational conditions. Therefore, through the intramolecular transport modelation, we can quantify the influence of each former conditions in the refered rejection phenomenon. This strategy provided promising results in the simulation of PEG-3400 aqueous solutions ultra-filtration (Brito et al., 2004, Ferreira et al., 2003). Now, the purpose is to test the ultra-filtration simulation performance for more massive solutes, specifically dextran-98000.

2 Model

The model considers both the concentration polarization and the transport through the membrane and incorporates a binary friction model based on the Maxwell-Stefan-Lightfoot equation (Kerkhof, 1996). Hence, for the polarization layer, we have:

$$\frac{\partial c}{\partial t} = -\frac{\partial N}{\partial z} \tag{1}$$

with the flux, *N*, defined as,

* Corresponding author. Tel + 351-273-303110. E-mail:paulo@ipb.pt

$$N = -(D + D_t)\frac{\partial c}{\partial z} + u_v c \tag{2}$$

where, $D = D_{12}\Gamma_c$, being D, the Fickian diffusion coefficient; D_t, the turbulent diffusivity; D_{12}, the Maxwell-Stefan diffusion coefficient; and Γ_c, the thermodynamic factor. The turbulent diffusivity is defined assuming an unitary turbulent Schmidt number ($\mathrm{Sc_t} = \nu_t / D_t$), and taking account the turbulent cinematic viscosity computed by the Vieth correlation (Brito et al., 2004):

$$\frac{\nu_t}{\nu} = \left(\frac{2}{9}\pi\sqrt{3}\right)^3 \left(\frac{f}{2}\right)^{3/2} \left(y^+\right)^3 \tag{3}$$

with the normalized distance from the membrane wall, y^+, calculated by,

$$y^+ = \frac{y\langle u_t \rangle \sqrt{f/2}}{\nu} \tag{4}$$

being f, the Fanning friction factor, defined by the Blasius equation, $f = (0.3164/4)\mathrm{Re}^{-0.25}$, and u_t, the circulating fluid velocity.

For the membrane, on the other hand, the molar concentration temporal gradient is given by:

$$\varepsilon \frac{\partial c'}{\partial t} = -\frac{1}{\tau}\frac{\partial N_m}{\partial z} \tag{3}$$

in which, τ is the tortuosity factor, and ε is the porosity. The intramembrane flux, N_m, is calculated by:

$$N_m = -\frac{\Gamma_c}{G}\frac{\partial c'}{\partial z} + u_v \frac{F}{G} c' \tag{4}$$

where, F and G are the convective and friction factors respectively, defined as in Kerkhof (1996) for a monosolute system, with the solute and the solvent represented by subscripts 1 and 2, respectively:

$$F = \left(\frac{1}{D_{12}} + \frac{{c_t}^2 \overline{V}_1 \overline{V}_2}{B_o}\kappa_2\right)\frac{\tau}{\varepsilon} \tag{5}$$

$$G = \left(\frac{1}{D_{12}} + \frac{c_t}{B_o}\left(\phi_2 \kappa_1 \overline{V}_1 + \phi_1 \kappa_2 \overline{V}_2\right)\right)\frac{\tau}{\varepsilon} \tag{6}$$

where, c_t is the total molar concentration, $B_o = r_p^2/4$, is the permeability parameter, r_p, the porous radius, and $\overline{V}_i$, ϕ_i and κ_i are the molar volume, the volume fraction and the viscosity fractional coefficient of component i, respectively. The thermodynamic factor Γ_c is given by (Kerkhof, 1996):

$$\Gamma_c = 1 + c\frac{\partial \ln \gamma}{\partial c} - \frac{c}{c_t}\left(1 - \overline{V}_1 / \overline{V}_t\right)$$

However, ideality is assumed.

The model is completed by the definition of: boundary conditions, fixed bulk concentration at the polarization layer extreme, and equilibrium and flux equalization conditions at the membrane/polarization and membrane/permeate interfaces;

$$z = -\delta \quad \Rightarrow \quad c = c_b$$
$$z = 0 \quad \Rightarrow \quad c' = K_{eq} c \; ; N = N_m \tag{7}$$
$$z = L_m \quad \Rightarrow \quad c' = K_{eq} c_p \; ; N = u_v c_p$$

and initial conditions, zero concentration profile start-up,

$$t = 0 \quad \Rightarrow \quad c = c_b \quad (z = -\delta) \quad \wedge \quad c = c' = 0 \quad (z > -\delta) \tag{8}$$

The problem is discretized in the spatial direction and solved in the temporal dimension until a steady-state profile is reached, which implies a constant profile for the flux over all the spatial domain. Therefore, a simulated stationary permeate concentration, c_p, becames available, that can be used to calculate the apparent solute rejection, R_{app}:

$$R_{app} = 1 - {c_p}/{c_b} \tag{9}$$

The fluxes profiles allow the computation of the pressure drop due to the flow and the simulated total pressure drop,

$$\Delta P_{flow} = \frac{\tau}{\varepsilon} \frac{RT}{B_o} \int_0^{L_m} c_t \sum_{i=1}^{2} \kappa_i N_i \overline{V}_i dz \tag{10}$$

$$\Delta P_{total} = \Delta P_{flow} + \sigma \, \Delta\Pi \tag{11}$$

where $\Delta\Pi$ is the osmotic pressure drop through the membrane and σ, the osmotic reflection coefficient. The membrane resistence may be computed relating the flow pressure drop and the flux using pure water filtration experiments.

$$R_m = \frac{\Delta P_{flow}}{\eta_w u_v} \tag{12}$$

On the other hand,

$$R_m = \frac{L_m}{B_o} \frac{\tau}{\varepsilon} = \frac{8 L_m}{r_p^{\,2}} \frac{\tau}{\varepsilon} \tag{13}$$

which allows the estimation of relations between the structural properties of the membrane, namely of τ/ε, a critical model parameter.

For the particular monosolute system under study (dextran-1 and water-2), the following relations are used in the computation of the specified properties (Blox, 2003):

$$D = 5.96 \times 10^{-11} + 2.12 \times 10^{-11} \tanh(0.0284\rho - 1.491) \tag{14}$$

$$\Pi = 37.0\rho + 0.752\rho^2 + 76.4 \times 10^{-4} \rho^3 \tag{15}$$

and

$$\kappa_1 = \kappa_2 \left(1 + \frac{\eta_{sp}}{\phi_1} \right) \tag{16}$$

$$\kappa_2 = {\eta_w}/{c_t RT} \tag{17}$$

with,

$$\eta_{sp} = a\rho \exp(b\rho) \tag{18}$$

where, ρ represents the solution mass concentration.

3 Numerical Solution

The numerical solution of a normalized version of the partial differential-algebraic equation system, defined over a space-time coordinate system of variables, is accomplished with an adaptive resolution algorithm, based on the Adaptive Method of Lines, and presented by Brito and Portugal (1998). This method is used to solve simultaneously the two modules of the model (polarization layer and membrane) over a one-dimensional discretized space direction, in the time direction until a steady state solute concentration profile is reached. The spatial derivatives are approximated by central finite differences and the time integration is accomplished with DASSL numerical integrator. The normalized concentrations (y and y') are defined in relation to the bulk concentration, c_b, and the spatial coordinate ($-\delta \le z \le L_m$) is normalized to the total spatial domain extent:

$$z^* = \frac{z + \delta}{L_m + \delta} \tag{19}$$

being δ, the polarization layer size and L_m, the membrane thickness. The operational conditions, the solution components and membrane properties, and the simulation parameters used in the obtainance of all results presented in the next section, are resumed in Table 1.

Table 1. Operational conditions, properties, and simulation parameters.

Properties	Operational conditions and parameters
$\overline{V}_1 = 45.6$ m^3/kmol	$\rho_b = 10$ kg/m^3
$\overline{V}_2 = 0.018$ m^3/kmol	$u_t = 0.76$ m/s; 1.57 m/s
$L_m = 5\times10^{-7}$ m	$T = 298$ K
$r_p = 4.5\times10^{-9}$ m	$\delta = 86\times10^{-6}$ m
$\varepsilon = 0.5$	

4 Results

A typical run provides evolutionary profiles like the ones presented in Figures 1 and 2, for normalized concentration (y and y') and space (z^*) variables. The formation of significant solute accumulation at the membrane/polarization interface (in the presented case, the solute concentration is roughly four times higher than bulk concentration - c_b) is verified, together with diminished permeate concentrations, leading to high levels of apparent rejection of solute.

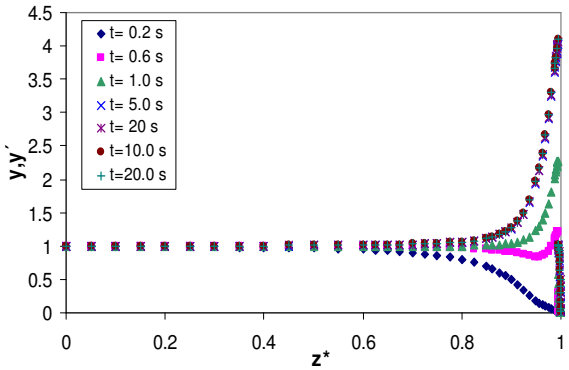

Figure 1. Normalized concentration profiles (polarization and membrane): u_t= 1.57 m/s, u_v= 1.0×10^{-5} m/s and K_{eq}= 0.25.

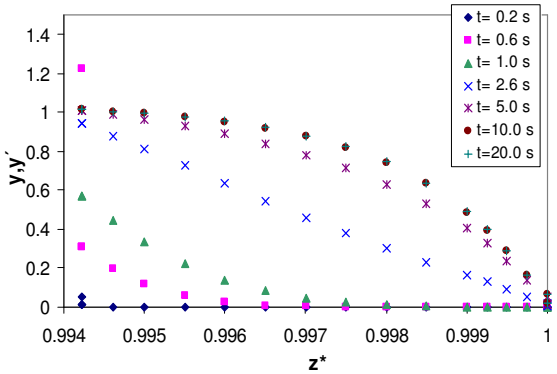

Figure 2. Normalized concentration profiles (membrane): u_t= 1.57 m/s, u_v= 1.0×10^{-5} m/s and K_{eq}= 0.25.

The large levels of rejection are maintained over a reasonable range of flux values (vd. Figure 3). It is verified that fixing K_{eq} at 0.25 allows a good agreement between experimental and simulated results in the practically constant rejection area. However, a sudden important decrease in rejection beyond a flux threshold is observed, which the model seems unable to

replicate, in spite of a slight decreasing tendency that does not fit at all to the experimental data.

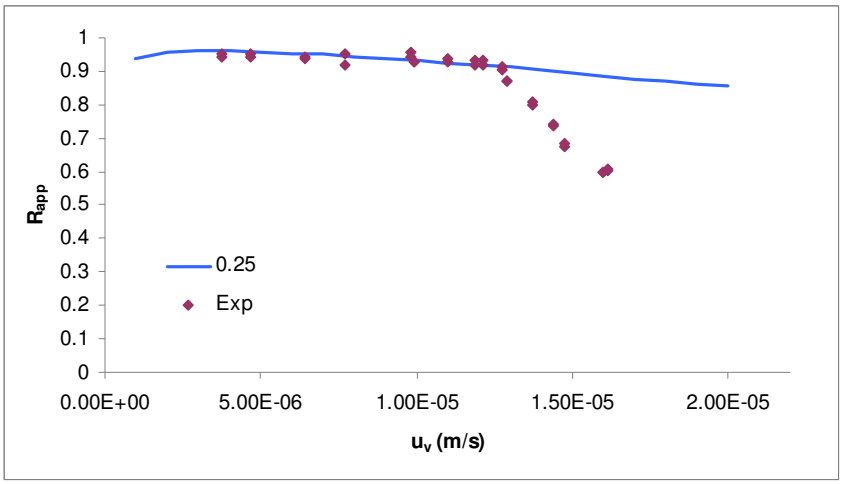

Figure 3. Apparent solute rejection profiles: u_t = 1.57 m/s, K_{eq} = 0.25.

The problem stated above becomes more notorious for results concerning u_t=0.76 m/s. In this case the decrease in rejection occurs earlier and in much stronger manner (vd. Figure 4). Again, the model can successfully replicate experimental results in the high plateau region with the same K_{eq} value, but fails to fit the sudden decrease.

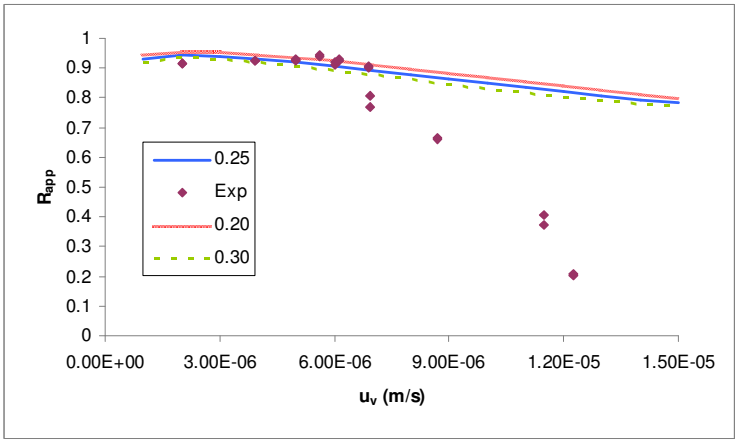

Figure 4. Apparent solute rejection profiles: u_t = 0.76 m/s, for various K_{eq}.

These discrepancies may be due to two major reasons: phenomenon driven, main phenomena enter a different regime in which the model considerations become no longer valid; or parameter driven, the assumptions concerning parameter non-variance in the problem conditions are invalidated. Considering the later case, two important parameters able to affect considerably the results are: membrane resistance, R_m and equilibrium constant, K_{eq}. R_m is estimated using Pure Water Filtration (PWF) experiments in the same conditions (vd. Figure 5; in this case, $R_m = 5.1394 \times 10^{12}$ m^{-1}), a questionable procedure since it is noticeable a typical lack of reproducibility of this kind of PWF data (Blox, 2003). For PEG-3400 filtration experiments this procedure seems to be acceptable, because the experimental pressure drop profiles are very similar to the PWF profiles (Brito et al, 2004). However this is clearly not the case in Dextran experiments. On the other hand, K_{eq} is assumed constant and it is the sole parameter tuned to fit the experimental data available, as stated above. Therefore, it is chosen to test the sensitivity of the model toward these two parameters in order to explain the sudden rejection drop.

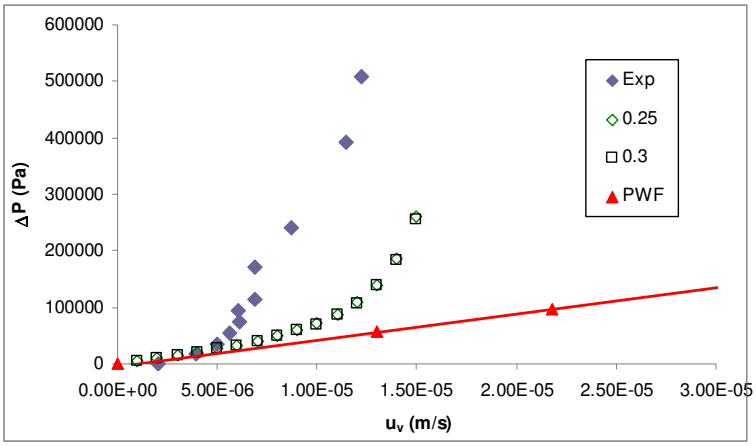

Figure 5. Total pressure drop profiles: u_t = 0.76 m/s, K_{eq} = 0.25; 0.30. (PWF- Pure Water Filtration)

It could be argued that this dramatic rejection drop would be due to sudden changes in the membrane geometry or structure. However, this behavior suggests an important drop in membrane resistance R_m, which is inconsistent with the also dramatic increase in the pressure drop that occurs simultaneously with the rejection fall (vd. Figure 5). In general, this pressure drop rising should be connected with a resistance increase. The same conclusions could be driven by the analysis of the model behavior to changes in K_{eq}. Changing these parameters values in the right direction to account the rejection evolution, will decrease its fitness of pressure data. Alternatively, the pressure drop rising conjugated with rejection drop could be explained with massive solute build-up at the membrane interface leading to extremely high solute concentration values (much higher than the computed by the model in these conditions – up to 25 times the bulk concentration). So, the pressure drop dramatic increase would be due essentially to the osmotic contribution. The model provides a rise in pressure drop and the osmotic pressure drop contribution increases significantly for higher fluxes but overall this rise is insufficient to follow the experimental data. Similar conclusions could be drawn by the analysis of the u_t =1.57 m/s experimental data, which are not presented here. Therefore, it is concluded that the behavior observed is explained by phenomenogical features that are not successfully represented by the model used in the rejection drop zone, and that are particularly visible for lower values of u_t.

5 Conclusions

It is concluded that the model successfully simulates experimental data in the high rejection/low flux region, but it is unable to replicate the observed rejection drop/pressure build-up which occurs for increased fluxes, which may be due to phenomenogical reasons or limitations of the model itself.

Keywords: CMSM, Pyrolysis, Gas Separation, Carbon Membranes
Topic: Advancing the chemical and biological engineering fundamentals.

Abstract

Carbon hollow fiber membranes have been prepared by pyrolysis of a co-polyimide P84/S-PEEK blend. The precursor was submitted to proximate analysis by thermogravimetry (TGA) revealing a yield of fixed carbon around 40%. This study aimed at understanding the influence of pyrolysis parameters: end temperature, quenching effect and soaking time on the membrane properties. Permeation experiments were performed towards N_2, He and CO_2. The specie N_2 was again tested after CO_2 to assess if any loss of performance of the membranes had occurred. Scanning electron microscopy (SEM) has been done for all carbon hollow fibers. The highest permeances and ideal selectivities were obtained for the membranes submitted to an end temperature of 750 ºC, previous to quenching.

1 Introduction

Carbon molecular sieve membranes (CMSM), pioneered by Koresh and Soffer in the 80's, are a very recent research topic in the area of gas separation. These inorganic membranes present great advantages over polymeric membranes, since they have comparatively high permeabilities and selectivities, together with high thermal and chemical stability (Saufi and Ismail, 2004; Ismail and David, 2001). The main applications for this type of membranes are, among others, air separation, landfill gas recovery, olefin/paraffin separation, hydrogen recovery and natural gas processing.

Carbon membranes are produced by pyrolysis of a polymeric precursor under an inert atmosphere (Saufi and Ismail, 2004). The preparation of CMSM should always be directed towards the tailoring of the final carbonaceous micropore network. The influence of the pyrolysis parameters and complementary treatments used for producing the final carbon membranes should be studied in order to better suit a certain application. Some previous studies indicate general requests to be fulfilled. The precursors should have high yield of carbon and should be thermosetting. The temperature programs followed in the pyrolysis, the cooling steps and the gas atmosphere employed, are all important aspects that have to be studied and optimized according to the precursor selected, having in mind the final application. Nevertheless, CMSM have two major disadvantages that still have to be overtaken: brittleness and aging effects (Ismail and David, 2001; Menendez and Fuertes, 2001). Nowadays, it is known that oxygen chemisorption on the surface of CMSM reduces the performance of these membranes (Menendez and Fuertes, 2001). This phenomenon may reduce the size of the pores affecting the separation of the gases. In cases that the feed mixture is humidified, the oxygen content on the carbon matrix may lead to the adsorption of water vapor which may block the passage of other species (Lagorsse et al., 2005).

2 Experimental

2.1 Precursor TGA

The precursor used in this study was a co-polyimide P84/S-PEEK blend. It was submitted to a proximate analysis performed in a Netzsch TG 209 F1 Iris, thermogravimetric balance, revealing a yield of fixed carbon approaching 40 %. The temperature protocol followed is described elsewhere (Ottaway, 1982).

2.2 Fabrication of carbon hollow fiber membranes

The pyrolysis occurred inside a quartz tube heated by a Carbolite® TZF 12/100 High Temperature Tubular Furnace, under a 50 $ml_N \cdot min^{-1}$ nitrogen atmosphere, together with a Eurotherm 2408 CP temperature controller. The temperature program employed is based on a temperature program described by Barsema (2004). The main differences from this protocol relate to the end temperature, quenching and soaking time.

The quenching consisted on a quickly cooling down inside a box with a nitrogen flow; *"No"* quenching means that the sole driving force for cooling was the difference between the temperature inside the furnace and the room temperature. The process of removing the carbon hollow fibers from the oven and introducing them into the quenching box was done as fast as possible, in order to minimize air exposure.

The influence of a final step – soaking time – in which the end temperature was kept constant for 2 h before quenching was also analysed.

These two steps, soaking and quenching, may probably lead to microstructural rearrangements, affect the pore size distribution and consequently the selectivity of the membrane.

Table 1 shows the identification of each kind of carbon membrane prepared, concerning its type and pyrolysis' parameters.

Table 1. Identification of the samples and pyrolysis' parameters.

Sample	T_{END} (ºC)	Soaking time (h)	Quenching
HF-700-A	700	0	Yes
HF-700-B	700	0	No
HF-750-A	750	0	Yes
HF-750-B	750	0	No
HF-800-A	800	0	Yes
HF-800-B	800	0	No
HF-700-ST2h	700	2	Yes

2.3 Scanning electron microscopy

All samples identified on table 1 were characterized by means of SEM. Through the pictures taken it was possible to measure the thickness, ℓ, of the selective layer, the inner and outer diameter of each fiber, and consequently the wall thickness. With this information the area, A_m of the membrane was calculated.

2.4 Permeation

After pyrolysis, the resulting carbon membranes were assembled on 3/8'' stainless steel cylinders filling it with a polyurethane resin isolating feed from permeate stream. Figure 1 illustrates the membrane module, where it is evidenced that the feed circulates on the shell side, whereas the permeate is evacuated from the bore side (right side). This edge of the membrane was left open for permeate removal. In order to protect the fibers from breaking, a PVC support rod was used. The other edge was introduced within a plastic tube full with glue. This was the closed edge (left side). These individual modules were then connected to a stainless steel housing which was introduced in a temperature controlled cabinet.

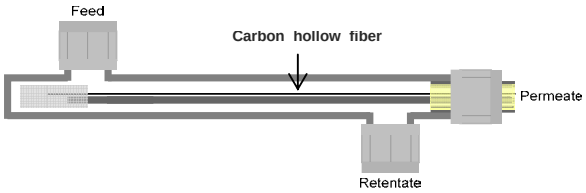

Figure 1. Scheme of the membrane module.

The permeation experiments were conducted at 30 ºC, using a pressure increment method. The several carbon membranes were tested towards N_2, He and CO_2. All the modules were submitted to 2 bar feed pressure on the shell side whereas vacuum was applied on the bore side. Here, ideal gas behavior was assumed and, hence, the monocomponent permeance, $\mathbf{P}$ was calculated according to equation (1),

$$\frac{\mathbf{P}}{\ell} = \frac{V_P \, \upsilon_M \, \left(P_l^t - P_l^0\right)}{\Re \, T \, t \, A_m \left(P_h - P_l\right)} \tag{1}$$

where V_P is the volume of the tank where the permeate is collected, P_l and P_h are respectively, the permeate pressure and the feed pressure, A_m is the effective area of the fiber, T is the absolute temperature, υ_M is the molar volume of the gas, $\Re$ is the gas constant, and t is the time. The ideal selectivity $\alpha_{i/j}$ for a certain pair of gases i and j is obtained by equation (2),

$$\alpha_{i/j} = \frac{\mathrm{P}_i}{\mathrm{P}_i} \tag{2}$$

where $\mathbf{P}_i$ and $\mathbf{P}_j$ are the permeances of species i and j, respectively.

3 Results and Discussion

3.1 Scanning electron microscopy

SEM pictures were taken to compare the structures of the different samples. Although fiber dimensions decrease in opposition to the end temperature, no further observations can be reliably taken. Figure 2 provides an example of micrographs taken for sample HF 700B.

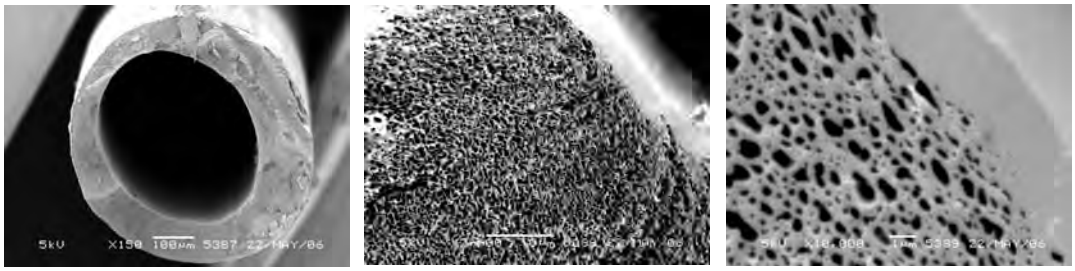

Figure 2. SEM pictures from HF 700 B carbon hollow fiber membrane.

3.2 End temperature effect

The effect of the end temperature on the performance of carbon hollow fiber membranes can be studied by determining monocomponent permeances. On table 2 are listed permeances and ideal selectivities for samples pyrolysed up to 700, 750 and 800 ºC towards N_2, He and CO_2. Figure 2 gives a better overlook on these results.

Table 2. Effect of end temperature on the permeance of carbon hollow fibers.

	Permeance / GPU*			Ideal Selectivity		
Sample	**N_2**	**He**	**CO_2**	**CO_2/N_2**	**CO_2/He**	**He/N_2**
HF-700-A	8	95	136	18	1.5	12
HF-750-A	24	151	356	15	2.4	6.4
HF-800-A	11	79	117	10	1.5	7.0

* $GPU = 10^{-6} cm^3 cm^{-2} s^{-1} cmHg^{-1}$

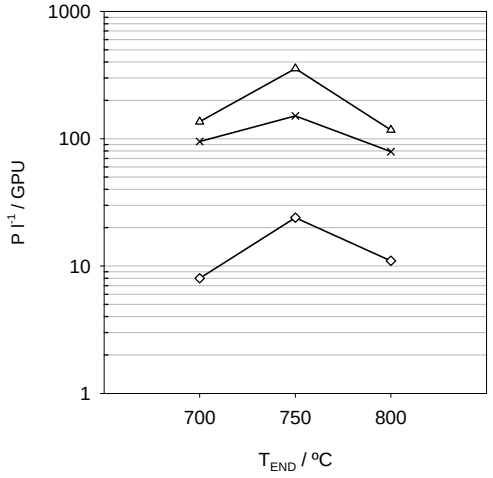

Figure 3. Permeation data through carbon membranes prepared up to 700, 750 and 800 ºC:
◇ - N_2, × - He and △ - CO_2.

From table 2 and figure 3 it is clear that for 750 ºC end temperature there is a maximum in permeance for all the species studied. For each end temperature, the species with lower

permeance is N_2 (L-J kinetic diameter 0.364 nm). However, despite CO_2 (0.33 nm) having a higher kinetic diameter than He (0.26 nm), the shape of the two species is different: the first one is linear and the second one is spherical. This difference in shape may be favorable to CO_2 that might get into smaller pores if it passes in it smallest dimension. Besides, it is known that normally CO_2 has a high affinity towards carbon matrixes, in opposition to He, which mostly does not adsorb. It is being assumed that adsorption plays a significant role in the mass transport mechanism through these membranes: molecular sieving combined with surface diffusion. A general look at the values of selectivities reflects that the highest are achieved for 700 ºC. From 700 to 750 ºC the increase in permeances for all species might indicate that the total pore volume has increases. On the other hand, the decrease in selectivity for the pairs CO_2/N_2 and He/N_2 is suggesting that the mean pore width is eventually enlarging.

3.3 Quenching effect

On this study, as previous mentioned, it was intended to analyze the permeance dependency on the way membranes are cooled from the pyrolysis end temperature to room temperature. Table 3 summarizes permeation data and ideal selectivities of the membranes obtained up to 750 ºC.

Table 3. Quenching effect on the permeance of carbon hollow fibers.

	Permeance / GPU			Ideal Selectivity		
Sample	**N_2**	**He**	**CO_2**	**CO_2/N_2**	**CO_2/He**	**He/N_2**
HF-750-A	24	151	356	15	2.4	6.4
HF-750-B	14	100	203	14	2.0	7.1

It is observed that the highest permeances are generically obtained when the membranes are quenched just after achieving 750 ºC. As for selectivities, table 3 shows that these values are reasonably constant. Qualitatively, it is possible to infer that the mean pore width was kept constant but the total volume of pore has decreased.

3.4 Soaking time effect

The soaking time consisted on keeping the membranes at the end temperature for a certain time interval, just before quenching. The effect of such a soaking time on the performance of carbon membranes is presented on table 4.

Table 4. Effect of soaking time on the permeance of carbon hollow fibers.

	Permeance / GPU			Ideal Selectivity		
Sample	**N_2**	**He**	**CO_2**	**CO_2/N_2**	**CO_2/He**	**He/N_2**
HF-700-A	8	95	136	18	1.5	12
HF-700-ST2h	14	118	159	11	1.3	8.2

In this case, from table 4, all the permeances are enhanced by the existence of a final isothermal step at 700 ºC end temperature but all the selectivities are lower. Higher permeances allied to lower selectivities might be an indication that the total pore volume has increased as well as the mean pore width.

3.5 CO_2 exposure

After exposure to CO_2 a reference experiment with N_2 was performed to assess any possible decrease in the permeance of the membrane. CO_2 is electron-deficient and thus, acts as a Lewis-acid (Raveendran et al., 2005). Although the membranes are essentially carbon, there may be some oxygenated groups on the surface (Brennan et al., 2001), acting as a Lewis-base, enhancing interactions with CO_2. Nevertheless, experiments showed no loss in permeance due to CO_2 exposure.

4 Conclusions

The pyrolysis parameters studied influence the characteristics of the resulting carbon membranes. The highest permeances and ideal selectivities were obtained for the membranes submitted to an end temperature of 750 ºC, previous to quenching. It was also concluded that the existence of a final soaking time after reaching the end temperature, just before quenching, improved the permeance of the carbon membranes, but causes a decrease in selectivity. Furthermore, it was observed that the membranes revealed higher permeances when quenched at the end of the process than the ones naturally cooled down to room temperature. No decrease in the performance of the membrane due to CO_2 exposure was observed.

Acknowledgments

The work of Marta Campo was supported by FCT, grant SFRH/BD/23833/2005. The authors would like to acknowledge the funding provided by FCT in the context of the research project POCI/EQU/60246/2004. The authors would also like to thank Doctor Tymen Visser, Doctor Kitty Nymeijer and Professor Matthias Wessling for their support during the stay of Marta Campo at MTG, Twente.

Keywords: linseed oil, supercritical CO_2 extraction, lipid composition.

Topic: Advancing the chemical and biological engineering fundamentals – extraction.

Abstract

The present study proposes to investigate the effect of pressure on the yield of supercritical CO_2 extraction of linseed oil and its influence on the lipid profile of the oil obtained. Moreover, the antioxidant potential of the linseed oil through thin-layer chromatography (TLC) and the evaluation of the co-oxidation of substrates of the system β-carotene/ linoleic acid were determined. The supercritical extractions were performed isothermally (at 50°C) for two extraction pressures (P = 150 and 250 bar) in a fixed bed extractor operating at a constant solvent flow of 1.5 gCO_2/min. Experimental extraction time was set at 5h. The yield values for each pressure condition tested in the supercritical CO_2 extraction assays varied from 3.8% (at 150 bar) to 8.3% (250 bar). The oil samples were esterified and submitted the chromatographic analysis. The main fatty acids (FA) found in the brown linseed oil were palmitic (6.51-6.52%), stearic (5.19-5.31%), oleic (21.96-22.09%), linoleic (13.85-13.86%) and α-linolenic (51.23-51.49%). The presence of antioxidant phenolics compounds was evidenced in all the samples, however, the best protection factor against the oxidation (21.33%) was obtained for the extracted oil samples at 250bar (volume of 200 μg/100g). The results showed that the linseed oil besides being an important source of essential fatty acids, also presents natural antioxidants, ratifying its role as an important food for the human nutrition.

1. Introduction

The extraction technique using supercritical fluids to obtain natural products has promoted a great deal of scientific and technological development in recent years, mainly in sectors linked to the food, pharmaceutical and chemical industries. In the food sector, in particular, there has been an explosion of interest on the part of consumers in the role of specific foods or physiologically active food components, the supposedly functional foods that improve health (Roberfroid, 1999). In this context, linseed (*Linum usitatissimum L.*), recognized for its rich composition of family acids of the ω3 family has received considerable attention.

Although it is an oleaginous seed widely used in industrial oil production, there are few published studies on linseed oil recovery using supercritical extraction. Accordingly, this study proposes to investigate the effect of operating extraction pressure on the yield of supercritical CO_2 extraction of linseed oil and its influence on the lipid profile of the linseed oil obtained.

2. Materials and Methods

Raw Material Preparation.

The brown linseeds (from a single lot collected in March 2007 in the city of Guarani das Missões, Brazil) were homogenized, sifted and stored in glass flasks at -20ºC until use. Sample moisture was determined according to the AOCS 2-54 method. To prepare the particle bed, the seeds were ground in a domestic multiprocessor for 10 seconds and separated in a sieve agitator containing Tyler sieves. Sample granulometry was composed of a mixture of particles with 30% of 24, 30% of 28, 20% of 32 and 20% of 48 mesh. A fixed mass of 140 ± 2 g of linseed was introduced into the extraction cell, forming the fixed particle bed for each experiment.

SC-CO_2 Extraction. The tests were performed isothermically (at 50ºC) for two extraction pressures (P = 150 and 250 bar) in a fixed bed operating at a constant solvent flow of 1.5 gCO_2/min (measured under ambient conditions). Experimental extraction time was fixed at 5 h. Linseed oil extraction at each pressure condition was carried out in duplicate and the mean of the results was used. The oil samples were collected at predetermined time intervals, weighed on an analytical scale, sealed and stored at -20°C for subsequent analyses.

Analyses. The oil samples obtained in supercritical extraction were sterified according to the Hartman and Lago method (1973) and submitted to chromatographic analyses. The analyses were performed in an Agilent 6850 series GC system capillary gas chromatography (CGC). The column used was the DB-23 Agilent (50% cyanopropyl) – methylpolysiloxane, 60m x 0.25mm x 0.25µm). The chromatographic conditions were as follows: 1) Temperature gradient: the initial temperature was 150°C/2 min, increasing 5°C/min up to 215°C, remaining at this temperature for 12 minutes; 2) Injector temperature: 250°C; 3) Detector temperature: 280°C; 4) Entrainment gas: nitrogen at a flow of 1mL/min and injector split ratio of 1/50. The identification of fatty acids in the samples was compared to the spectra of fatty acid patterns determined under the same conditions.

Antioxidant activity. Thin-layer chromatography (TLC) was used for the qualitative identification of the presence of antioxidant composites in the linseed oil samples. For the TLC, the plates were coated with Merck's silica gel G 60 (0.25mm) and activated at 110°C for 1 hour. We then applied 100µL (10µg/mL) of each sample, obtained at different operating pressures. Chromatographic development was performed using n-butanol: acetic acid: water (4:1:5) with a 15 cm path as solvent system. The developing reagents used were β-carotene/linoleic acid and ferric chloride/potassium/ferricyanide, according to procedures described by Nascimento (2002). The plates were exposed to natural light and were observed after 12h and 24h. The β-carotene developer is specific for identifying the presence of substances with likely antioxidant activity and can be observed by the orange coloration on the plates. Ferric chloride and potassium ferricyanide show the presence of likely phenolic composites, visualized by the blue coloration on the plates (Duve and White, 1991). According to Degani, Cass and Vieira (1998), the retention factor (Rf) is the most important parameter to be considered in TLC and is calculated from the ratio between the distance traveled by the substance under study and the distance traveled by the mobile phase. The antioxidant activity of the linseed oil was determined from the assessment of the co-oxidation of the substrates in the β-carotene/linoleic acid system, according to methodology developed

by Marco (1968) and modified by Miller (1971). This is an *in vitro* method that uses β-carotene and linoleic acid as oxidant agents and tween as emulsifying agent. The method is based on spectrophometric measures of decoloration (oxidation) of the β-carotene induced by the products of the oxidative degradation of linoleic acid. The concentrations of the samples used in the assays (100 and 200 µL/100g) were proposed by Moreira and Mancini Filho (2003a) and the spectrophotometric measures of the solutions were performed every 15 min for two hours. All the determinations were carried out in duplicate and were followed by a control without antioxidants. The results are expressed as a percentage of oxidation inhibition (%I), which is calculated considering the decline in optical density of the control (Dc) as 100% oxidation (Equation 1).

$$\%I = \left(\frac{Dc - Dam}{Dc} \right) 100 \qquad (1)$$

The decrease in the optical density reading of the samples (*Dam*) is given by $Dam = Abs_{initial} - Abs_{final}$ and for control $Dc = Abs_{initial} - Abs_{final}$.

3. Results and Discussion

The linseed sample had a moisture content of 7.6% and particle diameter of 0.42mm.

Process yield. The mean yield values for each pressure condition used in the supercritical extraction assays are shown in Figure 1. A yield of 3.8% was obtained for the minimum pressure used (150 bar), with an average collection of 5.2g of oil. For the maximum pressure used (250 bar), the mean yield was 8.3%, with an average collection of 12.01g of oil. The yield of each extraction was calculated from the ratio between the oil mass obtained in each assay and the linseed mass introduced into the extractor column.

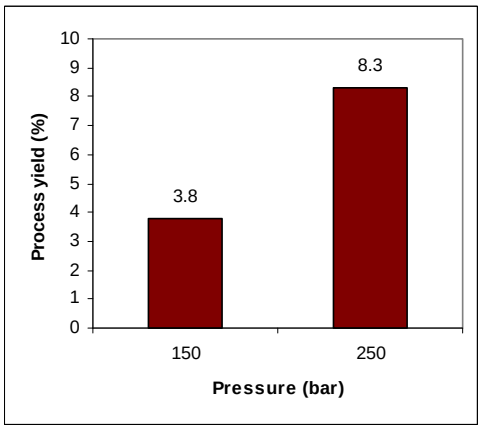

Figure 1. Process yield of the supercritical extraction of linseed oil as a function of extraction pressure**.**

Higher yield values were obtained with higher pressures. This result was expected, since increased operating temperatures cause a rise in CO_2 density, which induces better oil solubilization in supercritical CO_2, resulting in greater oil recovery.

Thin-layer chromatography (TLC). The chromatographic profiles of the linseed oil samples for the different extraction pressures studied are shown in Figure 2.

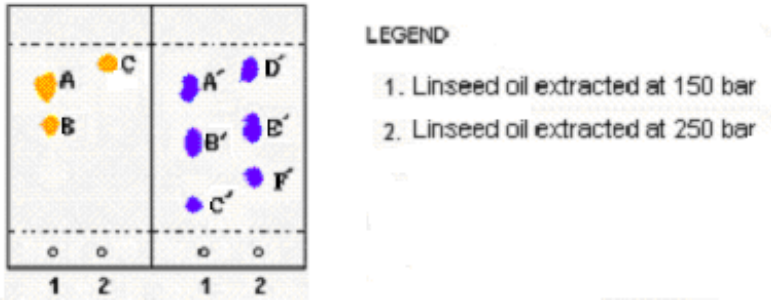

Figure 2. Chromatographic behavior of linseed oil samples obtained by supercritical CO_2 extraction at different operating pressures. (P = 150 and 250 bar)

All the linseed oil samples developed with β-carotene displayed bands with antioxidant activity. These bands were identified by the permanence of the orange coloration on the chromatographic plates, indicating the antioxidants present in the oil impeded the photooxidation of β-carotene. Retention factors varied between 0.64 and 0.96 for samples 1 (with linseed oil obtained at 150 bar) and 2 (with linseed oil obtained at 250 bar). Rf can vary according to a number of factors such as: adsorbent layer thickness, temperature and saturation of the vat containing the solvent system. The development of the plates with the ferricyanide/ferric chloride system showed the presence of phenolic composites, a fact indicated by the appearance of blue stains on the chromatographic plates, with a variation in Rf between 0.14 and 0.94. According to Moreira and Mancini Filho (2003b), phenolic composites are considered natural antioxidants. Thus, this result corroborates those obtained in the development with β-carotene, in which the linseed oil samples contained composites with antioxidant activity. A similar situation was observed by Nascimento (2002) for extracts of *Turnera ulmifolia* Linn., where he detected phenolic composites that inhibited β-carotene oxidation and therefore, had antioxidant activity.

Table 1**.** Rf of the linseed oil samples in TLC.

BANDS		**Rf**	
β-carotene	Ferricyanide/ Ferric Chloride	β-carotene	Ferricyanide/ Ferric Chloride
A	A'	**0.77**	**0.80**
B	B'	**0.64**	**0.63**

	D'	-	**0.94**
	E'	-	0.58
	F'	-	0.17

bold – bands relationship between phenolics compounds and antioxidant activity.

Antioxidant Activity. The presence of antioxidant activity in the linseed oil samples was determined in the β-carotene/linoleic acid system and the results are presented in Figure 3.

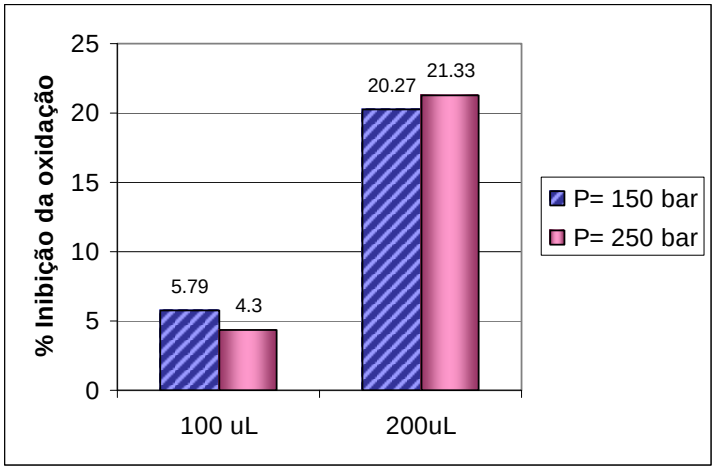

Figure 3 – Percentage of oxidation inhibition in the β-carotene/linoleic acid system for the linseed oil samples obtained at different extraction pressures.

The results show distinct levels of protection against the oxidative process; however, the best protection factor against oxidation (21.33%) was obtained for the oil samples extracted at 250 bar (sample volume of 200 μg/100g).

FA Composition. The main fatty acids (FA) found in the brown linseed oil were palmitic (6.51%), stearic (5.19-5.31%), oleic (21.96-22.09%), linoleic (13.85-13.86%) and α-linolenic (51.23-51.49%).

The percentage of each fatty acid found in linseed oil did not vary significantly with extraction pressure used. Brown linseed oil had a mean value of 65.22% of polyunsaturated fatty acids (C18:2n-6 and C18:3n-3), 22.03% of unsaturated fatty acids (C18:1) and 11.77% of saturated fatty acids (C16:0 and C18:0).

Table 2. Composition of brown linseed oil fatty acids (% m/m) obtained at different extraction pressures.

Fatty acid	150 bar	250 bar
Palmitic (C16:0)	6.51	6.51
Stearic (C18:0)	5.31	5.19
Oleic (C18:1)	22.09	21.96
Linoleic (C18:2n-6)	13.85	13.86
Linolenic (C18:3n-3)	51.23	51.49
Unidentified	1.01	0.99

4. Conclusions

The pressure range used in the supercritical extraction of linseed oil resulted in yield percentages of 3.8% and 8.3% (at 150 and 250 bar, respectively) for a total extraction time of 5h at a temperature of 50°C and mean solvent flow rate of 1.5 gCO_2/min. The results suggest a proportional relationship between the increase in linseed oil recovery and the rise in operating pressure. With respect to oil composition, no significant differences were observed between FA concentration values as a function of the extraction pressure used in the

experiments. In regard to the potential antioxidant of the linseed oil, the presence of antioxidant phenolic compounds was observed in all the samples; however, the best protection factor against oxidation (21.33%) was obtained for the extracted oil samples at 250bar (volume of 200 μg/100g). The results showed that linseed oil, in addition to being an important source of essential fatty acids, contains natural antioxidants, confirming its role as an important food for human nutrition.

Keywords: Supercritical Fluid Extraction, Enzymatic treatment, grape seed
Topic: Advancing the chemical engineering fundamentals.

Abstract

In this work, the supercritical fluid extraction of grape seed oil has been investigated. Grape (*Vitis vinifera*) seeds have been previously treated with an enzymatic cocktail of protease, xylanase, pectinase, and cellulose to increase the oil extractability upon partial hydrolysis of the vegetable cell walls. At 160 bar and 40ºC, the extraction yield of pre-treated biomass reached 16.5%, which is 43% superior to that of untreated samples. The first extraction curve clearly overcomes the one obtained for non-treated seed. Modelling has been accomplished providing good representations.

1. Introduction

Grape seed (Vitis vinifera L.) is a well known oilseed crop and a major by-product resultant from the wine industry, containing typically between 7-15% (w/w) of oil (Gomez, et al. 1996, Sovova 2005). It is also an appealing product due t its large availability, as a major by-product resultant from the wine industry. This research group is investigating ways of increasing the worth of such sub-products.

The extraction of vegetable oils using supercritical (SC) carbon dioxide is being studied as a potential alternative to conventional extraction methods. The most important reasons in this application come from the use of a harmless solvent, mild operating conditions, and the possibility to tailor inherent important properties such as solubility, selectivity, etc. Supercritical carbon dioxide is the usual solvent of choice, sometimes combined with polar co-solvents.

In recent years, supercritical fluid extraction (SFE) of grape seed oil has demonstrated that the amount of extracted oil is equivalent to that obtained by conventional soxhlet *n*-hexane extraction (Gomez, et al. 1996). Sovová et al. (2001) investigated the solubility of grape seed oil in SC CO_2 obtaining similar results to the one's presented in earlier studies from experimental extraction curves, where it was stated it becomes appreciable at 40°C for pressures around 200 bar, for vegetable oils whose main components are triglycerides (Bamberger, et al. 1988).

In the SFE process, the pressurised solvent flows continuously through the bed of particles and dissolves the solute. Behind the extractor, the pressure of the solution is reduced; solvent power of the fluid expanded to gaseous state dramatically decreases and the solute precipitates in a separator where its amount can be measured. The process is most easily characterised by extraction curve, i.e. the plot of the

[1] Corresponding author. Tel + 351-234-401549. E-mail:carlos.manuel@ua. pt

accumulated extract *versus* the time or the amount of solvent passed through the extractor.

To account for the sudden reduction of the extraction rate observed after a first extraction period, (that is particularly observed when vegetable oil is extracted from seed), the concept of broken and intact cells has been introduced (Sovova 1994). Close to the surface there is a region of broken cells whose walls have been damaged by pre-treatment processes, and particle core contains intact cells. Mass transfer resistance due to cell walls is high and therefore there is a large difference in diffusion rates from both regions; the initial fast extraction from broken cells is followed by a much slower extraction period from intact cells (Sovova 2005).

In this work, grape seed oil extraction is carried out using SC CO_2. To enhance the yield of the process, the extraction is combined with an enzymatic pre-treatment (cocktail of enzymes with pectinase, xylanase, protease and cellulase actions).

2. Experimental Procedure

2.1. Processing of the solid plant material

Seeds were collected from grapes (*Vitis vinifera* L.) of the red variety *Touriga Nacional* harvested at technological maturity in *Caves Messias* (Anadia, Portugal) during September 2007. Seeds were collected during transfer of the musts in wine fermentation, and separated from pulp and skins by decantation and sieving. A first wash removed immature grains floating at water surface. Subsequently, the seeds were submitted to several washes with water (200 g/L) under gentle stirring with a magnetic bar at 4 ºC during a minimum of three days, with two water exchanges per day, until a minimum constant turbidity was observed. The purified seeds were finally washed with ethanol, air dried at room temperature, and stored at 4 ºC until use. Finally, milling was carried out on a domestic coffee mill, and the particles classified in a standard sifter with several mesh sizes. For further analyses only paticles with a size diameter between 1.0-1.4 mm were selected.

2.2. Enzymatic pre-treatment

Prior to the SFE, an enzymatic pre-treatment was performed based on previous optimized results by Passos et al. (2008). Following to that essay, the experimental conditions selected are: reaction time of 24h, 40ºC, pH=4, and a concentration range of enzymes of 29, 142, 1191, and 21 U/g of seed sample of cellulase, pectinase, protease and xylanase, respectively.

2.3. Supercritical Fluid Extraction

Extraction measurements were run in a semi-batch flow extraction apparatus built/assembled at the University of Aveiro. It has been operated with nearly 95 g of crushed grape seeds, a CO_2 flow rate of 0.6 kg h^{-1}, at 160 bar and 40ºC. Two sets of experiments were carried out: one with enzymaticaly pre-treated seed, and another one with untreated seed for comparison. The extraction yield was defined (% w/w) as the quantity of oil extracted divided by the quantity of dried vegetable matrix loaded in the extractor multiplied by 100.

3. Mathematical Modelling

Among the various models presented in literature to describe SFE from solid biomass, the model developed by Sovová (2005) has been chosen in this essay. It represents experimental data fairly well. The model assumes that the oil is distributed between an easily accessible part of the seed and another fraction corresponding to the intact core cells where oil is entrapped. Therefore, three material balances were writhen (one to the extractor and one for each particle region):

a.1 (Fluid Phase)

$$\left[\varepsilon\rho_f \frac{\partial y}{\partial t}\right] + \left[\varepsilon\rho_f u \frac{\partial y}{\partial z}\right] = j_f = j_{f1} + j_{f2} \qquad [2]$$

a.2 (Solid phase with broken cells)

$$\left[(1-\varepsilon) r \rho_s \frac{\partial x_1}{\partial t}\right] = -j_{f1} \qquad [3]$$

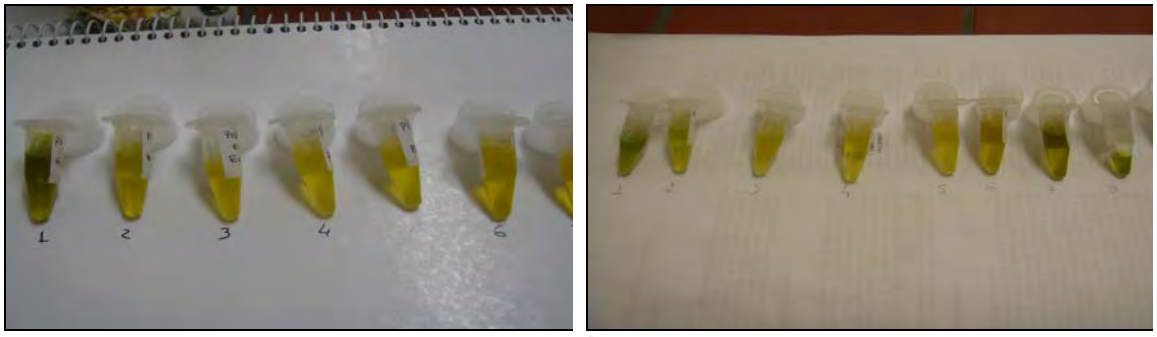
a.3 (Solid phase with intact core cells)

$$\left[(1-\varepsilon)\cdot(1-r)\rho_s \frac{\partial x_2}{\partial t}\right] = -j_{f2} \qquad [4]$$

During the extraction, solute diffuses from intact core cells to the broken ones at surface, and then from these to the bulk by convection.

4. Results and discussion

In Figure 1 some eppendorfs with collected oil for both treated and non-treated samples are shown. It may be observed at naked eye the colour gradient between extracts, the darker ones being obtained at the beginning and at the end of experiments.



a **b**

Figure 1 – Eppendorfs containing grape seed oil collected along time under supercritical conditions with (a) and without (b) enzymatic pre-treatment.

Figure 2 shows the results for the grape seed oil extraction with SC CO_2 at 160 bar and 40ºC, where yield is graphed against the ratio between solvent consumption and seed charge (m_{CO_2}/m_{seed}). Here, yield is expressed as the percentage ratio between extracted oil and seed charge. Two cumulative curves are plotted for samples which have and have not suffered the enzymatic pre-treatment. Both curves present similar trends, comprehending a first period approximately linear, and a second asymptotic period which represents only 3-8% of the total extracted oil, which justifies the hypothesis of the theory proposed by Sovová (Sovova 2005, 1994) and also adopted in this work.

The maximum oil yield obtained for the untreated seeds was 11.5%. This result agrees with a 4 h conventional *n*-hexane soxhlet extraction. When the enzymatic pre-treatment was introduced, the broken to intact cells ratio was enlarged, which explains why the corresponding extraction curve clearly overcomes the former for non-treated sample. In addition, maximum yield becomes 16.5%, representing an increase of about 43% over the first result. It is important to detach that 11.5% of oil is nearly attained for $m_{CO_2}/m_{seed} \cong 8$, whereas untreated biomass reaches the same recovery for $m_{CO_2}/m_{seed} \cong 4$. Such fact implies that only half of the CO_2 has to be spent to get the same oil quantity. Equivalently, the extraction time is reduced to one half also, for the same mass flow rate of SC solvent. In the whole, the contribution of the first extraction period, where equilibrium and diffusion in the film dominate, is increased, expanding the extractability of the grape seed oil,

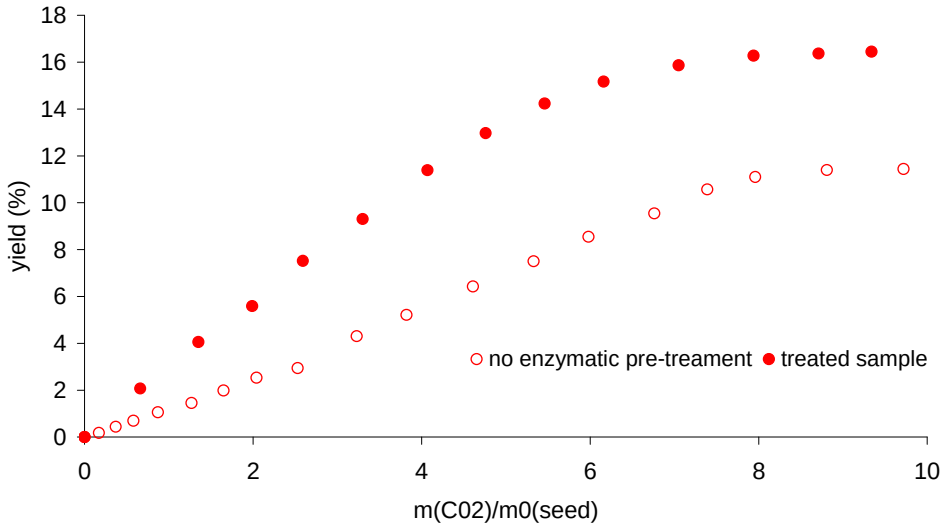


Figure 2 – SFE curves of grape seed oil at *T* = 40ºC and *P* = 160 bar. Comparison between treated and non-treated samples.

Modelling has also been carried out in order to represent and simulate the process. According to Figure 3, it may be concluded the SC CO_2 washes the easily accessible fraction of the crushed seed exhausting its oil content. The inner part, containing most non-easily accessible oil, exhibits somewhat smother profiles. Results corroborate experimental data plotted in Figure 2, as the contribution of the second extraction period to the global yield is almost negligible.

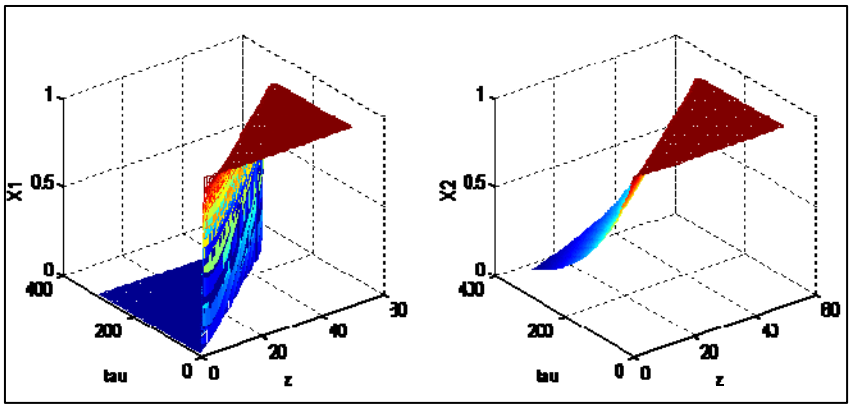

Figure 3 – Distribution of the oil normalised concentrations in easily and non-accessible fractions of grape seed (X_1 and X_2) as function of both the axial coordinate of the bed (z) and dimensionless time (tau). Experimental conditions: T =40ºC and P = 160 bar

4. Concluding remarks

In this essay, the SFE of grape seed oil using CO_2 achieved yields similar to those obtained by conventional soxhlet with n-hexane. Taking into account the well reported advantages of SFE and carbon dioxide, such results confirm that this is an efficient separation alternative.

By introducing an enzymatic pre-treatment, the broken/intact cells ratio was enlarged, thus increasing extraction yield by 43% for experiments at 40ºC and 160 bar. The corresponding extraction curve clearly overcomes the one for non-treated sample.

Results were modelled considering the fundamental assumption due to Sovová, i.e. the oil is distributed between broken and intact fractions of the grape seed. Good representations were accomplished, thus confirming such hypothesis.

5. Notation

$j_f = j_{f1} + j_{f2}$	$kg.m^{-3}s^{-1}$	mass transfer rate to the fluid phase;
j_{f1}	$kg.m^{-3}s^{-1}$	mass transfer rate between the free oil within the broken cells and the fluid phase;
j_{f2}	$kg.m^{-3}s^{-1}$	mass transfer rate between the oil entrapped in the intact core cells and the fluid phase;
r		fraction of broken cells, grinding efficiency;
t	s	extraction time;
u	$m.s^{-1}$	fluid velocity;
x_1	kg(solute)/ kg(insoluble solid)	concentration in broken cells;
x_2	kg(solute)/ kg(insoluble solid)	concentration in intact cells;
y	kg(solute)/ kg(solvent)	fluid-phase concentration;
ε	-	bed void fraction;
ρ_f	$kg.m^{-3}$	fluid density;

ρ_s	kg(insoluble solid) /m(solid phase)^3	solid density;

Key words: supercritical antisolvent, nanoparticles, precipitation, carbon dioxide, antibiotics

Abstract
Pharmaceutical preparations are the final product of a technological process that gives the drugs the characteristics appropriate for easy administration, proper dosage and enhancement of the therapeutic efficacy. The design of pharmaceutical preparations in nanoparticulate form has emerged as a new strategy for drug delivery [1]. Particle size (PS) and particle size distribution (PSD) are critical parameters that determine the rate of dissolution of the drug in the biological fluids and, hence, have a significant effect on the bioavailability of those drugs that have poor solubility in water, for which the dissolution is the rate-limiting step in the absorption process [2,3]. Supercritical AntiSolvent (SAS) processes have been widely used to precipitate Active Pharmaceutical Ingredients (APIs) [4, 5] with a high level of purity, suitable dimensional characteristics, narrow PSD and spherical morphologies.
SAS process is based on the particular properties of the supercritical fluids (SCFs). These fluids have diffusivities of two orders of magnitude larger than those of liquid resulting in a faster mass transfer rate SCFs properties (solvent power and selectivity) can be also adjusted continuously by altering the experimental conditions (temperature and pressure). As consequence, the SCFs can be removed of the process by a simple change from the supercritical to room conditions which avoid difficult post – treatments of waste liquid streams. Carbon dioxide (CO_2) at supercritical conditions, among all possible SCFs, is largely used because of its relatively low critical temperature (31.1 ºC) and pressure (73.8 bar), low toxicity and low cost.
In this paper, we show some results about processed antibiotics (ampicillin and amoxicillin), two of the worlds most widely prescribed antibiotics, when they are dissolved in 1-methyl-2-pyrrolidone (NMP) and carbon dioxide is used as antisolvent.

1.- Introduction

The utilization of supercritical fluids in the processing of pharmaceutical compounds has become important in recent years [6].
Advantages such as high purity products, environmental protection, and greater experimental versatility are significant and all combine to create a viable alternative to certain conventional processing currently used in the pharmaceutical industry [7].
The supercritical antisolvent process (SAS) uses both the high power of supercritical fluids to dissolve the organic solvents and the low solubility of the pharmaceutical compounds in supercritical fluids [8] to cause the precipitation of such compounds once they are dissolved in the organic phase.
The dissolution of the supercritical fluid into the organic solvent is accompanied by a large volume expansion and, consequently, a reduction of the liquid density, and therefore, of its solvent power, causing a sharp rise in the supersaturation within the liquid mixture. Because of the high and uniform degree of supersaturation, small particles with a narrow particle size distribution are expected [9].
Furthermore, antibiotics can be entrapped in nanoparticles of various formulations using supercritical antisolvent process. In particular, polymeric micro- and nano-particles have

been found successful in the preparation of sustained drug delivery systems, hence they display enhanced therapeutic performance compared to traditional formulations [10-12].
Ampicillin and amoxicillin are some of the most widely prescribed antibiotics. Using controlled-sized microparticles of ampicillin or amoxicillin it is possible to increase its bioavailability and decrease its therapeutic dosage (thus improving efficiency). It is also possible to change its drug delivery system (transdermal, tracheobronchial and pulmonary delivery systems) by eliminating undesired secondary effect as a result of oral consumption of this pharmaceutical compound [1].
In this work, ampicillin and amoxicillin have been processed at 90 bar, 308.15 K, 100 mg/mL, 5 mL/min solution flow rate, washing time 180 min, noozle 100 µm and 32 g/min CO_2 flow rate using 1-Methyl-2-pyrrolidone (NMP) as solvent.

2.- Material and Methods

2.1. Experimental equipment and procedures

A schematic diagram of the pilot plant, developed by Thar Technologies® (model SAS 200), is shown in Fig. 1. The SAS 200 system is made up of the follow components: two high pressure pumps, one for the CO_2 (P1) and the other for the solution (P2), which incorporate a low dead volume head and check valves to provide efficient pumping of CO_2 and many types of solvent; a stainless steel precipitator vessel (V1) with 2 L volume, consisting of two parts, the main body and the frit; it also has an electric heating jacket (V1–HJ1); an automated back pressure regulator (ABPR1) of high precision attached to a motor controller with a position indicator; a jacketed (CS1–HJ1) stainless steel cyclone separator (CS1) with 0.5 L volume to separate the solvent and CO_2, once the pressure is released by the manual back pressure regulator (MBPR1). Auxiliary elements are necessary too, such as: a low pressure heat exchanger (HE1); cooling lines and cooling bath (CWB1) to keep the CO_2 inlet pump cold and to chill the pump heads. An electric high pressure heat exchanger (HE2) is used to preheat the CO_2 to bring the temperature in the precipitator vessel to the required level rapidly; safety devices (rupture discs and safety valve MV2) are included; pressure gauges measure the pump outlet pressure (P1, PG1), the precipitator vessel pressure (V1, PG1) and cyclone separator pressure (CS1, PG1) and continuous temperature measurements are made by means of thermocouples placed inside (V1–TS2) and outside (V1–TS1) the precipitator vessel, inside the cyclone separator (CS1–TS1) and on the electric high pressure heat exchanger; a FlexCORTM coriolis mass flowmeter (FM1) is used to measure CO_2 mass flow rate and other parameters such as total mass, density, temperature, volumetric flowrate, and total volume. All parameters that influence in the precipitation process (temperature, flow rate, pressure) can be controlled either manually or automatically (using ICM software). All the experiments were performed following the same procedure described in a previous work [13].

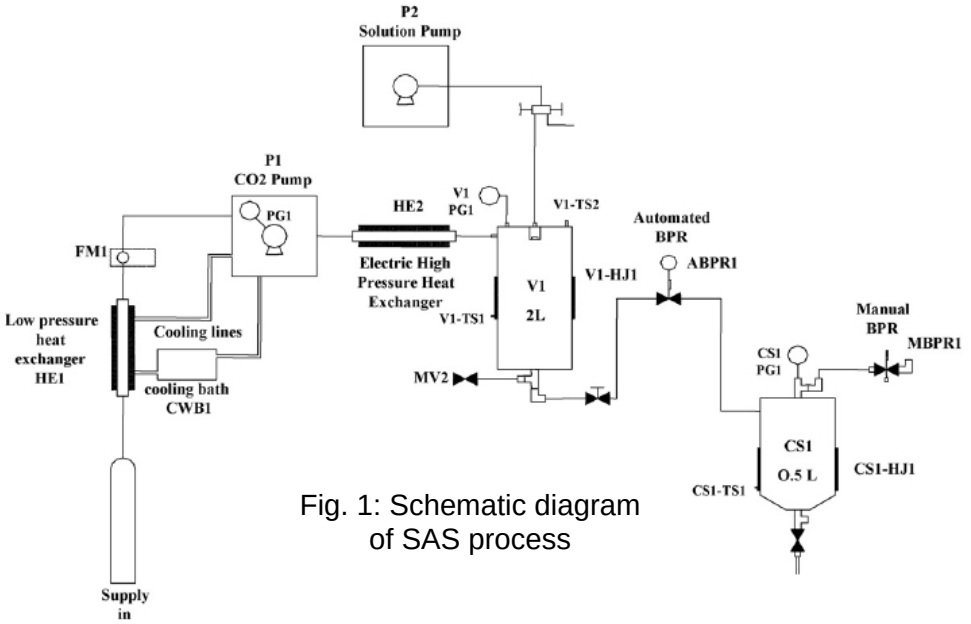

Fig. 1: Schematic diagram of SAS process

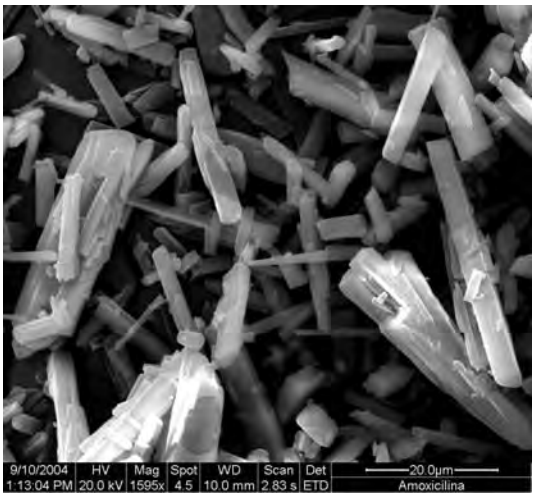
2.2. Materials and analytical methods

1-Methyl-2-pyrrolidone (NMP) (purity 99.5%) was purchased from Sigma–Aldrich Chemical (Spain). CO_2 with a minimum purity of 99.8% was supplied by Carburos Metálicos S.A. (Spain). Ampicillin sodium salt (minimum purity 91.0%) and amoxicillin (AMC) (purity ≥97%) were purchased from Sigma–Aldrich Chemical (Spain) and were used in the precipitation experiments. SEM pictures of amoxicillin and ampicillin as received are shown in Fig. 2. Samples of the powder precipitated both on the vessel wall and in the frit were observed using a Sirion scanning electron microscopy (SEM). Previously, the samples were put onto carbon tape and then were covered with a gold coating using a sputter coater.

(a)



(b)

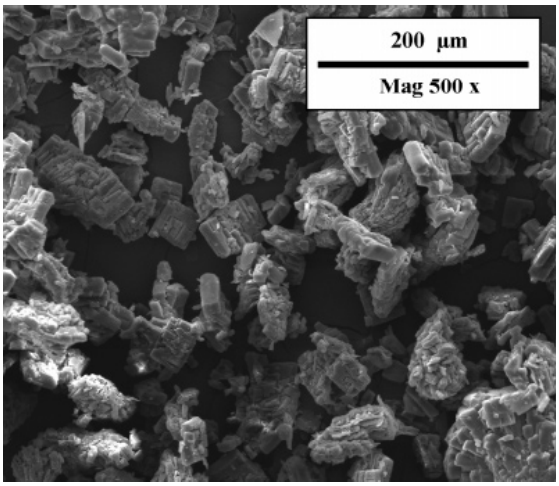


Fig 2. SEM images of unprocessed amoxicillin (a) and ampicillin (b)

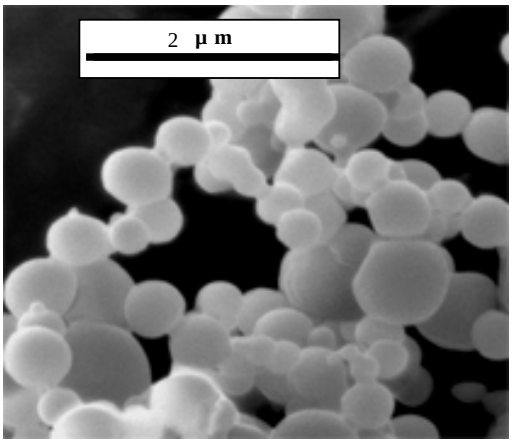
3.- Results

SEM pictures of processed amoxicillin and ampicillin are shown in Figure 3 [13, 14].

(a)



(b)

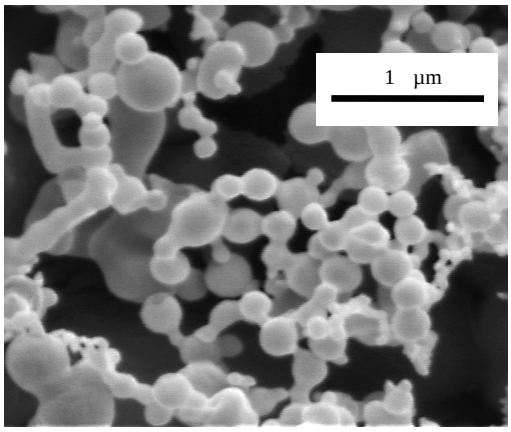


Fig. 3. SEM image of amoxicillin (a) and ampicillin (b) nanoparticles precipitated from 100 mg/mL, 308.15 K, 90 bar, 5 mL/min solution, 32 g/min CO_2, washing time 180 min, noozle 100 µm

The SEM images were processed using Scion image analysis software (Scion Corporation) to obtain the particle sizes. After that, the mean particle size (PS) and particle size distribution (PSD) were calculated using Statgraphics plus 5.1 software. More than 200 particles were counted to carry out the analysis in each experiment.
The SEM images of amoxicillin and ampicillin samples micronized show the formation of spherical nanoparticles with a mean particle size of 450 nm and 291 nm respectively, uniformly distributed with a coefficient of variation equal to 0.4.

Solvent effects on ionic association of 2,6-lutidinium chloride salt at 60.00 ºC: A QSPR study

M. Reis[1], L. Moreira[1], R. E. Leitão[2], F. Martins[1*]

[2] Departamento de Engenharia Química - ISEL, CQB, R. Conselheiro Emídio Navarro, 1950-007, Lisboa, Portugal

Keywords: Conductance, organic salts, association constant, QSPR, solvent effects.
Topic: Advancing the chemical and biological engineering fundamentals

Abstract

Conductivity values (σ_{sln}) for 2,6-lutidinium chloride were obtained in twelve protic and aprotic solvents at 60.00 ± 0.01 ºC, for ten concentrations ranging from 0.001 to 0.01 mol dm^{-3}. The obtained $c = f(\sigma_{sln})$ curves do not follow the Fuoss-Hsia equation, modified by Fernández Prini, but rather adjust well to the Ostwald´s law.

Molar conductivities at infinite dilution (Λ^0_m), association constants (K_A) and respective errors were determined from the application of an iterative curve fitting procedure which was also applied with success to another set of $c = f(\sigma_{sln})$ curves previously reported for other ten solvents at the same working temperature (60 ºC).

The application of a suitable equation within the QSPR (quantitative structure-property relationships) context, the enlarged TAKA equation, allowed a proper understanding of solvent effects on ionic association of this salt in solution and the discrimination and quantification of the involved physicochemical properties. It is shown that that the chosen equation is able to adequately model K_A in terms of specific and non-specific ion-solvent-solvent interactions which all contribute to enhance the dissociation process. Our results indicate that a considerable amount of positive charge density is located on the hydrogen directly attached to the nitrogen of the heterocyclic ring.

1 Introduction

Conductivity measurements of salts in a diversified set of solvents are of great importance due to their contribution for an in-depth understanding of solvent effects on ion association and mobility phenomena (Prini et al., 2000).

A considerable amount of work has been devoted to establish mathematical models to accurately reproduce molar conductivity (Λ_m) *vs*. concentration (c) curves. Expressions such as the Fuoss-Hsia equation (Hsia and Fuoss, 1968), later modified by Fernández-Prini (Prini, 1969) or newer models which use a full radial distribution function as given by the Mean Spherical Approximation (Blum and Turq, 1992) are some possible examples.

The ionic association of salts, defined as an equilibrium between dissociated ions and associated salt molecules [ion$^-$] + [ion$^+$] $\leftrightharpoons$ [ion pair], is among the first recognized influences on the referred plots. An association constant (K_A) can thus be defined from the equilibrium equation which represents the concentration dependence of the process of accounting for strong Coulombic forces at short interionic distances (Cotê et al., 1998).This description of the association constant implies that log K_A can be considered an energetic related term dependent on both salt and solvent features.

* Corresponding author. Tel +351-21-7500870. E-mail: filomena.martins@fc.ul.pt

Quite recently, the use of a suitable equation (eq. 1) allowed us to determine K_A values and respective errors at 60.00 ºC for 2,6-lutidinium chloride salt in ten different non-aqueous solvents (Moreira et al, 2006). In eq. 1 Λ^0_m represents the molar conductivity at infinite dilution, S is a dielectric constant and viscosity dependent parameter, α is the ionization degree and $f_\pm$ the mean ionic activity coefficient.

$$\Lambda_m = \Lambda^0_m - S(c\alpha)^{1/2} - K_A \Lambda_m f_\pm^2 c\alpha \qquad \text{eq. 1}$$

The obtained results revealed strong deviations from the predictions of classical dielectric theories. It was therefore reasoned that specific ion-solvent-solvent interactions could play an important role in explaining the observed results. The aim of this work is therefore the application of a suitable methodology to determine and quantify the relevant solvent properties which influence the ionic association of the above mentioned 2,6-lutidinium salt at 60.00 ºC.

Quantitative structure-property relationships (QSPR) are among the most powerful methodologies used to study solvent effects on physicochemical processes and, in particular, the TAKA equation (Abraham et al., 1987) has been one of the most used equations built upon these concepts. We have enlarged its scope by including an extra solvent property related to the solvent's stiffness, thus deriving the denominated enlarged TAKA equation, eq. 2 (Moreira *et al.*, 2005).

$$\text{Energetic term} = a_0 + a_1 \pi^* + a_2 \alpha + a_3 \beta + a_4 C + a_5 \log \eta \qquad \text{eq. 2}$$

According to the above equation, solvents are characterized by their dipolarity/polarizability (π^*), taken as a measure of non-specific solvent–solute interactions related to the capacity of the solvent to generate a spread of charges in the cybotatic region of the solute; their hydrogen bond donor (HBD) acidity (α) and hydrogen bond acceptor (HBA) basicity (β) abilities, regarded as measures of specific solvent–solute interactions of the Lewis type (see fig. 1); their structuredness, given by the cohesive energy density parameter, C, which accounts for solvent–solvent interactions determining the disruption and reorganization of the solvent structure; and the solvent's stiffness, given by the logarithm of viscosity ($\log \eta$). The a_i coefficients are the complementary solute-dependent coefficients of the solvent parameters.

The determination of K_A values in a diversified set of solvents allows a correct application of eq. 2, the accomplishment of statistically meaningful results and the quantification of solvent effects on ion association phenomena.

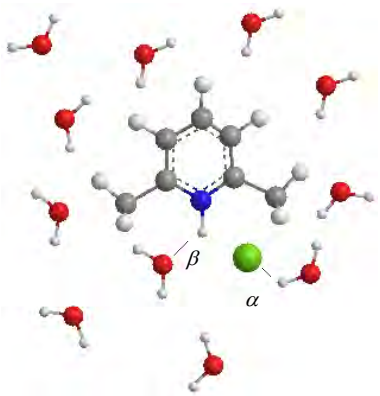

Fig. 1 - Scheme describing α (HBD) and β (HBA) solvation modes on a 2,6-lutidinium chloride – water cluster representation.

2 Results and discussion

The results here presented refer to conductivity measurements (σ_{meas}) of 2,6-lutidinium chloride in twelve protic and aprotic solvents for ten different concentrations ranging from 0.001 mol dm^{-3} to 0.01 mol dm^{-3}, at 60 ± 0.01 ºC. Together with these determinations, residual conductivity, emerging from the solvent itself, was considered and subtracted from σ_{meas} to determine the solution's conductivity (σ_{sln}).

Equation 1 was tentatively applied to the obtained data following a formerly optimised procedure (Moreira et al, 2006). However, for this particular set of solvents the methodology was not suitable to determine the necessary K_A (and Λ^0_m) values, since there was no convergence to a minimum in the fitting process.

A different approach, based on the Ostwald´s law for weak electrolytes (Robbins, 1972) was therefore devised to obtain the required values. Traditionally, the linearized form of this law (eq. 3) has been used with the argument that it allows a more reliable determination of Λ^0_m. However, this linearized form overweighs the lower concentration (and conductivity) data, for which the experimental uncertainty is higher. Also, considering that errors in c are always higher than those in σ_{sln}, it is more appropriate to derive a $c = f(\sigma_{sln})$ expression to compute K_A and Λ^0_m values. Equation 3 was therefore reorganized to equation 4, were K_A and c maintain the mol dm^{-3} units, as Λ^0_m remains in S cm^2 mol^{-1} and σ_{sln} in S cm^{-1}.

$$\frac{1}{\Lambda_m} = \frac{1}{\Lambda_m^0} + \frac{K_A \Lambda_m c}{\left(\Lambda_m^0\right)^2} \qquad \text{eq. 3}$$

$$c = \frac{1000\sigma_{sln}}{\Lambda_m^0} + \frac{1000^2 K_A \sigma_{sln}^2}{\left(\Lambda_m^0\right)^2} \qquad \text{eq. 4}$$

A formerly designed Microsoft Excel spreadsheet (Moreira et al, 2006) was modified to allow the determination of both K_A, Λ^0_m values and respective errors from an iterative curve fitting procedure. The obtained results for the eleven (σ_{sln}, c) curves are reported in table 1, together with those obtained by the application of the same procedure for the ten solvents previously reported at the same temperature (Moreira et al, 2006).

One of the most important aspects regarding QSPR studies is the importance of attaining results with statistical robustness and significance. Commonly, some general rules are considered: an adequate sample size must contain at least three points for each descriptor; the descriptor's space should be fully covered and homogeneous and have no leverage points; the set of descriptors should not be intercorrelated (the determination coefficient, R^2, among pairs of descriptors should be no greater than 0.50 and as low as possible for one descriptor against all others; the regression coefficients should have a significance level of at least 95%.

As referred before, the enlarged TAKA equation (eq. 2) was used to quantify solvent effects on K_A values derived from (σ_{sln}, c) curves. The five descriptors' values for each of the 22 solvents used in this work are also reported in table 1.

Table 1 - Solvent descriptors[a] and K_A, Λ^0_m values and respective associated errors determined at 60 ºC.

[a] Descriptors reported at 25ºC and assumed not to vary considerably with temperature.
[b] Solvents studied in this work are represented in bold.

Equation 2 was first applied to the full set of solvents. The regression presented poor statistical parameters (sd_{fit}=0.38, R^2_{adj}=0.76 and F=15), an apparent outlier and both C and log η with SL < 95%. However, the exclusion of either and both of these descriptors lead to worse regressions from a statistical point of view. Therefore, the descriptors space was analyzed to check the existence of possible leverage points. This procedure revealed that water and formamide were indeed leverage points in C. The removal of these solvents lead to a significant improvement in the statistical figures of merit (sd_{fit}=0.21, R^2_{adj}=0.92 and F=47), to the disappearance of any outliers and to a loss of statistical significance of log η (SL=49%). This descriptor was therefore withdrawn from the regression equation and a new fitting lead to equation 5:

$$\log K_A = 8.01_{\pm 0.45} - 2.74_{\pm 0.33}\pi^* - 1.34_{\pm 0.12}\alpha - 1.72_{\pm 0.26}\beta - 2.75_{\pm 0.40}C \qquad \text{eq. 5}$$

(N = 20, R^2_{adj} = 0.927, sd_{fit} = 0.203, F = 61, SL > 99%)

Results must also be externally validated. For that purpose, remaining data were divided in two sets: a training set, designed according to the above mentioned rules, which was used to determine regression coefficients; and a test set, with a similar descriptors' variablity, used to assess the ability of the established regression equation to predict log K_A values for solvents not used in the training set. Solvents 1 to 13 were chosen as the training set and solvents 14 to 20 were selected as the test set. Equation 6 shows the attained results. The magnitude and sign of regression coefficients are almost identical to the ones from eq. 5, confirming the

robustness of the fit. Figure 2 shows the quality of the fit and also that external validation was fully accomplished for the test set.

$$\log K_A = 8.04_{\pm 0.46} - 2.79_{\pm 0.29}\pi^* - 1.23_{\pm 0.11}\alpha - 1.71_{\pm 0.24}\beta - 2.80_{\pm 0.51}C \qquad \text{eq. 6}$$

(N = 13, R^2_{adj} = 0.960, sd_{fit} = 0.160, F = 74, SL > 99%)

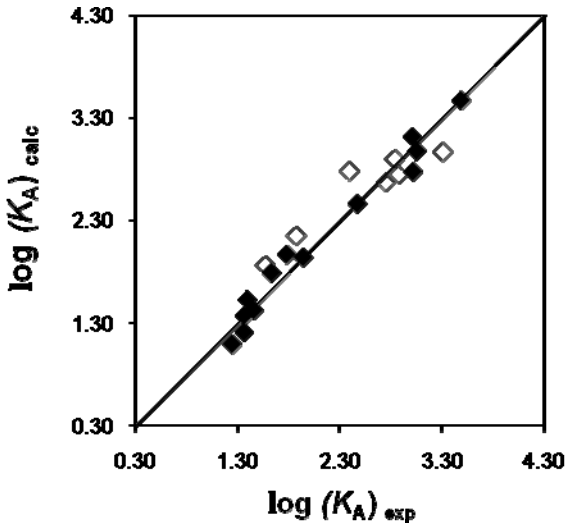

Fig. 2 – Calculated *vs*. experimental log K_A values:

◆ – training set (solvents 1 to 13)
◇ – test set (solvents 14 to 20)

The obtained model equation for the full data set, eq. 5, explains 93% of the overall log K_A variability with a standard deviation of 0.2 log units. Results also indicate that specific and non-specific solute-solvent interactions, together with the structuring degree of the solvent decrease K_A. All solvent effects contribute to increase the ionic character of the salt in solution. The relevance of π^* and α was foreseen, given the nature of the studied process. On the other hand, the significance and magnitude of the β parameter are rather unexpected and are only consistent with accepting a considerable amount of positive charge density located on the hydrogen directly attached to the nitrogen of the heterocyclic ring and not on the nitrogen itself, as usually assumed (see fig. 1).

This study's main outcome, *i.e.*, the abiltiy to model K_A through the TAKA equation, confirms our earlier conjecture (Moreira *et al.*, 2006) for the need to consider extensive ion-solvent and solvent-solvent interactions to correctly assess solvent effects on ion association phenomena.

3 Conclusions

Twelve new $c = f(\sigma_{sln})$ curves obtained at 60 ºC, together with previously reported curves for ten other solvents obtained at the same temperature, were successfully analysed using an equation derived from the Ostwald´s law for weak electrolytes. An iterative curve fitting approach allowed the computation of statistically meaningful and discernible Λ^0_m and K_A values and respective errors.

The gathered data allowed the analysis of log K_A values using a QSPR methodology. Dipolarity/polarizability (π^*), hydrogen bond donor (HBD) acidity (α) and hydrogen bond acceptor (HBA) basicity (β) abilities and solvent structuredness, were found to be the significant factors to explain the energetics of ion association phenomena showing therefore

its dependence on extensive ion-solvent and solvent-solvent interactions. Moreover, our results clarify specific charge localization features.

4 Experimental

Measurements were obtained using a digital Wayne Kerr B905 conductance bridge at a working frequency of 1 kHz. Temperature resistant commercial Sentek KI10 cells were used and their cell constants were determined using a 0.01 mol dm^{-3} solution of KCl. A thermostatic bath Haake V filled with silicon oil was used to maintain temperature within $\pm$ 0.01 ºC. For each solvent a 0.01 mol dm^{-3} stock solution was prepared, weighing the necessary amount of solvent in a Precisa 205A SCS balance (precision $\pm 10^{-4}$ g). All other solutions were subsequently prepared by dilution. Solutions were left in the oil bath for fifteen minutes to reach thermal equilibrium, after which conductance was measured. The reading was confirmed five minutes later. Anomalous measurements were always repeated.

The solvents, provided by Merck, BDH or Aldrich, were used without further purification. The salt was in-house produced from hydrochloric acid addition to 2,6-lutidine in acetone, followed by standard purification and drying procedures. ^{1}H NMR spectrum of the salt showed no contaminants, accessing therefore its purity.

Topic: Advancing the chemical and biological engineering fundamentals.

Abstract

Speciation of aqueous cadmium(II) chloride complexes and determination of the equilibrium extraction constant for cadmium(II) in neutral chloride medium by applying solvent extraction with organophosphorous solvating extractant Cyanex 923 have been investigated. The cumulative stability constants of Cd–Cl complexes in aqueous neutral chloride solutions have been evaluated. The modelling of the extraction equilibrium constant for cadmium(II) in Cyanex 923/Exxol D-100 system has been described.

1 Introduction

Cadmium is considered as one of the most dangerous elements. Because cadmium is widely used in a number of industries, cadmium-contaminated wastewaters can originate from a multitude of sources associated with human activities. Therefore, it is of paramount importance to find an effective method to remove it from liquid effluents. The removal of cadmium(II) from aqueous chloride solutions by solvent extraction (SX) using the phosphine oxides mixture Cyanex 923 as extractant has been reported to be promising, mainly due to high extraction efficiency [1, 2, 3]. As a result, the present study proposes the application of this extractant to the modelling of cadmium(II) solvent extraction in neutral chloride medium. Determination of the cumulative stability formation constants of Cd-Cl complexes and the equilibrium extraction constant of cadmium(II) from neutral chloride medium is described.

2. Experimental procedure

Chemicals

Cyanex 923 is a neutral solvating extracting agent; it is a mixture of four phosphine oxides with the general formulae R_3PO (8,5 %), $R_2R'PO$ (37,4 %), RR'_2PO (30,4 %), R'_3PO (16,1 %), where $R=CH_3(CH_2)_7$ and $R'=CH_3(CH_2)_5$ [4]. It was used as received (Cytec Ind. Canada). Aliphatic diluent Exxol D-100 was also used as supplied by the manufacturer (Exxonmobil Chemical Europe Inc. Belgium). Both of them were used without further purification. All other chemicals were of AR grade. Aqueous solutions of cadmium(II) chloride were prepared by dissolving the required amount of $CdCl_2 \cdot 2{,}5H_20$ (Probus, S.A. Badalona, Barcelona) in double-distilled water. The selected concentrations of chloride ions were obtained by adding NaCl. As the stripping agent was used double distilled water.

Apparatus and procedure

The liquid-liquid extraction experiments were carried out in separatory funnels in which the equal volumes (10 mL) of the aqueous and organic phases, containing the required concentrations of reagents, were shaken on a mechanical shaker (SBS Instruments SA) at room temperature (20±2) for 20 minutes to guarantee complete equilibration. The phases

* Corresponding author. Tel + 34 93 896 77 54. E-mail: agnieszka.leopold@upc.edu

were then allowed to separate. The cadmium(II) concentrations of the suitable aliquots of the aqueous phases were determined by atomic absorption spectrometry using VARIAN AA 240FS. The metal content of the organic phases was determined by mass balance between the total concentration of cadmium(II) in the feed solutions and the metal content measured by spectrometer in the aqueous aliquots.

3. Modelling of cadmium(II) solvent extraction from neutral chloride medium using Cyanex 923 as extractant

In aqueous neutral chloride solutions, cadmium(II) forms strong chloride complexes, presented by $CdCl^+$, $CdCl_2$, $CdCl_3^-$ and $CdCl_4^-$. Formation of the Cd-Cl complexes is described by the stability formation constants which represent the theoretical distribution of cadmium(II) presented in aqueous solution into different species at given conditions. Each complex of cadmium(II) chloride formed in the aqueous phase owns its stepwise formation constant expressed as K_1, K_2, K_3, K_4.

$$Cd^{2+} + Cl^- \xleftrightarrow{K_1} CdCl^+ \quad (1)$$

$$CdCl^+ + Cl^- \xleftrightarrow{K_2} CdCl_2 \quad (2)$$

$$CdCl_2 + Cl^- \xleftrightarrow{K_3} CdCl_3^- \quad (3)$$

$$CdCl_3^- + Cl^- \xleftrightarrow{K_4} CdCl_4^{2-} \quad (4)$$

The stepwise stability constants can be expressed as follows:

$$K_1 = \frac{\left[CdCl^+\right]}{\left[Cd^{2+}\right]\cdot\left[Cl^-\right]} \quad (5)$$

$$K_2 = \frac{\left[CdCl_2\right]}{\left[CdCl^+\right]\cdot\left[Cl^-\right]} \quad (6)$$

$$K_3 = \frac{\left[CdCl_3^-\right]}{\left[CdCl_2\right]\cdot\left[Cl^-\right]} \quad (7)$$

$$K_4 = \frac{\left[CdCl_4^{2-}\right]}{\left[CdCl_3^-\right]\cdot\left[Cl^-\right]} \quad (8)$$

where the ion concentrations are given in mol/L.
The nominators of Eq. (5) – (8) present the concentrations of neutral cadmium(II) chloride species formed in the aqueous phase in equilibrium.
Moreover it is possible to use the cumulative stability formation constants of cadmium(II) complexes which can be expressed as β_1, β_2, β_3, β_4. A cumulative constant can always be considered as the product of stepwise constants. Thus the relation between stepwise and cumulative stability formation constants can be expressed as:

$$\beta_1 = \mathrm{K}_1 \quad (9)$$

$$\beta_2 = \mathrm{K}_1 \cdot \mathrm{K}_2 \quad (10)$$

$$\beta_3 = \mathrm{K}_1 \cdot \mathrm{K}_2 \cdot \mathrm{K}_3 \quad (11)$$

$$\beta_4 = \mathrm{K}_1 \cdot \mathrm{K}_2 \cdot \mathrm{K}_3 \cdot \mathrm{K}_4 \quad (12)$$

The overall equation presenting the values of the cumulative stability formation constants of each Cd – Cl complex is as follows:

$$\beta_n = \frac{[CdCl_n^{2-n}]}{[Cd^{2+}]\cdot[Cl^-]^n} \quad (13)$$

where *n=1, 2, 3, 4* is the number of chloride ions complexed with the metal ion.
The concentration of cadmium(II) in the feed phase is the sum of all the species presented in aqueous solution:

$$[Cd]_{aq} = [Cd^{2+}] + [CdCl^{+}] + [CdCl_2] + [CdCl_3^{-}] + [CdCl_4^{2-}] \quad (14)$$

Deriving Eq. (5) – (8) for the concentrations of the neutral cadmium(II) chloride species which are formed in equilibrium in feed phase it is obtained:

$$[CdCl^{+}] = K_1 \cdot [Cd^{2+}] \cdot [Cl^{-}] = \beta_1 \cdot [Cd^{2+}] \cdot [Cl^{-}] \quad (15)$$

$$[CdCl_2] = K_2 \cdot [CdCl^{+}] \cdot [Cl^{-}] = K_1 \cdot K_2 \cdot [Cd^{2+}] \cdot [Cl^{-}]^2 = \beta_2 \cdot [Cd^{2+}] \cdot [Cl^{-}]^2 \quad (16)$$

$$[CdCl_3^{-}] = K_3 \cdot [CdCl_2] \cdot [Cl^{-}] = K_1 \cdot K_2 \cdot K_3 \cdot [Cd^{2+}] \cdot [Cl^{-}]^3 = \beta_3 \cdot [Cd^{2+}] \cdot [Cl^{-}]^3 \quad (17)$$

$$[CdCl_4^{2-}] = K_4 \cdot [CdCl_3^{-}] \cdot [Cl^{-}] = K_1 \cdot K_2 \cdot K_3 \cdot K_4 \cdot [Cd^{2+}] \cdot [Cl^{-}]^4 = \beta_4 \cdot [Cd^{2+}] \cdot [Cl^{-}]^4 \quad (18)$$

Having presented relations (15) – (18), it is possible to substitute the concentration of each of the Cd – Cl complex formed expressed in the Eq. (14), therefore it is got:

$$[Cd]_{aq} = [Cd^{2+}] + \beta_1 \cdot [Cd^{2+}] \cdot [Cl^{-}] + \beta_2 \cdot [Cd^{2+}] \cdot [Cl^{-}]^2 + \beta_3 \cdot [Cd^{2+}] \cdot [Cl^{-}]^3 + \beta_4 \cdot [Cd^{2+}] \cdot [Cl^{-}]^4 \quad (19)$$

By rearranging Eq. (19), the concentrations of all Cd-Cl species formed in neutral chloride medium in equilibrium can be known from the relations:

$$[Cd^{2+}] = \frac{[Cd]_{aq}}{M} \quad (20)$$

$$[CdCl^{+}] = \frac{[Cd]_{aq} \cdot \beta_1 \cdot [Cl^{-}]}{M} \quad (21)$$

$$[CdCl_2] = \frac{[Cd]_{aq} \cdot \beta_2 \cdot [Cl^{-}]^2}{M} \quad (22)$$

$$[CdCl_3^{-}] = \frac{[Cd]_{aq} \cdot \beta_3 \cdot [Cl^{-}]^3}{M} \quad (23)$$

$$[CdCl_4^{2-}] = \frac{[Cd]_{aq} \cdot \beta_4 \cdot [Cl^{-}]^4}{M} \quad (24)$$

where:

$M = 1 + \beta_1 \cdot [Cl^{-}] + \beta_2 \cdot [Cl^{-}]^2 + \beta_3 \cdot [Cl^{-}]^3 + \beta_4 \cdot [Cl^{-}]^4$.

Moreover, it is necessary to establish the concentration of free chloride ions in the system $[Cl^{-}]$. The concentration of chloride ions presented in the aqueous feed solution $[Cl^{-}]_{aq}$ can be divided between free chloride ions and chlorides forming the Cd – Cl complexes and which concentrations we already know from relations (20) – (24). It can be presented as follows:

$$[Cl^{-}] = [Cl^{-}]_{aq} - [CdCl^{+}] - 2 \cdot [CdCl_2] - 3 \cdot [CdCl_3^{-}] - 4 \cdot [CdCl_4^{2-}] \quad (25)$$

The extraction mechanism of cadmium(II) from chloride medium using neutral extractant Cyanex 923 is related to the solvation of the neutral $CdCl_2$ species and formation of the $CdCl_2 \bullet L_2$ complexes in the organic phase, where L is the extractant [2]. The extraction of the neutral $CdCl_2$ species and the equilibrium extraction constant can be decribed by the equations:

$$CdCl_2 + 2\ L_{org} \xleftrightarrow{K_{e1}} (CdCl_2 \bullet L_2)_{org} \quad (26)$$

$$K_{e1} = \frac{[CdCl_2 \bullet L_2]_{org}}{[CdCl_2] \cdot [L]^2_{org}} \quad (27)$$

where $[L]_{org}$ is the concentration of the free extractant in the system.

Working in neutral medium it is obvious that all of the cadmium(II) extracted into the organic phase is in the form of the $CdCl_2$ species complexed with the extracting agent. So that, the total concentration of metal presented in the feed solution is considered as cadmium(II)

divided between the both phases, the organic and the aqueous one:

$$[Cd]_{total} = [Cd]_{org} + [Cd]_{aq} \quad (28)$$

$$[CdCl_2 \bullet L_2]_{org} = [Cd]_{org} = [Cd]_{total} - [Cd]_{aq} \quad (29)$$

where: $[Cd]_{org}$ is the concentration of cadmium(II) in the form of complexes with extracting agent $[CdCl_2 \bullet L_2]$, it is calculated by the mass balance between the total concentration of cadmium(II) presented in the feed phase and cadmium(II) that has not been extracted into the organic phase, measured by spectrometry, and denominated as $[Cd]_{aq}$.
Applying the same way of thinking it is possible to determine the concentration of the free extracting agent in our system. Thus, the total concentration of the Cyanex 923, $[L]_{total}$, is distributed between the concentration of the free extractant, $[L]_{org}$, and the concentration of the extracting agent bound with extracted species $CdCl_2$, $[L]_{complex}$.

$$[L]_{total} = [L]_{org} + [L]_{complex} \quad (30)$$

As it was stated before, all of the cadmium(II) extracted into the organic phase is in the form of the $CdCl_2$ species forming complexes with the extracting agent, thus the extractant complexed with neutral species is the concentration of cadmium(II) in the organic phase; taking into account the stoichiometry of the extraction the latter one has to be multiplied by two, as it is supposed that each $CdCl_2$ extracted is bounded with two molecules of the extractant [2].

$$[L]_{org} = [L]_{total} - 2 \cdot [Cd]_{org} \quad (31)$$

Eq. (28) – (31) allow simplifying the Eq. (27). Thus, we obtain:

$$K_{e1} = \frac{[Cd]_{total} - [Cd]_{aq}}{[CdCl_2] \cdot ([L]_{total} - 2 \cdot ([Cd]_{total} - [Cd]_{aq}))^2} \quad (32)$$

The presence of the extracting agent also changes the concentration of free chlorides in the system. Apart from the aqueous cadmium(II) chloride species, which have to be subtracted from the total concentration of chlorides presented in the feed solution phase, there must be taken into account also the chlorides bounded with the extractant as the $CdCl_2 \bullet L_2$ complexes. So we obtain:

$$[Cl^-] = [Cl^-]_{total} - [CdCl^+] - 2 \cdot [CdCl_2] - 3 \cdot [CdCl_3^-] - 4 \cdot [CdCl_4^{2-}] - 2 \cdot [Cd]_{org} \quad (33)$$

4. Model resolution

Series of solvent extraction experiments in neutral chloride medium have been carried out. The influence of the concentration of extractant in the organic phase, the concentration of chloride ions in the feed phase, and the extraction isotherm have been investigated. The experimental results have been applied to an Excel programme where using a numerical solution method the theoretical models based on all of the previously presented equations have been calculated. The curve-fitting simulation technique along with consequent comparison of the experimental data with the modelling resolution have been used to determine the unknown variables which include cumulative stability constants of aqueous Cd-Cl complexes and equilibrium extraction constant of cadmium(II) in neutral chloride medium.
There are a few reviews reporting the determination of the speciation of aqueous cadmium(II) chloride species [5, 6, 7, 8]. It has been tried to adjust all of these sets of stability constants of Cd-Cl complexes to the presented in this work model of cadmium(II) solvent extraction and, as a result, only the ones obtained through the chemical equilibrium software MEDUSA worked out. In the cited programme there is no data for the $CdCl_4^-$ species, thus this one has been obtained on the modelling way. Adding the latter one to the speciation system has forced us to change the value for the $CdCl_3^-$ complex.
As a continuation, the results for the experiments, where determined model of the extraction

system is fitted to the experimetal data, are presented. At the end the values of the unknown variables are proposed.

Influence of the Cyanex 923 concentration in the organic phase

Carrier plays a decisive role in making the extraction process efficient and economically viable. Influence of the extracting agent on the extraction process has been studied with concentration of Cyanex 923 ranging from 0 to 20% (v/v) and in two different constant initial concentrations of chloride ions in the feed phase, namely 0,5M and 1M. The initial metal content has been maintained as 1 g/L. It can be seen in Fig. 2 and 3 that in smaller concentrations of extractant the theoretical model of extraction fits better to the investigation's data. Cadmium extraction increases practically lineally by raising the carrier concentration in the organic phase. In both of the experiments, at concentrations of extractant higher than 15% (v/v) the experimental data and the results obtained by modelling of the extraction system don't fit to each other. That is why, the further experiments of extraction properties of Cd(II) were done with 5 or 10% the Cyanex 923 in Exxol D-100 (v/v).

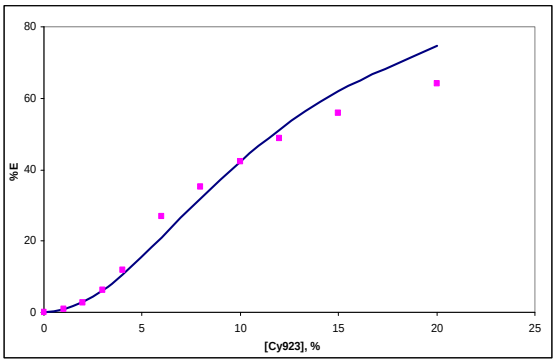

Fig. 2. Effect of the concentration of Cyanex 923 in the organic phase: $[Cd]_{total}$=1 g/L, $[Cl^-]_{total}$=1M, $[Cy923]_{total}$=0-20% (v/v); ■ experimental data, – model results.

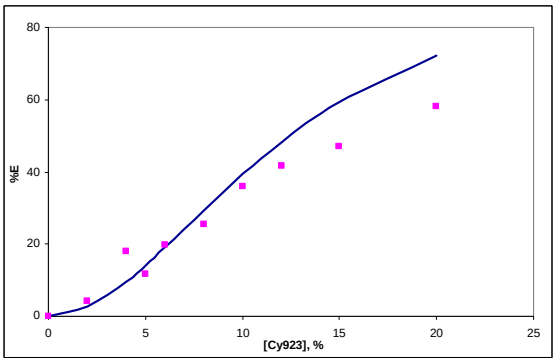

Fig. 3. Effect of the concentration of Cyanex 923 in the organic phase: $[Cd]_{total}$=1 g/L, $[Cl^-]_{total}$=0,5M, $[Cy923]_{total}$=0-20% (v/v); ■ experimental data, – model results.

Influence of the concentration of chloride ions Cl^- in the aqueous feed phase

The studies of the effect of $[Cl^-]$ ions in neutral medium have been performed in two different constant initial concentrations of extractant: 5% and 10% (v/v). In both of the cases initial metal content has been kept as 1 g/L. Total chloride concentrations have varied from 0,1M to 3M. The results in Fig. 4 and 5 show that the concentration of Cl^- ions in the aqueous phase has effect on the extraction of Cd(II) and the metal extraction increases with the $[Cl^-]$ up to 1M and reaches to maximum of 43% and 17% for studies with Cyanex 923 of 10% and 5%, respectively. Then the percentage of extraction slightly decreases. The first increase in the extraction is due to the Cl^- ion effect, which enhances the formation of extractable $CdCl_2$ species in the aqueous phase [42]. For the experiments made by with 10% (v/v) Cyanex 923, the experimental data fit better to the theoretical model of extraction.

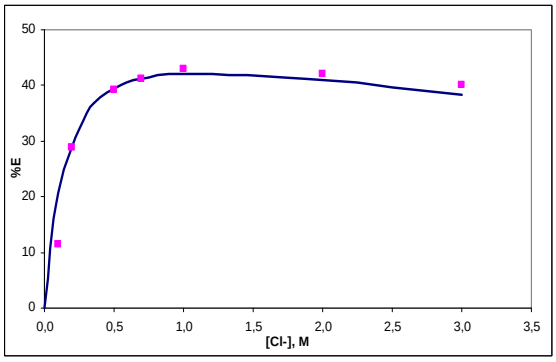

Fig. 4. Effect of the concentration of chloride ions in the aqueous phase: $[Cd]_{total}$=1 g/L, $[Cl^-]_{total}$=0,1-3M, $[Cy923]_{total}$=10% (v/v);■ experimental data, – model results.

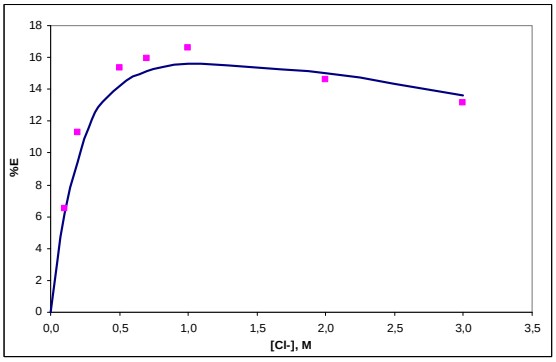

Fig. 5. Effect of the concentration of chloride ions in the aqueous phase: $[Cd]_{total}$=1 g/L, $[Cl^-]_{total}$=0,1-3M, $[Cy923]_{total}$=5% (v/v); ■ experimental data, – model results.

Extraction isotherm

The study of the extraction isotherm has been carried out in the range of initial cadmium and chloride concentrations in aqueous phases of 0,3 – 10 g/L and 0,5M, respectively. The Cyanex 923 of 5% has been chosen as a concentration of extractant. The experimental data and the modelling results fit well to each other. The extraction percentage of Cd(II) is slightly superior in the case of smaller concentrations of metal ions in the aqueous feed phase, what can be seen in Fig. 6.

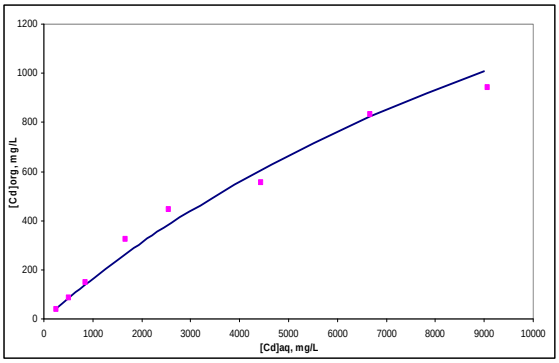

Fig. 6. Extraction isotherm of cadmium(II): $[Cd]_{total}$=0,3 – 10 g/L, $[Cl^-]_{total}$=0,5M, $[Cy923]_{total}$=5% (v/v); ■ experimental data, ─ model results.

Application of the numerical resolution method presented above to the experimental data has resulted in determination of the cumulative stability constants of aqueous Cd-Cl complexes and equilibrium extraction constant of cadmium(II) in neutral chloride medium which are proposed to be as follows: $\beta_{CdCl^+} = 95{,}5(L/mol)$, $\beta_{CdCl_2} = 398(L^2/mol^2)$, $\beta_{CdCl_3^-} = 60(L^3/mol^3)$, $\beta_{CdCl_4^{2-}} = 6(L^4/mol^4)$ and $K_{e1} = 19{,}8$ (L^2/mol^2), respectively.

5. Conclusions

Experimental and teorethical data fit to each other.As a future objective it is planned to apply the determine unknown variables to the modelling of cadmium(II) solvent extraction from acidic chloride medium using Cyanex 923 as extractant.

Models to correlate the surface tension of solvent mixtures

Alicia G. Abuín[1*], Diego Gómez-Díaz[1], José M. Navaza[1], Isabel Vidal[1]
[1] Department of Chemical Engineering – ETSE. Lope Gómez de Marzoa s/n. University of Santiago de Compostela. E-15782, Santiago de Compostela. Spain.

Keywords: surface tension, chemical model, empiric model
Topic: Advancing the chemical and biological engineering fundamentals

Abstract

Surface tension has high industrial importance in chemical reactions as the reactions in the surface region are quite different from the bulk region. The surface tension also is an essential property in mass-transfer calculations, in various chemical engineering processes such as, distillation, extraction and absorption, because surface tension has a determining effect. In electrochemical reactions, biological membranes operation, environmental engineering and several other processes namely; corrosion, adherence, detergency, floating and lubricating the surface tension plays a significant role.

The aim of this study is to analyse the different models to correlate surface tension of mixed solvents and pure liquids, for the purpose of the simplest applications, as the property which determines the degree of dispersion, the dynamics of motion of liquids or the wettability, models are looked for.

1. Scope

Several approaches to describe surface tension of pure liquids and mixtures have been proposed. Some of them are empirical; others have more complexity. The most complicated models include an activity coefficient.

It is a review adapted to an actual interest: to design mixtures for fine chemistry. These mixtures are pirrolydone-based, aqueous two phases systems-based and ionic liquids. For the purpose of the simplest applications of the surface tension, as the property which determines the degree of dispersion, the dynamics of motion of liquids or the wettability, models are looked for.

The aim is to collect models with a minimum of parameters to describe the systems with sufficient accuracy for a practical purpose, not for an in-depth academic knowledge. The interest is not prediction *ab initio*. The scope is on a systematic approach in order to design new systems in knowing some basic ones. It is interesting to correlate surface tension after collecting a reasonable number of experimental data and then prediction with interpolation techniques.

There are several kinds of issues that can be approached in different ways - the true speciation in reactive systems, the activity coefficients in strong non-ideal aqueous systems or multicomponent– but there is insufficient data in the fine chemistry literature to test possible applications, moreover, with the scope of designing new mixtures and evaluate their potential as separation or reaction media, the use of complicated thermodynamic models –and surface tension is not a thermodynamic property- or models with a lot of parameters seems to be too much effort and it is not meaningful for people in fine chemistry industry. The correlation of extra-thermodynamics properties is not as rigorous as that of thermodynamic ones.

* Corresponding author. E-mail: alicia.garcia@rai.usc.es

For these reasons the search will be directed towards models that describe surface tension with the concentration of apparent components or other physical properties.

2. Models

2.1 Classification

The models selected according to the scope are presented in Table 1

2.2 Description

Any of the method presented here must not be seen as a substitute of other method: They must be seen as complementary schemes because it is frequently useful to have different methods available for estimating physical properties,

For organic compounds, Mcleod *(via* Reid, Prausnitz and Poling,1987) proposed a relation between surface tension and vapour and liquid densities based on the *parachor*, a temperature independent parameter which is estimated from the structure of the molecule, but it must be emphasized that surface tension depends on $([P])^4$ and therefore is very sensitive to the values of *parachor* . Below boiling point, at low pressure, $\rho_v << \rho_L$ and then the vapour density term is neglected.

Goldhammer and Gambill (*via* Reid, Prausnitz and Poling,1987) suggest correlating the density by relating it to temperature. The exponent *n* is 0.25 for alcohols, 0.29 for hydrocarbons and ethers and 0.31 for other organic compounds.

Brock and Bird (1955) suggested a method based on the corresponding states. Mcleod's method requires knowledge of the liquid densities, whereas this method requires critical properties and normal boiling point. The corresponding states method is a more general method capable of being applied to a variety of properties, whereas Mcleod's method is more specific and the main problem lies in the structural determinations needed.

About the simple methods proposed by Pelofsky (1966) and Schonhorn (1967) no more comments are needed.

The surface tension of a liquid mixture is not a simple function of the surface tension of pure components because the composition of the surface is not the same as that of the bulk and usually surface composition is not known.

For mixtures, parameter [P] can be obtained from structural data as for pure liquids or from regression of experimental data. The modified Macleod-Sugden's method has the advantage the, at the extremes of composition, it yields the correct values ($\sigma_m \rightarrow \sigma_i$ as $x_i \rightarrow 1$).

The equation of state based methods result in complex calculations, as well as the method proposed by Escobedo and Mansoori (1997), but they provide general expressions and accurate results if neededd.

The method proposed by Rice and Teja (1982) is based on the corresponding states principle. The main disadvantage of this method is that two reference fluids are needed as well as acentric factor and an interaction parameter for polar liquids.

Both classical and statistical thermodynamics have been employed to derive expressions for σ_m and the most arrive at a similar equation. The main difficulty of this class of methods is that a model for activity coefficients is needed and then a more complicate calculations. Santos et. Al. (2002) present an extensive review of thermodynamic methods and no more comments will be presented here.

Connors and Wright (1989) proposed a simpler model based on involving binding to the surface, an approach from adsorption theory. An example of the behaviour of this method is shown in figure 1. In the way of simple models, Jouyban et. Al. (2004) provide a model based on Nearly Binary Solvent/ Redlich-Kister equation. Both of them show good agreement.

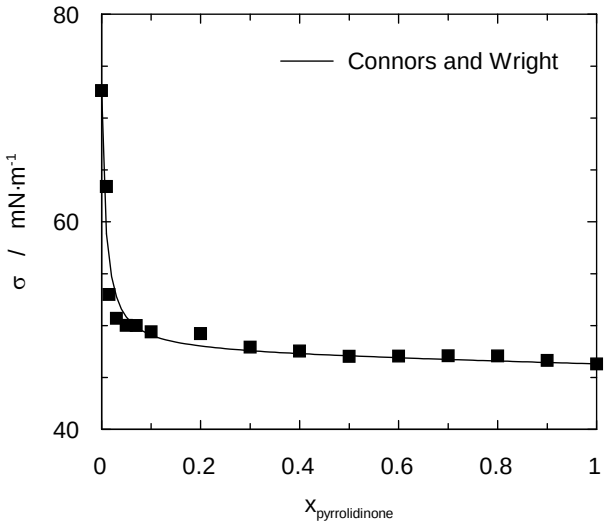

Figure 1. Fit behaviour of Connors and Wright model for water+2-pyrrolidinone mixture.

Keywords: 2-pyrrolidone, N-alkyl-2-pyrrolidone

Topic: Advancing the chemical and biological engineering fundamentals.

Abstract

In the present study, the surface tensions of aqueous solutions of several pyrrolidones have been determined using a Krüss K-11 tensiometer using the Wilhelmy plate method to different concentrations and different temperatures from 20 to 50 ºC and its behaviour has been analysed.

The addition of small quantities of pyrrolidone to water produces a drastically decrease in surface tension value. The bigger decrease in the surface tension was produced in low concentration of pyrrolidone. However, in high concentrations of pyrrolidone, the influence of the mixture composition can be considered negligible. This behaviour seems to indicate that an aggregation phenomenon exists between the two components pyrrolidone and water.

1. Introduction

2-Pyrrolidone is an organic compound consisting of a five-membered lactam. When the proton on the lactam is replaced for an alkyl group, this results in a great solvency (C_1P is the most active member) and as N-alkyl chain increases the surface activity increases. This reaches a maximum at a chain with 12-14 atoms of carbon (1).

The polarity of the N-alkyl-pyrrolidones makes possible strong hydrogen bonding with organic molecules and solvents.

Nowadays, pyrrolidones have increased their industrial interest as solvent for a wide variety of applications such as hard-surface cleaners because of its wetting properties and synergy with anionic surfactant, extractor agents of antibiotics which contain a phenolic- or carboxylic-group, formulation agents for shampoos, personal care products such as dyeing, bleaching or permanent waving and agricultural products like herbicides or plant virus growth inhibitors, etc. This is possible because pyrrolidones besides being surface-active compounds, they have low vapour pressure and low toxicity.

During the last few years the N-alkyl-pyrrolidones have also been porposed as skin-penetration enhacers. The use of these enhacers allow the administration of therapeutic agents to the bloodstream without pain and in a controlled manner.

2. Experimental section

2-Pyrrolidinone (CAS number 616-45-5) and 1-ethyl-2-pyrrolidinone (CAS number 2687-91-4), were supplied by Fluka with a purity of > 99 % and > 98 %. Respectively. Bidestilled water was used to prepare the mixtures of water and amine. All the mixtures were prepared by

* Corresponding author. E-mail: alicia.garcia@rai.usc.es

mass using an analytical balance (Kern 770) with a precision of 10^{-4} g. The uncertainty of the samples preparation in mole fraction was ± 0.0002.

The surface tension was determined employed a Krüss K-11 tensiometer used the Wilhelmy plate method. The plate employed was a commercial platinum plate supplied by Krüss. The platinum plate was cleaned and flame-dried before each measurement. The surface tension of pure water was determined and compared with literature to confirm that this method contribute suitable results [1]. The uncertainty of the measurement was ±0.05 $mN \cdot m^{-1}$. The detailed experimental procedure has been described elsewhere. In general, each surface tension value reported was an average of ten measurements. The samples were thermostated in a closed vessel under stir, before surface tension measurements to prevent evaporation. Surface tension measurements were carried out at different temperatures between 20 and 50 ºC.

3. Results and Discussion

Effect of Composition

In the present work we have determined and analysed the surface tension of aqueous solutions of 2-pyrrolidinone and 1-ethyl-2-pyrrolidinone over the entire range of mixture composition. The experimental values of this physical property for the mixtures used in this study have been collected for different values of temperature and composition. The trends observed abour the influence of mixture composition upon the experimental data obtained for these mixtures are shown in Figure 1 for both systems at a constant temperature.

The behaviour shown in this figure proved that the addition of small quantities of solutes to water produces a drastically decrease in surface tension value for all systems. The higher decreases in the surface tension was produced in low concentration of pyrrolidinones. The behaviour shown for these two systems is similar that the observed by other authors for mixtures i.e. employed amines [2].

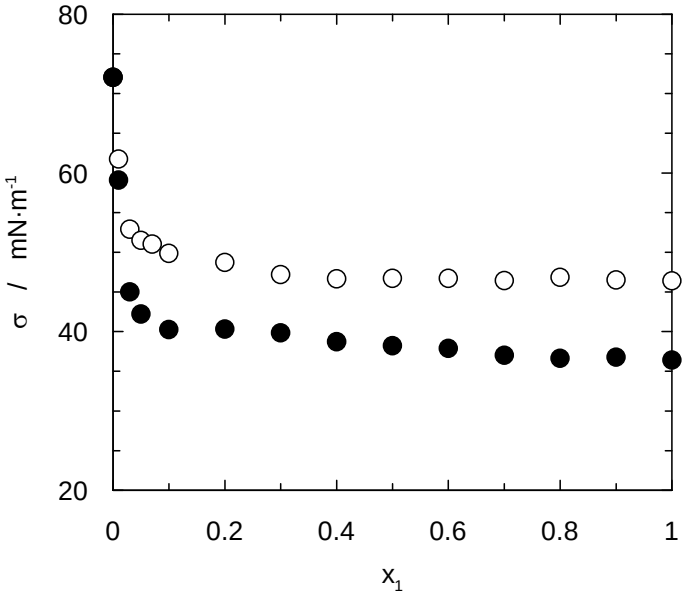

Figure 1. Influence of composition on surface tension of (○) water + 2-pyrrolidinone and (●) water + 1-ethyl-2-pyrrolidinone at 25 ºC.

Effect of temperature

The effect of the temperature upon the value of surface tension has been analysed and the behaviour observed is shown in Figure 2. A decrease in this property is produced when the operation temperature increases, and this behaviour was observed for both analysed systems.

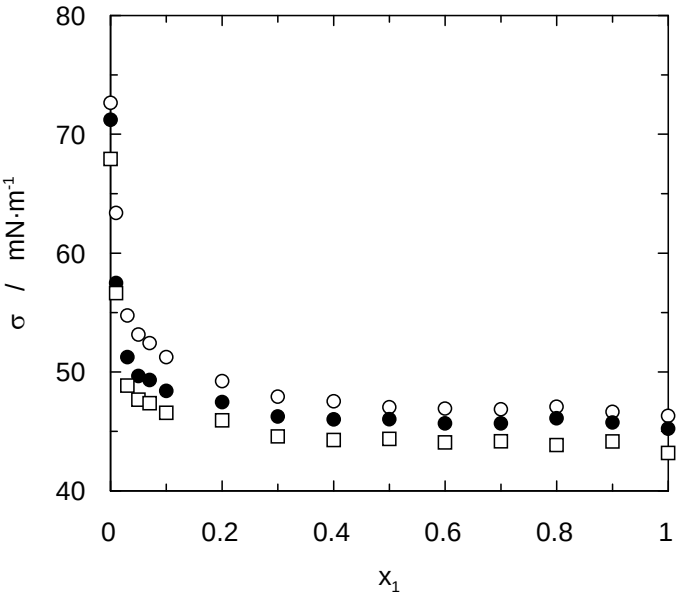

Figure 2. Influence of composition and temperature on surface tension of water + pyrrolidinone system. (○) T = 20 ºC; (●) T = 40 ºC; (□) T = 50 ºC.

Also, a linear trend was observed when the plot of surface tension versus temperature was carried out. Our research group has observed this behaviour for other binary systems. In previous work of our group and other authors [3] the surface tension *vs* temperature data has been fitted with a linear regression employing eq. 1.

$$\sigma = K_1 - K_2 \cdot t \qquad (1)$$

where σ is the surface tension, t is the temperature, K_1 and K_2 are fitting coefficients corresponding to equation 1.

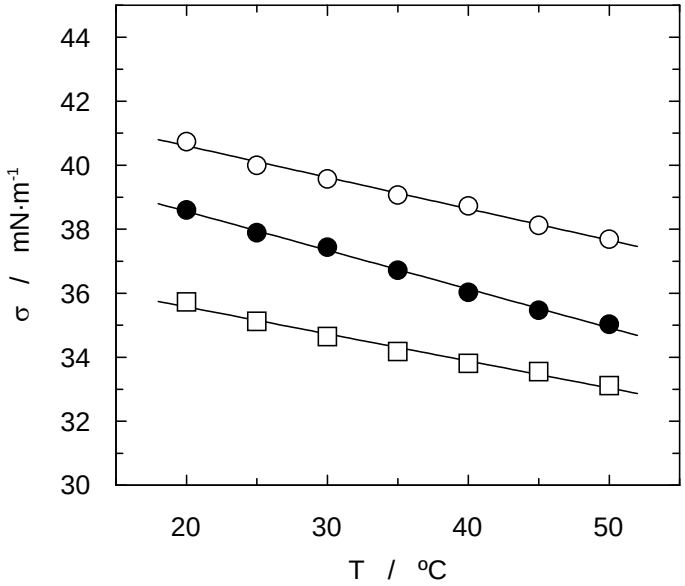

Figure 3. Influence of temperature on surface tension of water + 1-ethyl-2-pyrrolidinone system. (○) x = 0.3; (●) x = 0.6; (□) x = 1.

Surface thermodynamics

The last point has been related with the thermodynamic properties of the surface for this kind of mixtures. The surface enthalpy and entropy have been calculated using equations employed by Glinski et al [4] (eqs. 2 and 3).

$$S = -\left(\frac{\delta\sigma}{\delta T}\right)_{C,P} \qquad (2)$$

$$H = \sigma - T\left(\frac{\delta\sigma}{\delta T}\right)_{C,P} \qquad (3)$$

In relation with the trend observed for the entropy, this parameter has a constant value along the compositions upper the 0.5 molar fraction and near to pure water a notable increase in its value is produced. Other authors have found maximas for other systems [1] related with the molecular organization of different substances in the water surface.

The value of surface enthalpy corresponding to the water + 1-ethyl-2-pyrrolidinone system is shown in figure 4. The behaviour is similar than the effect of mixture composition on the surface tension because an important decrease was observed at very low 1-ethyl-2-pyrrolidinone concentration.

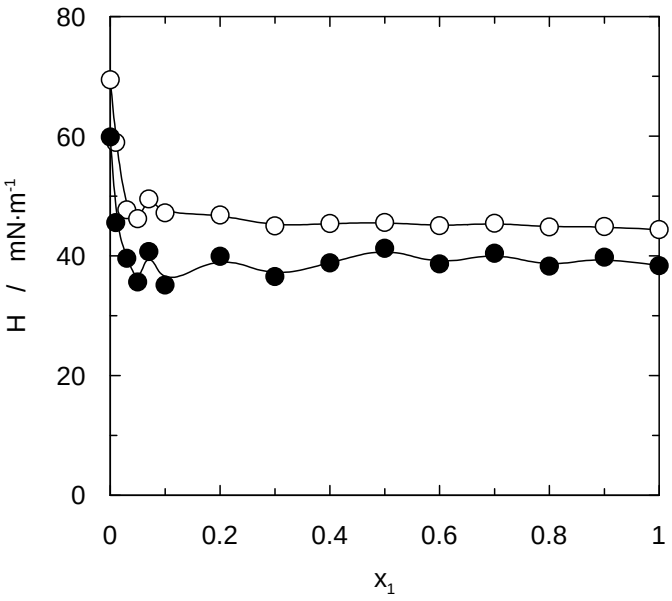

Figure 4. Surface enthalpy for water + 1-ethyl-2-pyrrolidinone system. (○) T = 20 ºC; (●) T = 50 ºC.

Topic: Advancing the chemical and biological engineering fundamentals

Abstract

Densities have been measured for the ternary mixture methanol-formamide-acetonitrile as a function of mole fraction at 298.15 K. The correspondent molar volume was determined along with two relevant connected properties: the excess molar volume and the partial molar volume of the mixtures. Excess molar volumes of the binary mixtures have been fitted with a Redlich-Kister type relationship and ternary fractions with the Cibulka polynomial relationship. Results have been used to interpret the nature of solvent-solvent interactions among mixtures' components.

1 Introduction

An increasing number of chemical industrial processes use mixtures of organic solvents, and a significant number of these show non-ideal behavior. Optimization and adequate design of equipment are conditioned by the correct assessment of mixing properties of these mixtures. Mixing properties and their corresponding derived values are also of primary interest for theoretical purposes namely for model development, estimation of parameters, etc.

Following previous studies on characterization of solvent mixtures (Leitão *et al.*, 2002) we now present the volumetric results for the ternary mixture methanol-formamide-acetonitrile. The experimental results have been used to calculate excess molar volumes (V^E), and partial molar volumes of the mixtures' components ($\overline{V_i}$) and interpret the behavior of the liquid mixtures under study.

2 Experimental

All the solvents used in the study were reagent grade, methanol (Riedel de Häen, HPLC, >99.5% purity), formamide (Aldrich, HPLC, >99.5% purity) and acetonitrile (Aldrich, HPLC, >99.5% purity) and were used without further purification. In all cases the water content was less than 0.1%.

Mixtures were prepared by weight, using a Mettler H35 balance with a precision of ± 0.1 mg. Densities were measured using an Anton-Paar vibrating-tube digital densimeter (cell unit DMA 512, processing unit DMA 60 and temperature unit DT 100-30).

A total of 61 molar fractions including ternary, binary and pure solvents were obtained at 298.15 ± 0.01K, with each value resulting from at least three individual density measurements.

3 Results and Discussion

Molar volumes have been calculated from density results according to the relationship

$$V = \sum_{i}^{n} \frac{x_i M_i}{\rho} \tag{1}$$

where x_i and M_i are the mole fraction and molecular weight of component i and ρ the solution density.

Figure 1 summarizes the obtained volumetric results for the ternary mixture, along with the corresponding 3D surface.

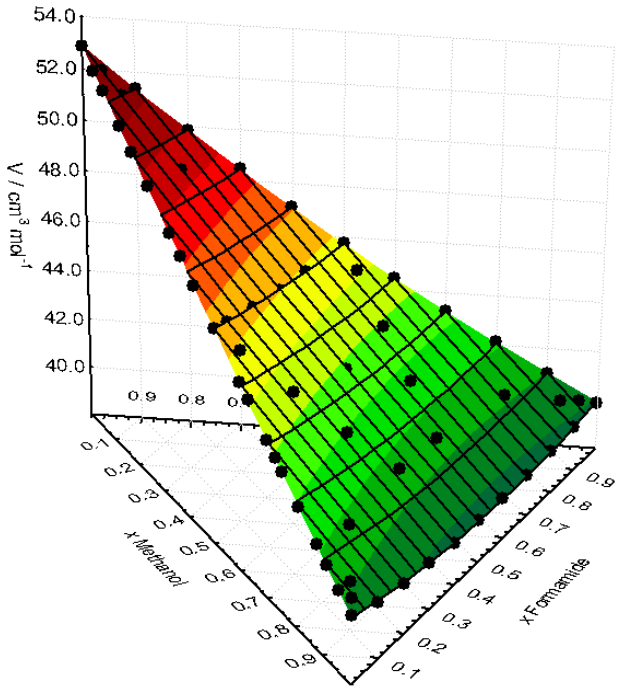

Figure 1 – Molar volume surface for the ternary mixture methanol-formamide-acetonitrile at 25 ºC.

The analysis of the molar volume of the mixtures shows a monotonous variation with no apparent singularities. In order to investigate the interactions between the mixtures' components, it is therefore necessary to determine excess molar volumes, V^E, which were calculated for each binary mixture from the volume data according to,

$$V^E = V - \sum_{i=0}^{N} x_i V_i \tag{2}$$

where V is the experimentally obtained molar volume and V_i the molar volume of each component.
For these mixtures, excess molar volumes were fitted using the Redlich-Kister equation (Redlich-Kister, 1948),

$$V^E_{i,j} \,/\, \mathrm{cm^3 mol^{-1}} = x_i x_j \sum_{P=0}^{n} a_P (x_i - x_j)^P \qquad (3)$$

Estimates of coefficients a_P were obtained by the least squares method and are summarized in table 1, along with the relevant statistical figures of merit. The standard deviation of the fit was calculated according to,

$$\sigma(V^E) = \sqrt{\frac{\sum (V^E - V^E_{calc})^2}{N - P}} \qquad (4)$$

where N is the number of observations and P the number of parameters.

Table 1 – Redlich-Kister equation and statistical parameters for each binary mixture

Parameters \ Mixtures	methanol / acetonitrile	formamide / acetonitrile	methanol / formamide
$a_0 \pm \sigma\ (a_0)$	–0.547 ± 0.007	–2.48 ± 0.03	–2.56 ± 0.05

Figure 2 represents the determined excess molar volumes along with the surface defined by volumes calculated by the Cibulka equation.

Analysis of figure 2 shows the existence of a negative deviation from ideal behavior for all binary mixtures. Volume contraction is smaller in methanol/acetonitrile, but it suggests, nevertheless, the presence of hydrogen bond of the type OH---N≡C and also of specific interactions between OH groups and the π system electrons which cause the observed volume contraction. In methanol/formamide and formamide/acetonitrile mixtures, large volume contractions are observed which are probably linked to formamide molecules since this is a highly polar component and also highly associated by hydrogen bonding, due to a strong H-bond acceptor group (C=O) and a proton donating group ($-NH_2$). The negative excess molar volume clearly points out the presence of specific interactions between formamide and the other components, and with the breakdown of some of the original hydrogen bonds, new heteromolecular ones can occur, such as OH---N-H e CN---H-N. Other negative contributions seem attributable to acetonitrile (in methanol/acetonitrile mixture) and to methanol (in methanol/formamide mixture) which are accommodated in pre-existing free spaces. Figure 2 also shows that there is a ternary interaction: in fact, the largest negative deviation is observed for the ternary fraction 0.350/0.500/0.150, which indicates that the strongest interaction among all three components occurs for this mole fraction, along with the most effective mutual component accommodation.

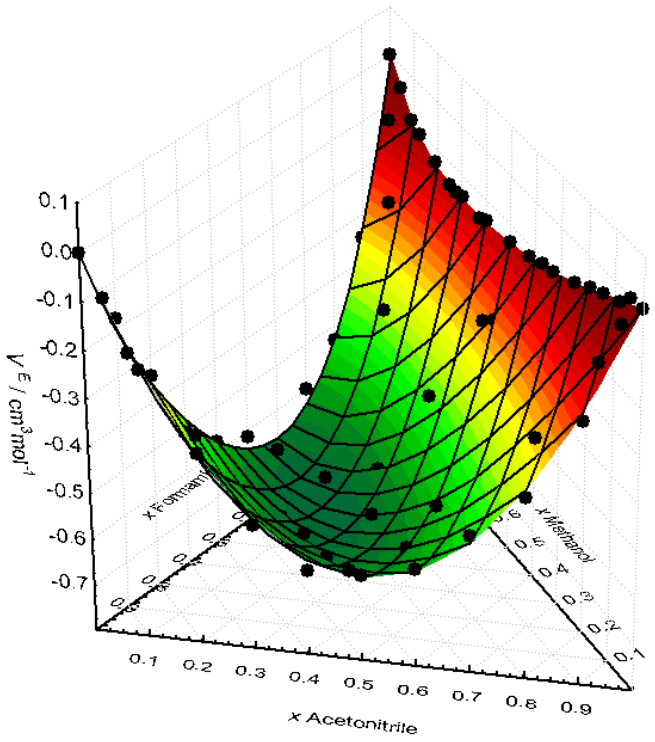

Figure 2 – Excess molar volume surface for metanol/formamide/acetonitrile at 25 ºC.

Partial molar volumes, $\overline{V_i}$, were also calculated in order to better identify the various molecular interactions present. The chosen relationship for the determination of $\overline{V_i}$ (Lepori, 1998) is based in the excess partial molar volume, $\overline{V_i}^E$

$$\bar{V}_i^E = V^E - x_j \left(\frac{\partial V^E}{\partial x_j} \right)_{T,p,x_k} - x_k \left(\frac{\partial V^E}{\partial x_k} \right)_{T,p,x_j} \quad (6)$$

which is then added to the components' molar volume, V_i^0

$$\bar{V}_i = V_i^0 + \bar{V}_i^E \quad (7)$$

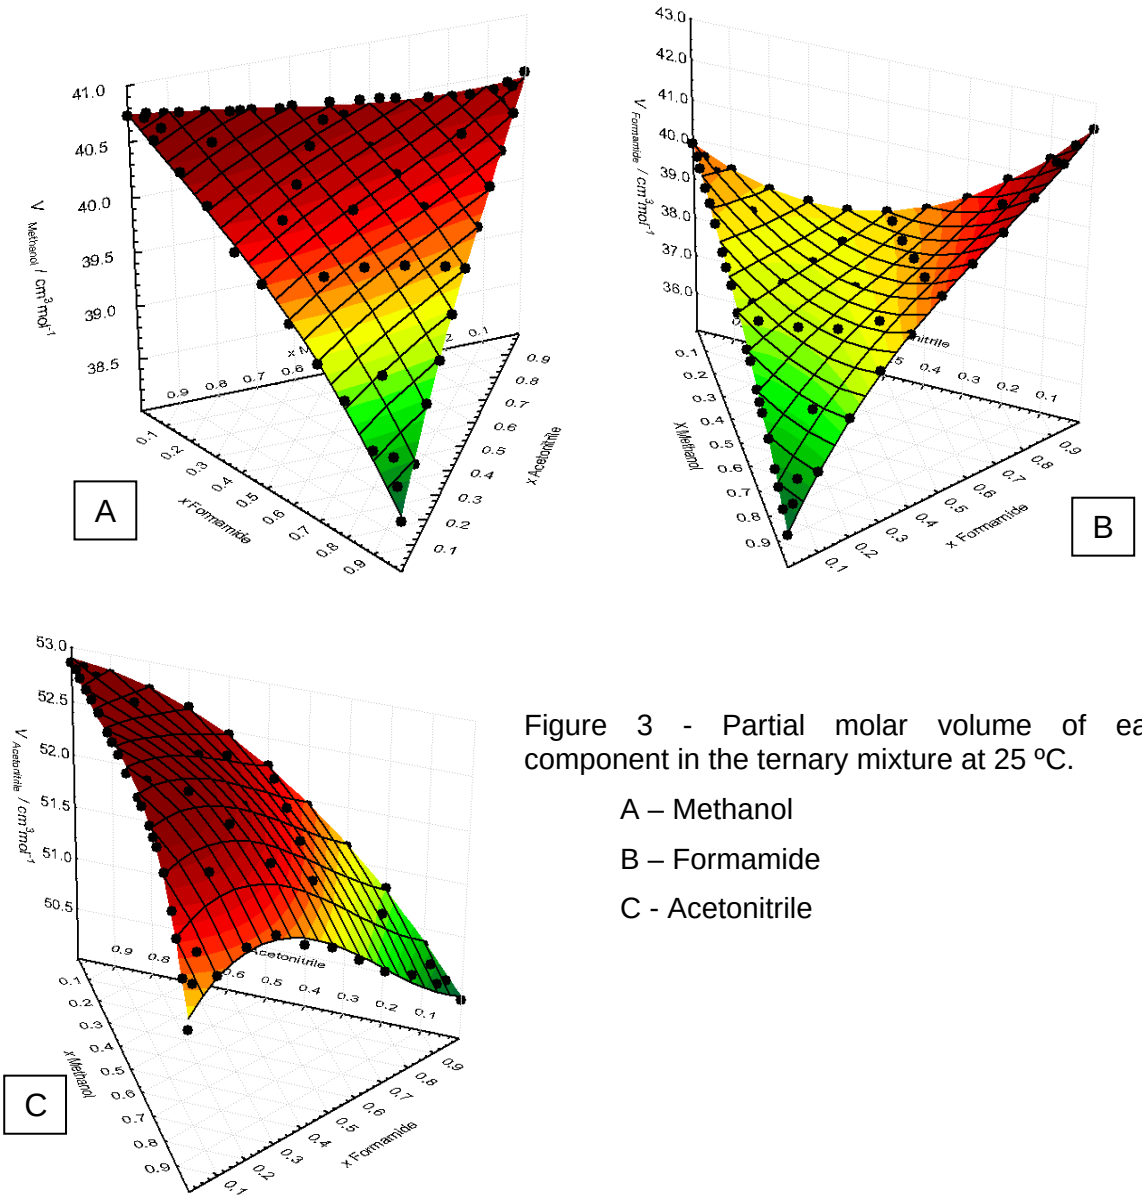

Figure 3 - Partial molar volume of each component in the ternary mixture at 25 ºC.

A – Methanol

B – Formamide

C - Acetonitrile

Figure 3 confirms some of the assumptions previously discussed within the context of excess molar volumes. In acetonitrile containing mixtures, the partial molar volume of methanol shows a slight decrease to a minimum (close to rich acetonitrile fractions). This is possibly

due to the accommodation of acetonitrile molecules within the methanol structure, and to interactions established between acetonitrile and methanol.
In the methanol/formamide mixture there is strong contraction of methanol's volume with the increase of formamide's fraction, characteristic of the formation of new bonds, particularly hydrogen bonds.

The partial molar volume of acetonitrile molecules increases with the increase of their mole fraction. For formamide a gradual and constant rise is observed whereas for methanol one observes a rise followed by a plateau. This type of behavior reveals the accommodation of acetonitrile molecules in the original structural network, and the increase of specific interactions, especially in acetonitrile poor regions.

The partial molar volume of formamide shows a decrease as its mole fraction decreases. In acetonitrile mixtures the minimum value occurs at an acetonitrile mole fraction of 0.65. This situation suggests that until this fraction of acetonitrile is reached, formamide is progressively forming new H-bonds, and from this fraction on, acetonitrile molecules break down some of the formamide bonds. In mixtures with methanol, the partial molar volume of formamide always decreases, suggesting that the eventual breaking of bonds is well compensated by the formation of new ones.

Keywords: azeotropy, global optimization, chemical equilibrium, phase equilibrium
Topic: Advancing the chemical and biological engineering fundamentals.

Abstract

In this work we introduce an alternative approach to find homogeneous azeotropes in reactive and nonreactive mixtures. Specifically, the Simulated Annealing optimization method is used to solve a system of nonlinear equations that results from the equalities of the orthogonal derivatives of the Gibbs energy, and the Gibbs energy of mixing in the vapor and liquid phases. For nonreactive systems, this system is solved using conventional composition variables while for reactive cases we use the transformed variables proposed by Ung and Doherty. Numerical performance of this approach is illustrated using several examples and results show that this method is effective for the calculation of homogeneous azeotropes in mixtures with or without chemical equilibrium.

1. Introduction

Azeotropy is a phase equilibrium phenomenon that occurs in many industrial applications and its presence restricts the separation grade of a multi-component mixture that can be achieved by distillation. In particular, the description of homogeneous azeotropy is essential for the selection of strategies in the synthesis, design, and operation of separation units. This description consists on establishing the temperature, pressure, and composition as well as the component number of the azeotrope.

An azeotrope can occur in reactive and nonreactive mixtures. For nonreactive systems, several methods for finding homogeneous azeotropes have been proposed. For example, Fidkowski *et al.* (1993) developed a robust method to locate all the homogeneous azeotropes using a homotopy technique together with a robust phase stability analysis. Harding *et al.* (1997) used a deterministic global optimization procedure with convex underestimating functions for the thermodynamic equations to perform a global minimization. The success or failure of this technique depends upon proper construction of the convex functions. Maier *et al.* (1998) used an interval-Newton/generalized-bisection algorithm to locate all the solutions of the thermodynamic conditions for homogeneous azeotropy using solution models and ideal gas behavior. Recently, Aslam and Sunol (2006) used a homotopy continuation method to study the sensitivity of azeotropic states to activity coefficient model parameters and operating conditions.

For systems with chemical equilibrium, few robust methods have been developed to address the problem of locating all reactive homogeneous azeotropes. Okasinski and Doherty (1997) reported a homotopy continuation method to locate multi-component reactive azeotropes. Later, Harding and Floudas (2000) applied their deterministic optimization method in the calculation of all reactive azeotropes of multi-component systems. This method offers a theoretical guarantee for finding all azeotropes, but depending on the thermodynamic model, it is necessary to reformulate the problem. Maier *et al*. (2000) have also extended their

interval-Newton/generalized-bisection algorithm to locate all reactive azeotropes using solution models and ideal gas behavior. Finally, Qi and Sundmacher (2005) proposed a geometrical approach to locate all kind of azeotropes (reactive, nonreactive and kinetic). Although these methods have demonstrated to be very promising, some of them are model dependent, may require problem reformulations or a significant computational time for multi-component systems.

In this context, stochastic optimization methods offer some advantages for the calculation of homogeneous azeotropes and may overcome the difficulties described above. These methods are robust numerical tools that present a reasonable computational effort in the optimization of multivariable functions; they are applicable to ill-structure or unknown structure problems; they are efficient and require only calculations of the objective function. Many thermodynamic problems that are very difficult to solve by conventional techniques can be solved using stochastic methods. In Thermodynamics, Simulated Annealing and other stochastic methods have been successfully applied in phase equilibrium and stability problems, critical point calculations, parameter estimation in non-linear models, among other applications. To the best of our knowledge, these methods have been not applied in the calculation of homogeneous azeotropes in both reactive and nonreactive mixtures.

In this work we introduce an alternative technique to find homogeneous azeotropes in reactive and non-reactive mixtures which is based on the application of Simulated Annealing optimization technique. Specifically, this optimization method is used to solve a system of nonlinear equations that results from the equalities of the orthogonal derivatives of the Gibbs energy, and the Gibbs energy of mixing in the vapor and liquid phases.

2. Formulation of Thermodynamic Problem

Recently, Iglesias-Silva *et al*. (2003) have shown that two-phase equilibrium in a nonreactive mixture of c components results from solving

$$\left(\frac{\partial g}{\partial x_i}\right)^{\alpha}_{T,P,x_{j\neq i}} - \left(\frac{\partial g}{\partial x_i}\right)^{\beta}_{T,P,x_{j\neq i}} = 0 \quad i = 1,2,\cdots,c-1 \tag{1}$$

$$\left(g^{\beta} - g^{\alpha}\right) - \sum_{j=1}^{c-1}\left(x_j^{\beta} - x_j^{\alpha}\right)\left(\frac{\partial g}{\partial x_j}\right)^{\alpha}_{T,P,x_{l\neq j}} = 0 \tag{2}$$

$$z_i = x_i^{\alpha}\varphi^{\alpha} + x_i^{\beta}\varphi^{\beta} \qquad i = 1,2,\cdots,c-1 \tag{3}$$

where g is the Gibbs free energy of mixing, z_i is the mole fraction of component i in the feed, x_i^k is the mole fraction of component i in the phase k, φ^k is the fraction of moles in phase k, α and β denote the vapor and liquid phases, respectively. If this mixture shows homogeneous azeotropy ($z_i = x_i^{\alpha} = x_i^{\beta}$), the above equations simplify to

$$F_1 = g^{\alpha} - g^{\beta} = 0 \tag{4}$$

$$F_{i+1} = \left(\frac{\partial g}{\partial x_i}\right)^{\alpha}_{T,P,x_{k\neq i}} - \left(\frac{\partial g}{\partial x_i}\right)^{\beta}_{T,P,x_{k\neq i}} = 0 \quad i = 1,2,\cdots,c-1 \tag{5}$$

where Eqs. (4) and (5) are a system of c nonlinear equations with $c-1$ unknown compositions (mole fractions, x) plus the unknown temperature or pressure of the azeotrope. For reactive systems, Eqs. (1)–(3) can be extended if we consider the transformed composition variables proposed by Ung and Doherty (1995). These variables depend only on the initial composition of each independent chemical species and restrict the solution space to the compositions that satisfy stoichiometry requirements. As a consequence, they reduce

the dimension of the composition space by the number of independent reactions. Thus, the transformed mole fractions X of a mixture with R independent chemical reactions are given by

$$X_i = \frac{x_i - \nu_i N^{-1} \vec{x}_{ref}}{1 - \nu_{TOT} N^{-1} \vec{x}_{ref}} \quad i = 1,..., c - R \tag{6}$$

where $\vec{x}_{ref}$ is the column vector of R reference component mole fractions, ν_i is the row vector of stoichiometric coefficients of component i for each reaction, ν_{TOT} is a row vector where each element corresponds to the sum of the stoichiometric coefficients for all components that participate in reaction r, and N is a square matrix formed from the stoichiometric coefficients of the reference components in the R reactions. Using these transformed variables as an alternative for the conventional composition quantities (mole numbers or fractions), the Gibbs free energy in a reactive system behaves as in a non-reactive system. Therefore, all thermodynamic properties of the reactive mixture are functions of the transformed composition variables.

Hence, the two-phase equilibrium in a reactive system can be calculated using

$$\left(\frac{\partial \hat{g}}{\partial X_i}\right)^{\alpha}_{T,P,X^{\alpha}_{j\neq i,\, j\in\{1,...,c-R-1\}}} - \left(\frac{\partial \hat{g}}{\partial X_i}\right)^{\beta}_{T,P,X^{\beta}_{j\neq i,\, j\in\{1,...,c-R-1\}}} = 0 \quad i = 1,..., c - R - 1 \tag{7}$$

$$\hat{g}^{\beta} - \hat{g}^{\alpha} - \sum_{i=1}^{c-R-1} (X_i^{\beta} - X_i^{\alpha}) \left(\frac{\partial \hat{g}}{\partial X_i}\right)^{\alpha}_{T,P,X^{\alpha}_{j\neq i,\, j\in\{1,...,c-R-1\}}} = 0 \tag{8}$$

$$Z_i = X_i^{\alpha}\Phi^{\alpha} + X_i^{\beta}\Phi^{\beta} \qquad i = 1,..., c - R - 1 \tag{9}$$

subject to

$$K_{eq}^{r} = \prod_{i=1}^{c} a_i^{\nu_i^r} \qquad r = 1,..., R \tag{10}$$

where $\hat{g}$ is the transformed Gibbs free energy of mixing, Z_i is the transformed feed composition of component i, K_{eq}^{r} is the reaction equilibrium constant, a_i is the activity of component i, Φ^{α} and Φ^{β} are the transformed fractions of moles at the vapor and liquid phases, respectively.

Ung and Doherty (1995) showed that $Z_i = X_i^{\alpha} = X_i^{\beta}$ is a necessary and sufficient condition for the presence of a homogeneous reactive azeotrope. If we replace this condition into Eqs. (7)-(9), then

$$F_1 = \hat{g}^{\beta} - \hat{g}^{\alpha} = 0 \tag{11}$$

$$F_{i+1} = \left(\frac{\partial \hat{g}}{\partial X_i}\right)^{\alpha}_{T,P,X^{\alpha}_{j\neq i,\, j\in\{1,...,c-R-1\}}} - \left(\frac{\partial \hat{g}}{\partial X_i}\right)^{\beta}_{T,P,X^{\beta}_{j\neq i,\, j\in\{1,...,c-R-1\}}} = 0 \quad i = 1,..., c - R - 1 \tag{12}$$

These equations can be used to find $c - R - 1$ transformed composition variables and the temperature or pressure of reactive azeotrope. The material balance is meaningless for both reactive and nonreactive azeotropes. If the Gibbs energy, or transformed Gibbs energy, is plotted for both liquid and vapor phases *versus* the corresponding composition variable at the homogeneous azeotrope pressure and temperature, the Gibbs curves of each phase will intersect at one point satisfying the equality criterion of the tangent plane and the equality of chemical potentials. Note that Eqs. (4)-(5) and (11)-(12) are an alternative set of

thermodynamic conditions to locate all homogeneous nonreactive and reactive azeotropes in multi-component systems, which can be applied with any thermodynamic model. They are nonlinear and may have one, more than one or no solutions (one azeotrope, several azeotropes or the nonexistence of a homogeneous azeotrope). Conventional root-finders are not suitable for solving these equations. Hence, a reliable and efficient numerical strategy must be used for the calculation of homogeneous reactive and nonreactive azeotropes. In the next section, we describe our approach to solve this thermodynamic problem.

3. Description of solution approach

We use an optimization approach to locate all solutions of Eqs. (4)-(5) and (11)-(12). These equations are formulated as a single objective function that should minimize by a suitable optimization technique. This objective function is given by

$$F_{obj} = F_1^{\,2} + \sum_{i=2}^{nec} F_i^{\,2} \tag{13}$$

where nec = $c-1$ for nonreactive mixtures and $nec = c - R - 1$ for reactive mixtures, respectively. At azeotropy condition, the global minimum of this function must be zero, but we assume that an azeotrope is found when we find the composition variables (x_i or X_i) and temperature or pressure that make the value of the function less than or equal to 1×10^{-9}; otherwise, we consider that an azeotrope does not exist in the mixture at the given conditions. For systems with polyazeotropy, this function have several optimums where F_{obj} $\leq 1\times10^{-9}$. The following procedure is used to locate all homogeneous azeotropes. First, we define the initial search intervals for the composition variables and the temperature or pressure. In these intervals, the objective function is minimized using a suitable optimization method and, once a minimum is found, we create new search intervals using the found solution for the temperature or pressure. In these new intervals, we again minimize the objective function. This procedure is repeated until the convergence criterion cannot be satisfied. For polyazeotropy, the objective function is penalized in the limits of the intervals obtained from segmentation to avoid convergence to the last solution. Usually, the value of the objective function is greater than 1×10^{-4} if testing conditions do not contain an azeotrope.

The Simulated Annealing method (SA) is used to find the global optimum of Eq. (13). In general, SA method overcomes most of the numerical difficulties that local optimization methods show. Because of the stochastic nature of SA, a local minimum can be avoided much more easily than in conventional methods. SA simulates the process of slow cooling of metals to achieve the minimum function value in a minimization problem. The cooling phenomenon is modeled by controlling a temperature like parameter introduced with the concept of Boltzmann probability distribution. Using a proper decrease of temperature, the convergence of the algorithm can be manipulated. In the present study, the SA algorithm developed by Corana *et al.* (1987) was used. This algorithm has been successfully applied in several thermodynamic problems (e.g., Bonilla-Petriciolet *et al*., 2006). Note that the numerical performance (reliability and efficiency) of SA method is affected by the cooling schedule. SA is a robust optimization method if an appropriate cooling schedule is used. So, the parameters of cooling schedule were tuned for the current application.

4. Case of study

We have calculated the homogeneous azeotropes of several binary, ternary and quaternary reactive and nonreactive mixtures that appear in the literature for testing the numerical performance of proposed strategy. In these calculations, solution models and equations of state were used. In all performed calculations, our method finds all azeotropes without any numerical problem independently of the initial values for optimization variables. In fact, our

method is very reliable for finding homogeneous azeotropes in both reactive and nonreactive mixtures.

With illustrative purposes, Figure 1 shows the performance of our method in the calculation of the homogeneous azeotrope for the reactive mixture: isobutene (1) + methanol (2) ⇔ methyl ter-butyl ether (3) with n-butane (4) as inert at 20 atm. Wilson model and ideal gas behavior are used to calculate the thermodynamic properties of this mixture, where three transformed mole fractions (X_1, X_2, X_4) and temperature are used as decision variables.

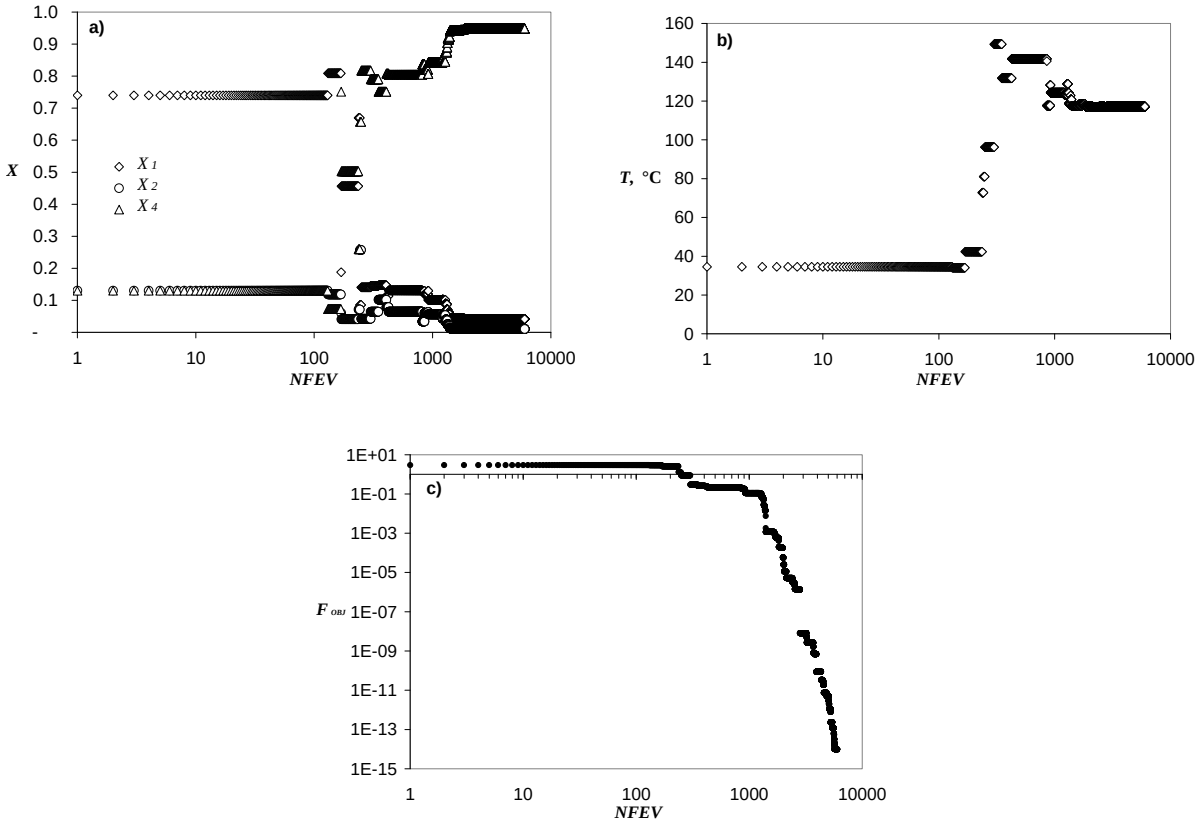

Figure 1. Performance of decision variables in the calculation of a reactive azeotrope using the Simulated Annealing method. a) Transformed mole fractions vs. NFEV, b) Temperature vs. NFEV, c) F_{obj} vs. NFEV.

From Fig. 1, we can observe that SA method requires a significant number of function evaluations (NFEV) for improving the accuracy of azeotrope conditions after F_{obj} has reached a value lower than 1x10^{-04}. Based on these results, we tried a hybrid approach starting with SA method as a robust algorithm for ensuring certain progress from poor initializations, and ending with a more efficient local method to accelerate convergence. Specifically, we used the Newton method as local strategy to solve Eqs. (4)-(5) or (11)-(12) using the solution obtained by SA method. The switch to the Newton method takes place once F_{obj} is lower or equal than 1x10^{-04}. All examples were solved using this approach with random initial values and, for all performed calculations, the azeotropes were found without any numerical problem. Note that a proper initialization for Newton method is available after application of SA method, and convergence is easily achieved. However, computational time is significantly reduced for both reactive and nonreactive systems. Generally, there is a 3:1 rate between the computational times of SA method and SA-Newton hybrid method.

Our experience with local solvers for finding homogeneous azeotropes indicates that these methods may show a success rate from 70 to 99 % using random initial values. When the unknown number increases, the performance of local solvers is poor. Clearly, local methods are more efficient than SA method; however they are less reliable and more dependent on the initial guesses.

5. Conclusions

We present an alternative set of thermodynamic conditions to locate all homogeneous azeotropes in multi-component reactive and nonreactive mixtures. Specifically, we showed that a homogeneous azeotrope (reactive or nonreactive) must satisfy an equality of the Gibbs free energy of mixing between vapor and liquid phases and an equality of the orthogonal derivatives of Gibbs energy with respect to composition variables in each phase. The resolution of these thermodynamic conditions can be done with confidence using the Simulated Annealing method. This optimization method is robust for finding all homogeneous azeotropes in reactive and nonreactive mixtures, and is almost independent of the initial values and its algorithm parameters. Finally, our method can be used with any thermodynamic model without the problem reformulation and it is suitable for multi-component calculations.

Keywords: Vapor-liquid equilibrium, thermodynamic library, object oriented, Thermolib.
Topic: Systematic methods and tools for managing the complexity.

Abstract

A new thermodynamic library programmed in Java named Thermolib is presented. It is designed to be portable, command friendly and versatile. It is proposed as a pedagogical and research tool for performing vapour-liquid equilibrium and thermodynamic properties calculations directly from command driven computing environments.

1 Introduction

This work presents the development of a portable and embeddable numerical library aimed at the calculation of equilibrium and thermodynamics properties. This library, identified as ThermoLib, is being developed using object-oriented concepts. It was created with part of the core code from an arcane application called Ekilib (Báez, et al., 1990; Vieira, 2007). That application was compressed by a group of six thermodynamic modules assembled with a user friendly interface, using classical procedural programming in Turbo-Pascal, being free distributed in the academic community. At that time, the availability of easy to use thermodynamic number cruncher applications was rare and commercial software only ran in huge mainframes. The portability of the code was constrained by tough limitations in hardware. Fortran 77 language was the “king of hill” in the scientific computing area and C language was directed to operating system development.

Nowadays, computer power and its availability are fairly common and software development has been revamp with object-oriented paradigms, allowing the management of complexity with well established patterns. The object-oriented paradigm is well supported in languages like C++ and Java, which in last years have been shifting Fortran from scientific programming crown. In this work, we have chosen Java as developing language platform, because it adopts a shorter but a flexible sub-set of C++ powerful characteristics, due to its omnipresence, even increasing performance and acceptation by scientific computing community (Pang, 2006).

The scenario in thermodynamic libraries for process modeling continues to be limited. It has raised recently a free object-oriented library developed in C++ (Landschützer, 2007), which seems will become in a large open source process simulator application, shareware packages callable from inside worksheets or thermodynamic packages with too narrow application. However, a portable, embeddable, easy to use, command driven, wide thermodynamic numerical library continues to be scarce or expensive, most of them restricted to commercial applications environments or not easily portable.

* Corresponding author. Tel +351-234 401 549. E-mail:fsilva@ua.pt

General propose computing environments as Matlab or Octave are used in academy and research, normally solving problems with thermodynamic requirements. It is always hard to include in dynamic models, rigorous thermodynamic treatment for determining properties and/or solving equilibrium equations. This library will try to fulfill this gap, both pedagogically and as a research working toolbox. The new library uses a database with critical data for pure components, easily accessible with single commands. The possibility to have a live object in memory for direct inspection with the “pure” component data and behavior, ready to use “mixture” objects allocating all data and methods for computing mixture properties and “mixture-stream” objects with vapor-liquid capacities are the main add-ons of the library we are developing.

2 Library Structure

Figure 1 shows the main class diagram of Thermolib library where at the middle is placed the package thermo, where all thermodynamic calculations implemented are located. Figure 2 shows a detailed class diagram for the package thermo, where it is prominent the Pure ← Mixture ← MixtureStream ← skeleton, inherited from Ekilib simulator (Báez *et. al.,* 1990). Pure class defines the behaviour of a single component and the access to pure component database. Mixture is an extension of single component where all mixture properties are assembled, while MixtureStream allocates all vapour-liquid equilibrium calculations: Flash, Bubble and Dew points. At the left side of Figure 2 it is shown the Eos and ExcessProperties interfaces, where new models extensions will be anchored, not originally avalilable in Ekilib.

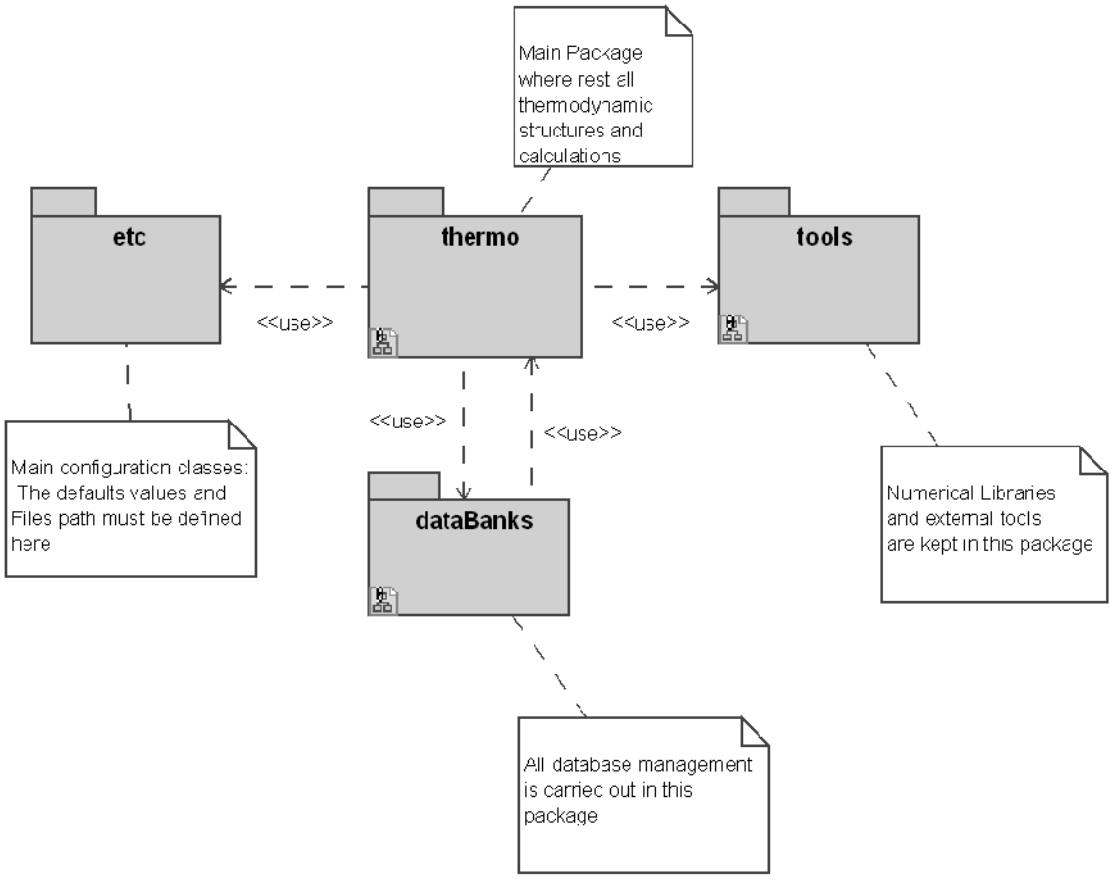

Figure1: Global class diagram of Thermolib toolbox written in Java language.

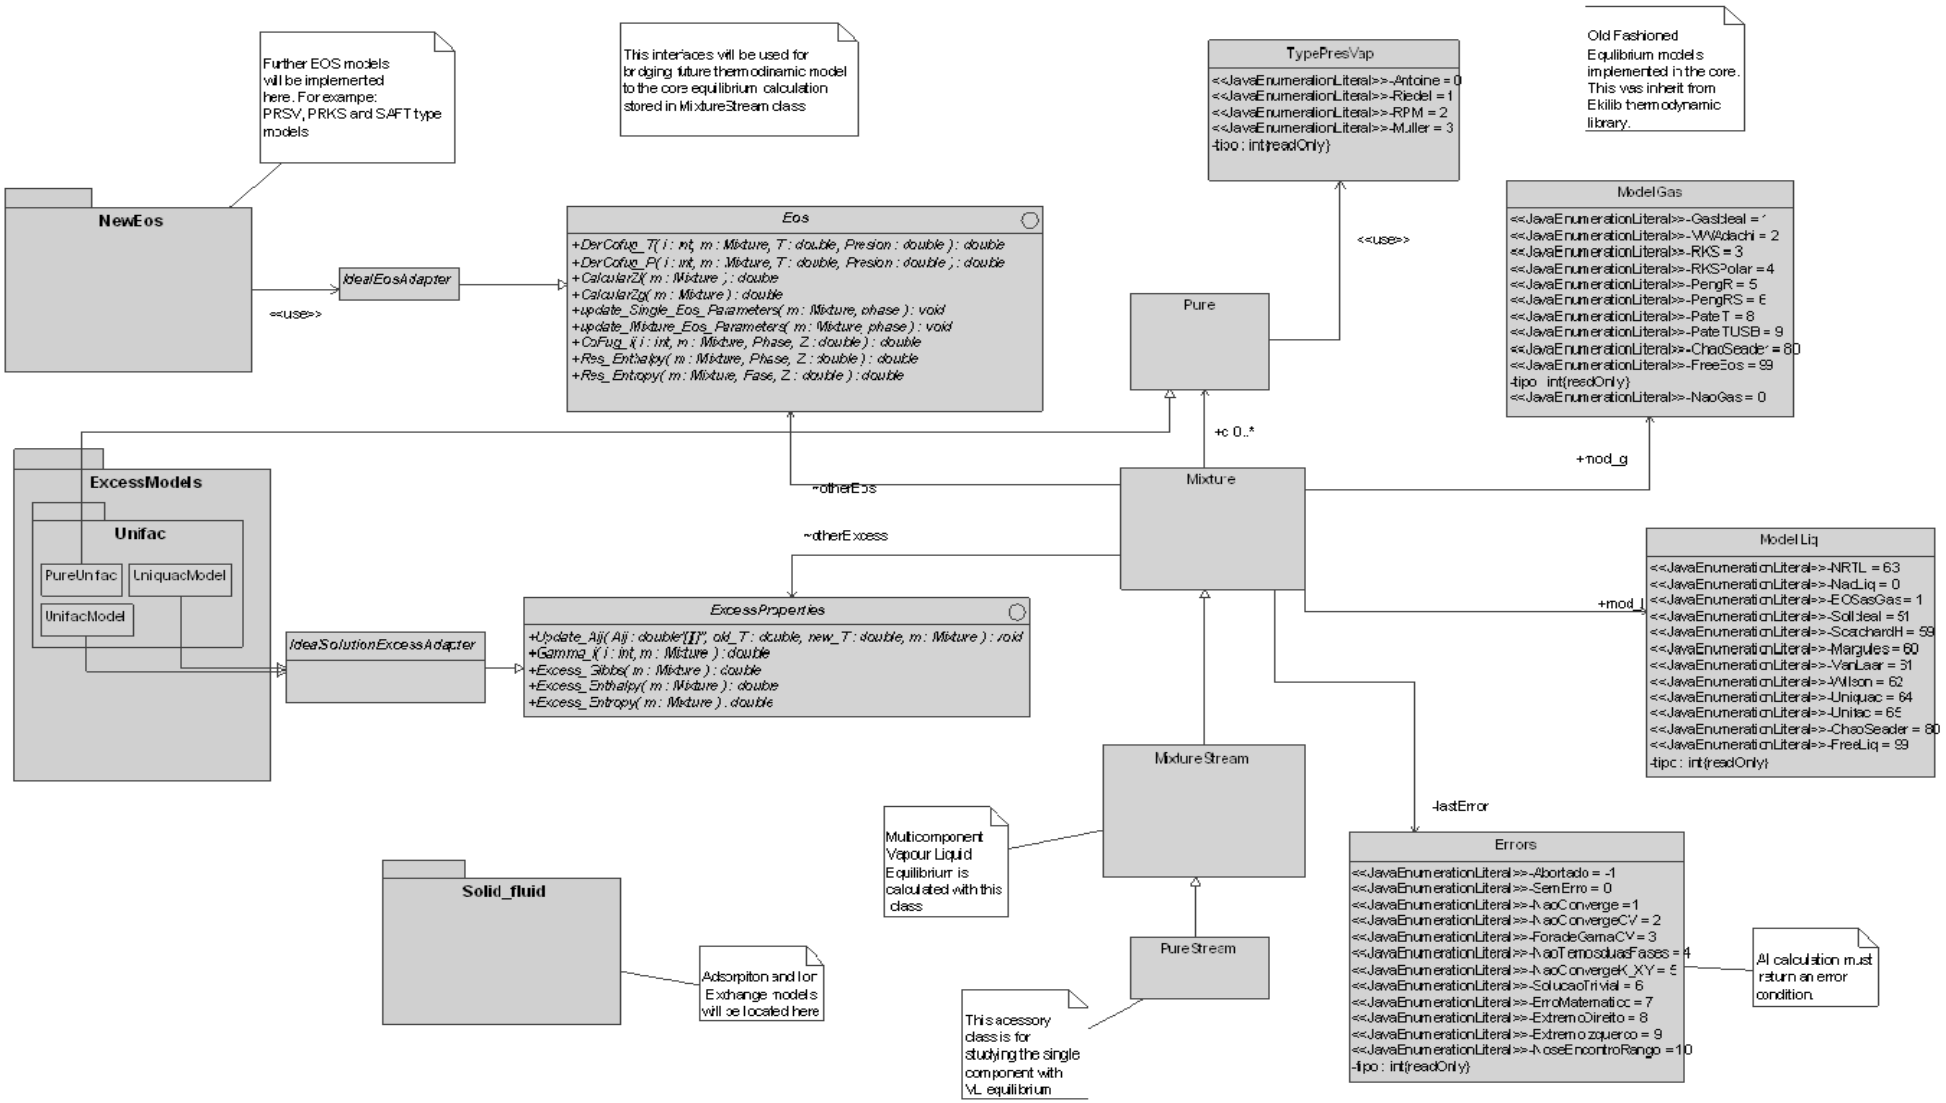

Figure 2: Detailed class diagram of “Thermo” package showed in Figure 1.

3 Simple examples

Figure 1 shows a textbook problem (Smith, *et al.*, 2005) solved with our library, using Matlab. The plots are obtained from standard commands, while the thermodynamic calculations where carried out with Thermolib embedded or imported directly in the computer environment. Figure 2 shows how to create an instance of a pure component directly from Matlab console window, after three commands, and a simple vapor pressure calculation. The scroll-window over the white pane shows the internals of the pure component available in memory at a finger distance. Further pedagogical examples and research application of Thermolib library can be found elsewhere (Viera, 2007; Silva, 2008).

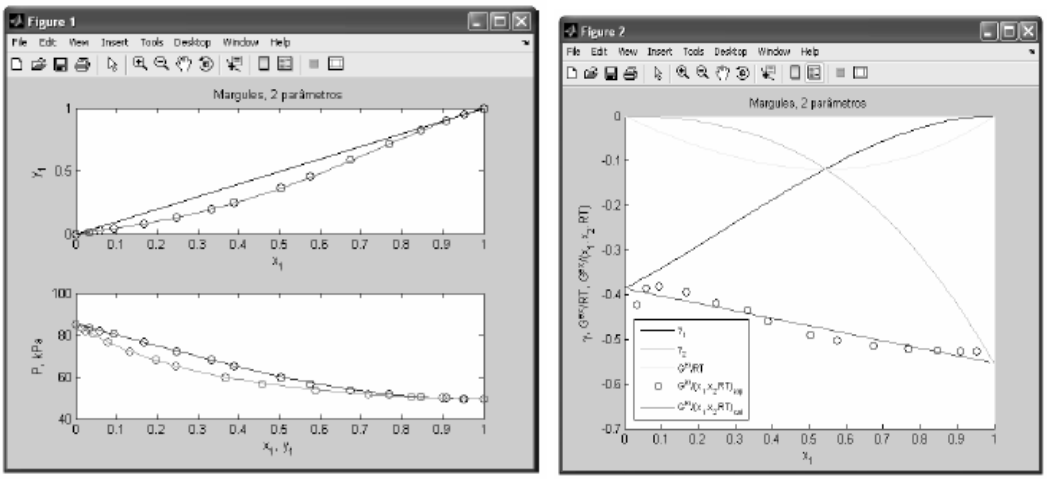

Figure 1: VLE data for tert-butyl ether(1)/dichloromethane(2) at 308.15K and equilibrium calculations using two-parameters Margules equation (A12 = -0.3861, A21=-0.5534). Problem adapted from Smith *et al.*, 2005.

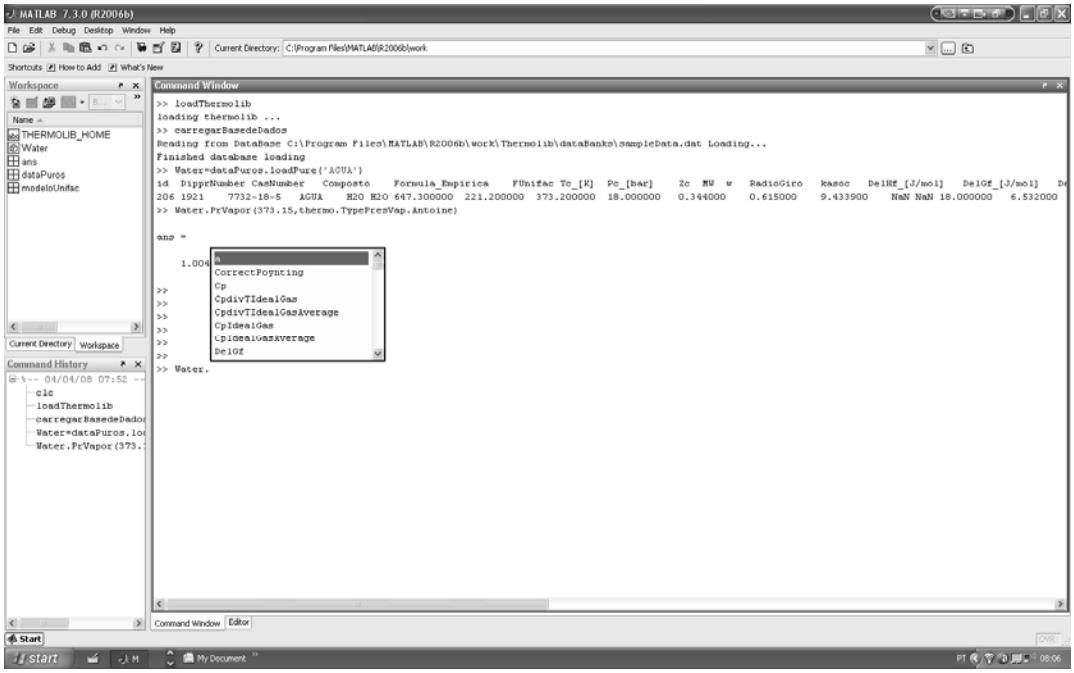

Figure 2: Using ThermoLib in a direct command driven session, showing how to get a “water molecule”, its internal class data and methods.

4 Conclusions

A promising thermodynamic library is being developed called Thermolib. It is aimed to be portable, command driven and direct accessible from the main console of well known numerical/computing systems. In the midterm, we expect to have a robust thermodynamic library easy to use with pedagogical and research interest.

Topic: Thermophysical Properties

Abstract

This article reports an experimental study on the flow characteristics of the aqueous suspensions of carbon nanotubes (CNTs) and also a suspension of CNT-EG (ethylene glycol). The viscosity of nanofluids was measured using a rheometer over a wide range of temperatures (298.15 to 318.15K), shear rate and carbon nanotubes concentration. Nanofluids with particle volume fraction ranging from 0.25 to 4 vol% were examined. Non-Newtonian behaviour was observed for the particle volume fraction of CNT-Water; the results show that CNT-Water and CNT-EG suspensions exhibit shear thinning behaviour at low shear rates. However the CNT-EG suspension exhibits at higher shear rate a Newtonian behaviour. The viscosity of nanofluids decreases with an increase of temperature independently of the CNTs concentration. It´s observed that viscosity of the nanofluids increases by increasing the concentration of CNTs even at high temperature and high shear rate.

1 Introduction

Nanofluids are diluted liquid suspensions of nanoparticles with at least one of their critical dimensions smaller than about 100 nm [1]. Such a type of composite materials has been shown to exhibit certain enhanced behaviour such as heat transfer and mass transfer [2]. Nanofluids can be regarded as functionalized colloids with special requirements of low particle loading, high thermal performance, great physical and chemical stability over a wide range of temperature and solution chemistry, and favorable flow/rheological behaviour. Because of the unusually high thermal conductivity of CNTs, it can be expected that the suspensions containing CNTs would enhance thermal conductivity and their improved thermal performance would be applied to energy systems [3]. Multiwalled carbon nanotubes (MWNTs) have an interesting set of properties with a wide variety of potential applications in liquid suspensions, polymer solutions, polymer melts, and polymer composites. Their unusual properties include excellent thermal and electrical conductivities, and magnetic properties [4]. Thought nanofluids can be used as a replacement for conventional oil, their rheological properties are needed to be known because they influence the required pumping power in a heating system [5].

* Corresponding author. Tel +351-239798728 ; Fax: +351-239798703 E-Mail: fonseca@eq.uc.pt

The measurement of viscosity of the nanofluids is essential to establish adequate pumping power as well as the convective heat transfer coefficient, since the Prandtl and Reynolds numbers will be influenced [6]. Presently there are two major areas in which CNTs are being used, which include electronics [7] and nano electromechanical systems [8] – mechanical memory elements, nanoscale electric motors. In electronic applications, CNTs are used to dissipate unwanted static charge build-up and are used as a conducting agent to aid in electrostatic painting [7].

2 Experimental

2.1 Materials

The multiwalled carbon nanotubes were purchased from M/s Shenzhen Nanotech Port Co., Ltd, China. The specifications of MWCNTs are as follows: range of diameter 60-100nm, length of the tubes 5-15 micron, density 2.16g/cc and purity $\geq$ 95%

2.2 Chemical treatment on CNTs

The effective utilization of nanotubes in nanofluids depends on the ability to disperse CNTs homogeneously in the fluid without destroying their integrity. It is also required to perform a chemical treatment on CNTs to have a homogeneous dispersion of CNTs in water [9]. The required quantity of CNTs was suspended in the mixture of concentrated nitric acid (65%) and sulphuric acid (95-97%) by the volume ratio of 1:3 and refluxed at 140ºC for 30 minutes. After washing the nanotubes with deionised water until the supernatant attained a pH around 7, the samples were dried at 100ºC. The chemically treated CNTs were studied in FTIR where it was observed different functional groups like carboxyl, carbonyl and others. The advantages of processing CNTs with chemicals are to modify their surface with functional groups, purify the tubes and to increase the surface area and pore volume of CNTs.

2.3 Preparation of nanofluids

In this study, a stable and homogeneous dispersion of chemically treated CNTs were prepared in deionised water by reducing the hydrophobic linkage of CNTs. The chemically treated CNTs were added with deionised water and sonicated for 1 hour to have a homogeneous and uniform dispersion of CNTs in water. In this study, nanofluids are prepared with difference concentration of CNTs.

2.4 Rheological study of nanofluids

The viscosity was measured using a controlled stress rheometer, Haake, Model RS1. The rheological tests were carried out with a sensor system Z34 DIN that comprises one rotor and one beaker, with a connected thermocontroller. The spindle used was 20.00 mm (radius) at a clearance to bottom 7.2 mm. The measurements were performed in the shear rate range from 0 to 1200 sec^{-1} for temperatures from 298.15 to 308.15K; at 318.15K the shear rate was from 0 to 600 sec^{-1}. For all the nanofluids at least three measurements were made, to test the precision of the results, including 250 or 125 data points, depending on the range of shear rate. The maximum precision was ±0.01 and ±0.17 the minimum, for the range of shear rate from 50 to 150 sec^{-1}. The accuracy of data was performed using a Brookfield viscosity standard (4.30 mPas) from Engineering Laboratories, Inc., Stoughton, U.S.A.

3. Results and discussion

3.1 Viscosity of CNT nanofluids

Figure 1 represents the viscosities of CNT-EG nanofluids (0.1 vol%) at two temperatures, 298.15 and 308.15K. There is a slight shear thinning behaviour for both temperatures at lower shear rate. It can be seen in Fig. 1 (a) that the viscosity is almost independent of the shear rate, indicating a close Newtonian behaviour of EG based

nanofluid. In Fig.1 (b) shear stress developed in the nanofluids is directly proportional to the shear rate being applied at any temperatures. At particular shear rate, the stress developed in the nanofluid decreases with an increase of temperature.

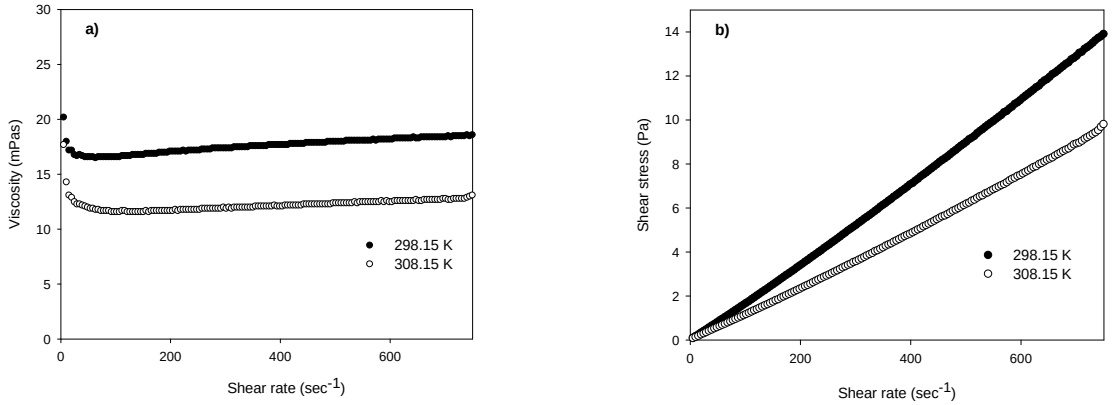

Fig.1. (**a**) Viscosity of EG-water nanofluids as a function of shear rate at 298.15 and 308.15 K; (**b**) Shear rate as a function of shear stress at same temperatures

In Table 1 the viscosities for the CNT based water nanofluid are presented as a function of temperature and composition. This data are plotted in Figure 2.

Table 1: Viscosity (mPas) for CNT nanofluids at three different shear rates at 298.15 and 308.15 K

T (K)	γ (sec^{-1})	Viscosity of CNT Nanofluids (mPas)								
		0.25%	***0.50%***	***0.75%***	***1.00%***	***1.50%***	***2.00%***	***2.50%***	***3.00%***	***4.00%***
298.15	10	3.22	3.46	3.52	3.58	3.60	3.82	3.69	4.22	4.66
	50	1.53	1.53	1.58	1.64	1.71	1.69	1.88	2.09	2.34
	100	1.64	1.72	1.75	1.76	1.77	1.78	1.73	1.88	2.10
308.15	10	3.31	3.30	3.29	3.45	3.73	3.71	3.90	4.02	5.84
	50	1.55	1.56	1.46	1.58	1.60	1.72	1.74	2.24	2.51
	100	1.58	1.595	1.66	1.65	1.69	1.71	1.76	1.96	2.04

With the increasing of CNT concentration, the viscosity increases for all fixed values at shear rate considered. At 4 vol% the nanofluid exhibits higher values of viscosity, at 10 sec^{-1}, as expected. However, for the remaining shear rates similar viscosities were found.

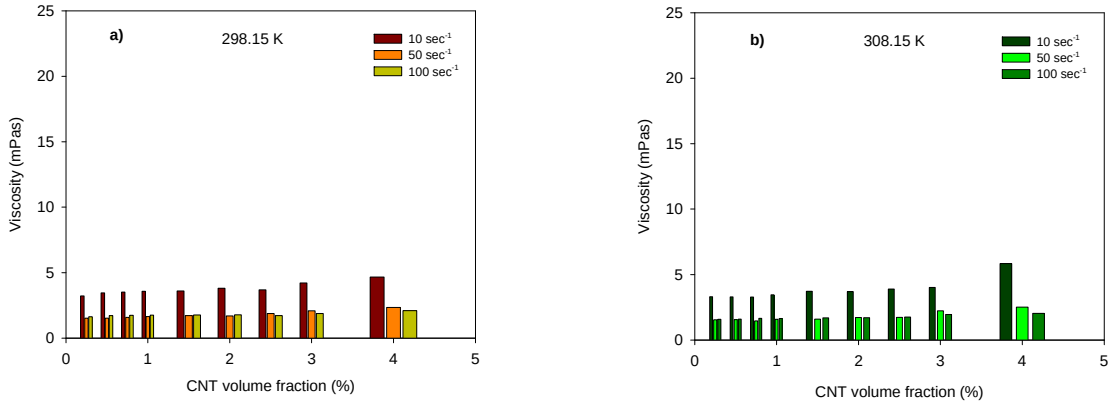

Fig. 2. Viscosity as a function of particle volume fraction, at shear rates of 10, 50 and 100 sec^{-1}, at (**a**) 298.15 K and (**b**) 308.15 K

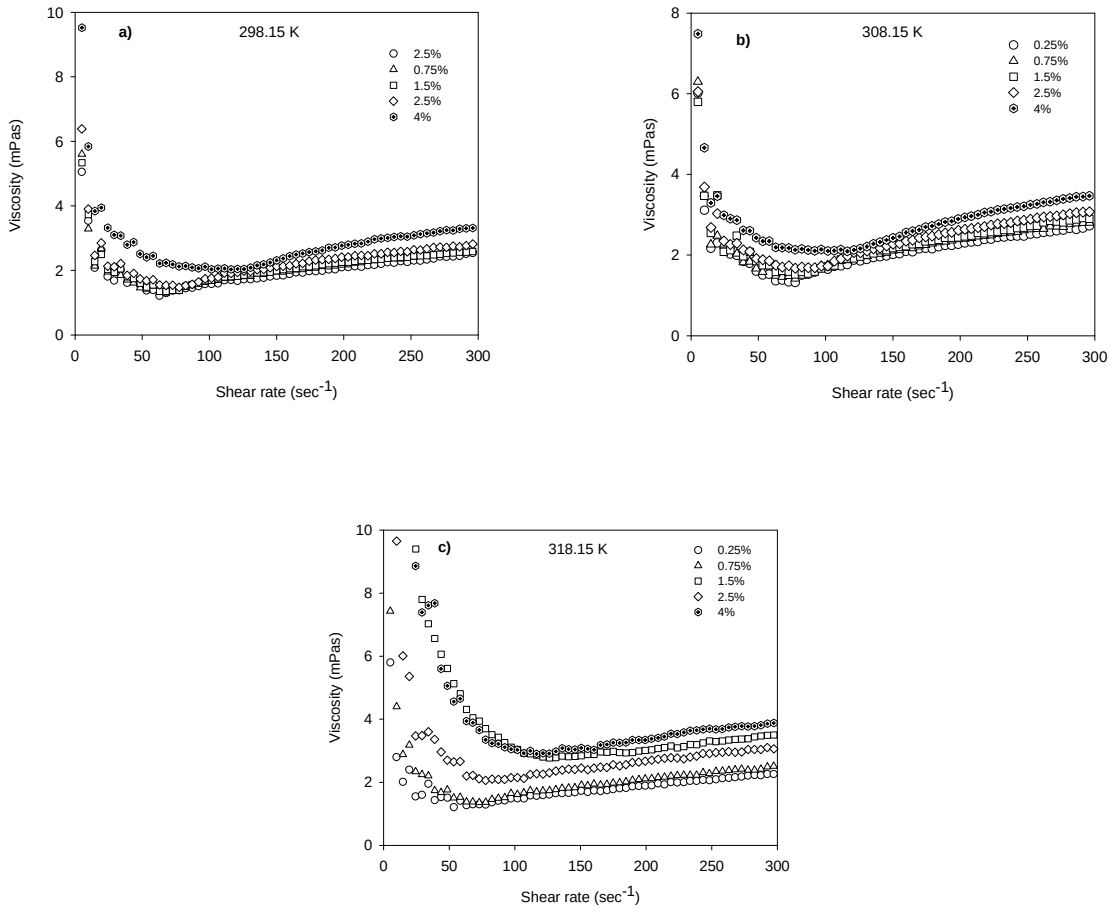

Fig.3. Viscosity as a function of shear rate for nanofluids 0.25 vol%, 0.75 vol%, 1.5 vol%, 2.5 vol% and 4 vol% at (**a**) 298.15 K, (**b**) 308.15 K and (**c**) 318.15 K

Figure 3 illustrates the viscosity as a function of shear rate at temperatures of 298.15, 308.15 and 318.15 K, for three different volume concentrations from 0.25 to 4.0 vol%. It can be seen that the viscosity increases with increasing CNT volume fraction and at lower shear rate the dispersions exhibits shear thinning behaviour. This non-Newtonian behaviour, probably the most common, is often observed for the polymers solutions, like paints, emulsions and dispersions of many types. It is well-known in rheology studies that in polymer solutions, the thread-like structured polymers, which are initially entangled, are rearranged along the flow direction under the shear stress, and consequently the viscosity of the solution decreases with shear rate. However, shear thinning behaviour is not the only non-Newtonian behaviour present on these CNT nanofluids. An increasing of viscosity with an increase in shear rate characterizes the dilatant fluid or shear thickening flow behaviour. Although less common than pseudoplasticity, dilatancy is frequently observed in fluids containing high levels of deflocculated solids, such as slurries, candy compounds and sand/water mixtures.
Figure 4 shows the variation of viscosity with the temperature and volume fraction for CNT nanofluids 0.25, 0.75 and 3.0 vol%. The viscosity of nanofluids decreases with an increase of temperature and increases with an increase in the CNT concentration. All the nanofluids samples exhibit the same trend. However, only at higher concentrations we observed a reasonable rise on the viscosity of CNT nanofluids; for example, doesn´t exist a large difference in viscosity between nanofluid 0.25 and 0.50 vol%, or even between 1.0 and 1.5 vol% nanofluids.

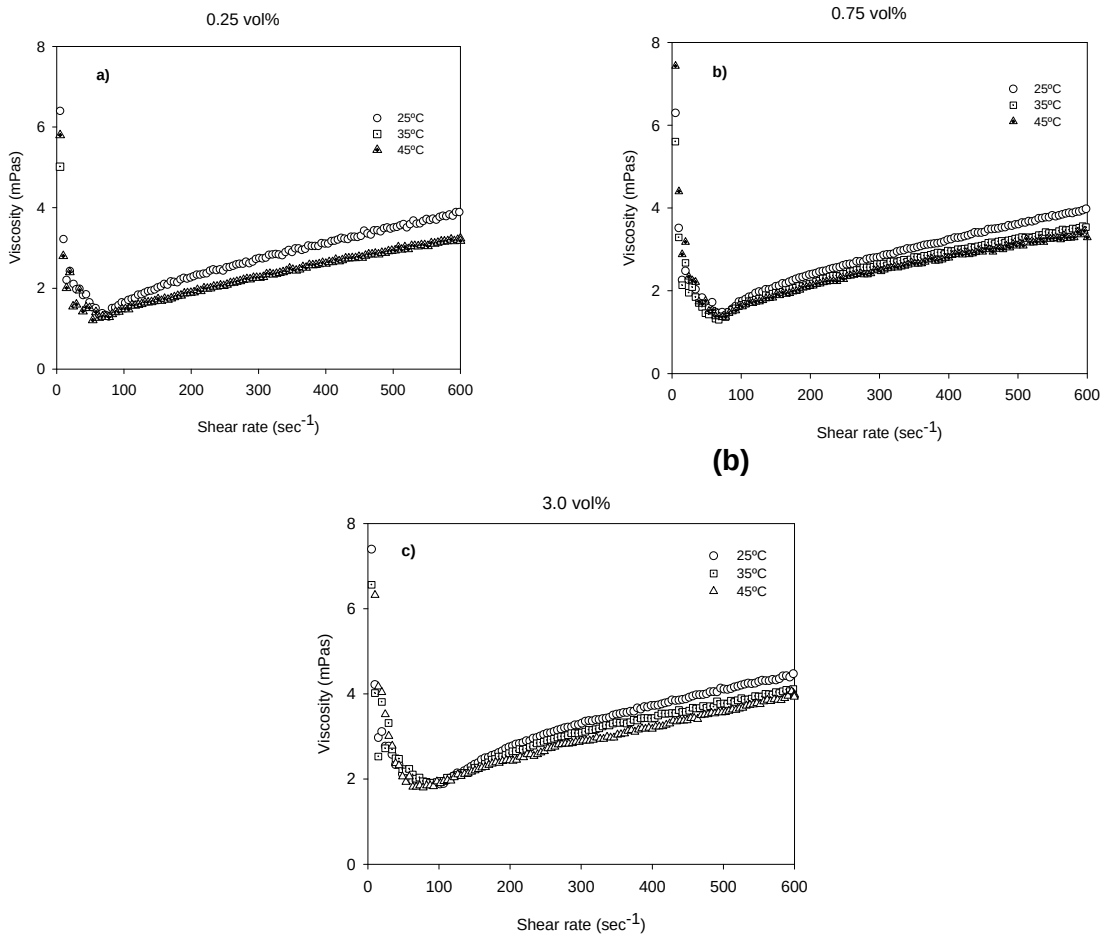

Fig.4. Viscosity as a function of shear rate for nanofluids **(a)** 0.25 vol%, **(b)** 0.75 vol% and **(c)** 3.0 vol% at 298.15 K, 308.15 K and 318.15 K

4. Conclusions

In this study we have measured the viscosity of the CNT nanofluids and the effects of the CNTs concentration and temperature were investigated. CNT nanofluids show the features of shear thinning behaviour, at low shear rate, for which viscosity increases with decreasing shear rate. At higher shear rates, the nanofluids behave like a dilatant fluid or shear-thickening. The viscosity of nanofluids increases with the increase on volume concentration of nanoparticles but more importantly the viscosity difference becomes much larger at high volume fraction. We found that the EG-water nanofluid is close to the Newtonian behaviour, with the viscosity depending strongly on temperature, though it also exhibits shear thinning behaviour but only at shear rates below 25 sec^{-1}. As the temperature increases, viscosity of CNT-water and CNT-EG nanofluids decreases. The shear thinning behaviour is much high for the CNT-Water nanofluids than for the CNT-EG nanofluid.

Keywords: LLE; Interfacial tension; Water ; N-Butyl Acetate; 1- Propanol
Topic: Thermodynamics and Thermophysical Properties

Abstract

This work belongs to a systematic study of this property for binary and ternary systems of the type water + ester + alcohol which has being developed by our research group. Liquid-liquid equilibrium (LLE) data are determined for the system water+N- butyl acetate+1-propanol at 323.15 K and atmospheric pressure. The experimental tie-line data was correlated by UNIQUAC equations and were predicted by UNIFAC. The empirical method of Othmer and Tobias is used for tie-line correlation, and the method of Pick et al was applied for binodal data correlation. The liquid interfacial tension has been measured for the corresponding tie-lines at the same temperature and pressure and this property was correlated using the relation proposed by Li and Fu.

1 Introduction

The importance of liquid-liquid extraction in separation technology has increased over the last 30 years. It is now usually used in pharmaceutical and food industries for recovering valuable organic materials for example the alcohols from aqueous solutions. The published studies on liquid-liquid equilibrium and on the thermophysical properties data of ternary systems of practical interest are scarce when compared with the wide variety of binary systems which have been investigated. The surface and interfacial tensions of solutions have a great effect on the efficiency of the extraction. In the last years we have made measurements of this properties and we have correlated the data for systems of the type water+alcohol+ester.[1-3] The aqueous solutions of alkanols can be efficiently extracted with esters and precise liquid-liquid equilibrium (LLE) data are needed for extraction processes. Some LLE measurements on ternary systems of the type water+alkanol+aliphatic ester can be found in the literature.[4-7]. The purpose of this study is to determine the liquid-liquid equilibria for the water+N-butyl acetate+1-propanol at 323.25 K and to study the interfacial tension at this temperature. The experimental tie-line data were regressed to the UNIQUAC model to obtain the interaction parameters of the model and addicionaly the data were compared with those predicted by means of UNIFAC group contribution method [8] using the LLE interaction parameters reported by Magnussen et al [9]. The tie line data have been correlated by the simple method of Othmer and Tobias [10], and the binodal curve was represented following a method proposed by Pick et al [11]. For the ternary system studied, the interfacial tension was determined in the immiscible range at the same temperature and the experimental data was correlated with the Li and Fu model [12].

2 Experimental

2.1 Materials. Tridistilled water was used. 1-Propanol (Riedel de Häen) was supplied with a weight fraction purity better than 0.995. N-butyl acetate was supplied by Sigma-Aldrich with a stated purity better than 0.995. The purity of the chemicals was checked by measuring their density, viscosity and surface tension.

* Corresponding author. Tel +351-239798729 ; Fax: +351-239798703 E-Mail: abel@eq.uc.pt

The liquid mixtures were prepared by mass using a Mettler AT 200 balance with a precision of $\pm 1\times10^{-5}$ g. The uncertainty of the mole fraction is estimated to be of the order $\pm 1\times10^{-4}$.

2.2 Methods

Binodal curve. The binodal curve was determined by the cloud-point method. Water+1-propanol or N-butyl acetate+1-propanol binaries of known compositions were shaken in an equilibrium cell equipped with a magnetic stirrer and a jacket for circulating water from a HAAKE circulator. The temperature was controlled up to ±0.01 K. The third component (the ester or the water) was added until the transition point was reached. Next some alcohol was added until the disappearance of the cloud point occurs. The return to the transition point was next made by adding the third component used for a particular binary initial mixture. The contents of the components were determined by mass.

Chromatographic calibration curve. The analysis of the conjugate phases was carried out by gas chromatography in a TRE METRICS 9001 gas cromatograph equipped with a capillary column (J & W Scientific DB1: 25m×0.2 mm; film thickness, 0.3 µm). The internal standard method was used for the calibration of the detector (FID) response in order to achieve high reproducibility on the concentration of each compound in the conjugate phases on the binodal curves. N-butanol was the internal standard in the studied systems and was chosen because it has chromatographic properties close to those of the compounds in the considered multicomponent systems. Each point on the calibration curve for each compound was obtained from multicomponent systems of different known concentration prepared in the completely miscible region. All the mixtures of known concentration used for the calibration curves of the ternary system studied in this work were prepared by mass.

The FID's response (i.e. chromatographic areas) as a function of mass of each compound, so called response factor, was fitted to a straight line, Eq 1, by the least square method:

$$w_i = \left(\frac{A_i}{A_s} - b\right)\left(\frac{w_s}{m}\right) \qquad (1)$$

where w_i is the mass of the i component of the system, A_i the chromatographic area of the component *i*, A_s the chromatographic area of the internal standard (buthanol), w_s the constant mass of the internal standard, m and b the slope and the ordinate of the fitted straight line, respectively.

Liquid-liquid Phase Behavior. The experimental investigation on the liquid-liquid equilibrium of the ternary system water+n-butyl acetate+1-propanol was made in an equilibrium cell built of Pyrex glass with a total volume of 25 cm^3, which was enough to take samples from the two equilibrium liquid phases to perform the quantification of their concentration, and interfacial tension. This cell represented schematically in Figure 1 is similar to that used by Garcia-Flores et al [13]. The temperature control in the equilibrium cell was achieved by means of a constant temperature bath-circulator, Haake D8-G with a temperature precision of ±0.02 K, which uses water as thermal fluid in the thermal jacket of the cell. The temperature was measured in the cell thermowell with a Alpha Technics digital thermometer, model 4400, with a platinum resistance probe, certified by NIST, whose readings have an accuracy of 0.015 K and resolution of 0.01 K.

Five different tie-lines of known global concentration were prepared by weighing. The heterogeneous liquid mixtures were transferred into the equilibrium cells and stirring was carried out with magnetic bars during a period of at least 4 h, then allowed to settle for a 10 h period to obtain two liquid phases in equilibrium in each cell, at 323.15 K. The samples of both phases were obtained simultaneously with syringes with a capacity of 5 cm^3 through the sampling glass capillaries in the equilibrium cells (Figure 1), to ensure the right amount of sample for measuring the LLE, the density of the saturated liquid phases, and the interfacial tension between the liquid phases.

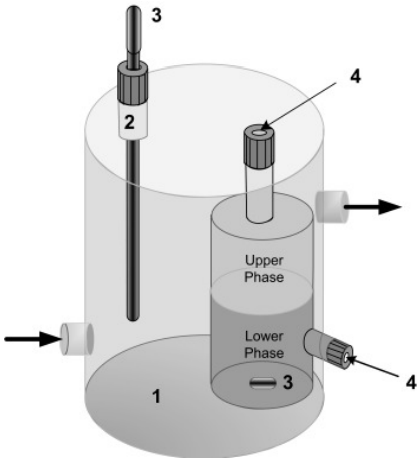

Figure 1. Equilibrium cell used for study the LLE: 1.Thermal jacket; 2.Thermowell; 3. Digital thermometer probe; 4. Sampling port.

Interfacial tension . Equilibrium liquid-liquid interfacial tensions were measured using a PC controlled KSV Sigma 70 tension balance which employs the Du Noüy ring-detachment method. The temperature inside the surface tension measurement vessel was maintained and controlled at 323.15±0.10 K using a UltraTerm bath.

For the liquid interfacial tension measurements, the liquid mixtures with a known global composition were prepared and kept at 323.15 K in a thermostated cell and shaken several times during a period of at least 24 h to reach the equilibrium.

3. Results and Discussion

In Table 1 the experimental equilibrium concentration results of the conjugate phases are given. Each result is the average of at least four injections of the same equilibrium sample into the chromatograph.

Table 1. Experimental values of the mole fraction, x, for the liquid-liquid equilibrium and liquid Interfacial Tension, γ, for the ternary system water(1)+n-butyl acetate(2)+1-propanol(3) at 323.15 K.

The experimental LLE data were correlated using UNIQUAC model. The parameters of this model were determined by fitting using an iterative computer program which uses simplex method [14] by minimizing the objective function

$$F = \sum_{k}^{n} \sum_{i}^{3} \sum_{j}^{2} (x_{i,exp} - x_{i,calc})_j^2 \qquad (2)$$

where n is the number of tie lines, (n=5), x_{exp} indicates the experimental mole fraction, x_{calc} is the calculated one, the subscript i indexes components, j phases and k=1,2,…, n are the tie-lines.

The LLE of the ternary mixtures were predicted using UNIFAC. The group-interaction parameters used for estimating the activity coefficients in the liquid phases were those given by Megnussen et al. [9] obtained from experimental LLE. Figure 2 shows the experimental LLE diagram, the correlation by UNIQUAC model, and the predictions from UNIFAC. As it can be seen the correlation results from UNIQUAC (point lines) are in poor agreement with the experimental data (solid lines) with exception of the aqueous phase and the organic

phase far from the critical point. The UNIFAC predicts a two-phase region in good agreement with that observed experimentally. The slopes of the predicted tie-lines are similar to those measured. The uncertainty of correlation and estimation has defined by the root mean square deviation (RMSD):

$$RMSD = \left\{ \sum_{k}^{n} \left[\sum_{i}^{3} \sum_{j}^{2} (x_{i,exp} - x_{i,calc})_j^2 / 6n \right] \right\}^{1/2} \quad (3)$$

The values of RMSD for UNIQUAC and UNIFAC are espectively 4.3×10^{-2} and 2.94×10^{-4} .

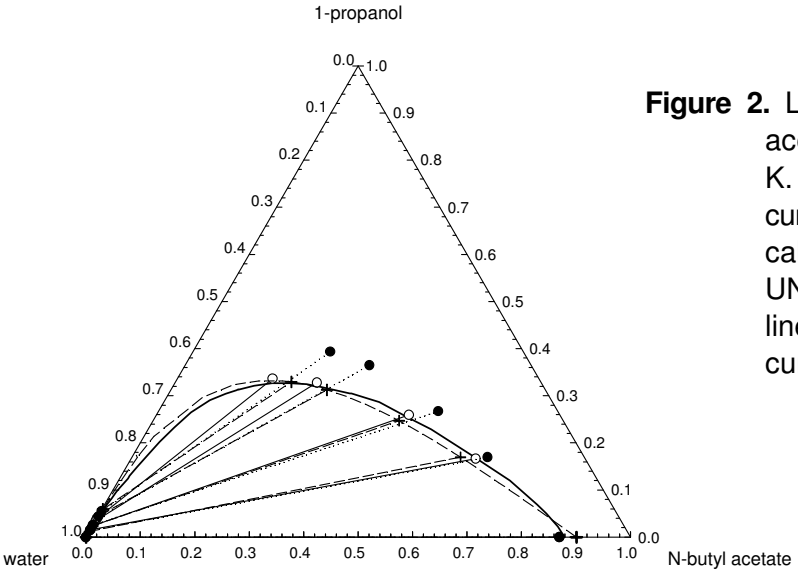

Figure 2. LLE data for water+N-butyl acetate+1-propanol at 323.25 K. Experimental: (–), binodal curve; (–○–) tie-lines; (●···●) calculated UNIQUAC tie-line; UNIFAC predictions: (+) tie-line data, and (----) binodal curve.

The reliability of experimentally measured tie-lines was determined by the application of Othmer-Tobias [10] one of the most used correlation for this purpose. This method employs the linear relationship

$$\ln[(1 - w_{1,aq}) / w_{1,aq}] = m + k \ln[(1 - w_{2,org}) / w_{2,org}] \quad (4)$$

where $w_{1,aq}$ and $w_{2,org}$ are respectively, the mass fraction of water (component 1) in the aqueous phase and ester (component 2) in the organic phase. The linearity of the plot in Figure 3 indicates the degree of consistency of the measured data. The values of parameters are m= -2.0413 and k=0.4911 and the standard deviation is σ =0.050.

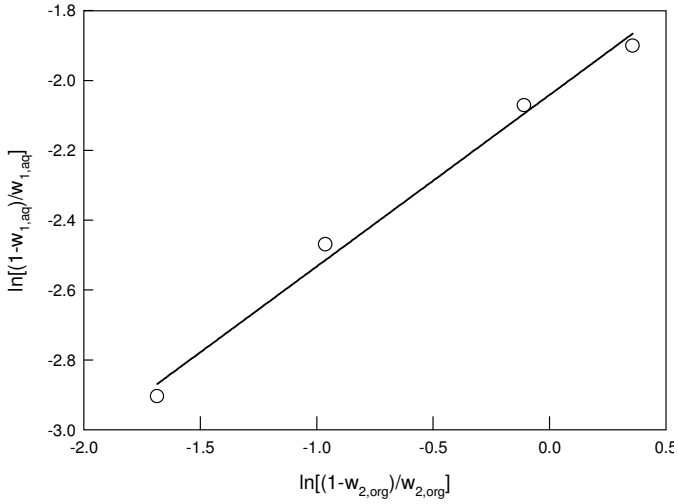

Figure 3. Othmer-Tobias correlation for water(1)+N butyl acetate(2)+1-propanol(3) at the temperature of 323.15 K, where w_i denotes the mass fraction of component i. The symbols refers to the experimental tie-line data and the line to the correlation.

The binodal curve has been correlated using the method of Novák et al. [11] obtaining

$$\ln[(x_1 / x_2)]/(x_1 - x_2) = 2.8536 + 0.9218(x_1 - x_2) + 1.0762(x_1 - x_2)^2 + 3.004(x_1 - x_2)^{10} \quad (5)$$

where x_1 and x_2 are molar fractions on the binodal curve. The standard deviation of the fit is σ= 0.097. In Figure 4 the experimental data and the results of correlation from equation (5) are compared. We conclude that the equation (5) describes very well the binodal curve data.

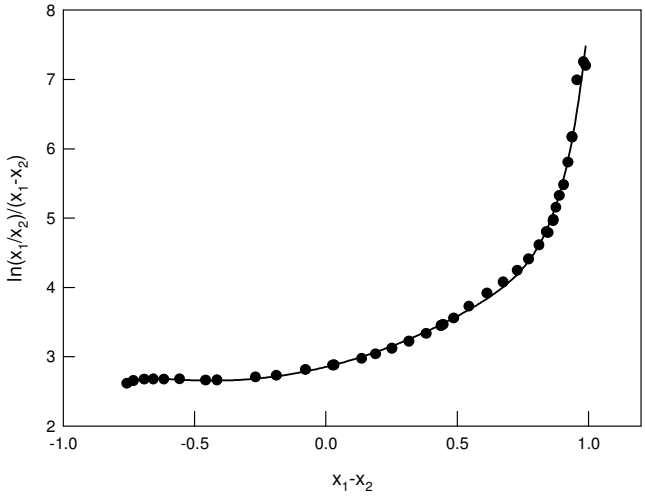

Figure 4. Dependence of

$[\ln(x_1/x_2)]/(x_1-x_2)$ on (x_1-x_2)

for the binodal curve. The symbols refers to the experimental data and the line to the correlation with equation (5).

To correlate the liquid interfacial tension, the Li and Fu model [12] was used. The equation of the model is

$$\gamma' = \gamma_0' \left(\frac{X}{X_0} \right)^k \quad , \quad X = -\ln\left[x_1^{\alpha} + x_2^{\beta} + x_{3p} \right] \tag{6}$$

γ' is the interfacial tension between the two immiscible liquid phases α and β in the ternary system and γ_0' is the interfacial tension of the partially miscible binary pair which corresponds x_3 = 0 and $X = X_0$ in Eq. (6). x_1^{α} is the mole fraction of component 1 in the liquid phase α richer in component 2, x_2^{β} is the mole fraction of component 2 in the phase richer in component 1 and x_3^{p} is the mole fraction of component 3 in the phase poor in it. The parameter k is adjustable in Eq. (6) and a general form, $k = \sum_{i=0} k_i X^i$ can be used. The results for the fitting of the Li and Fu model trough Eq. (6) to the liquid interfacial tension, γ', are shown in Figure 5. The use of one parameter in the fitting (k= 2.0775) results in an inadequate representation. A satisfactory representation of γ' is obtained taking into account the dependence of k on the composition (k=-6.1638-8.1540X+3.7210X^2). The same conclusion was already taken from past studies on the same type of systems [1].

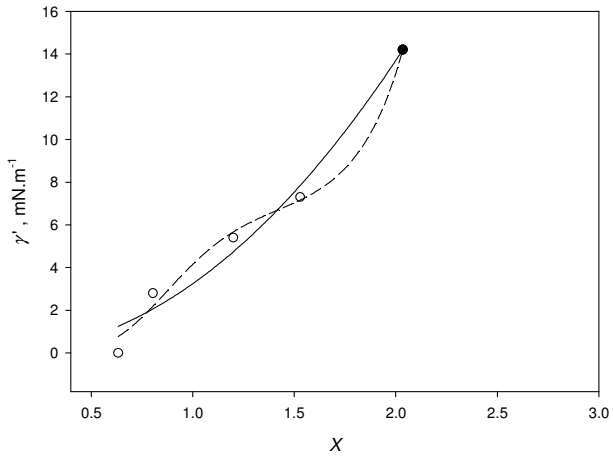

Figure 5. Liquid interfacial tension,γ' , as a function of X for the ternary system water+ N-butyl acetate +1-propanol at 323.15 K. The symbols (•, ○) represent the experimental data of the binary and ternary systems respectively, and the lines the curves fitted with the Li and Fu model, eq 4: (—) k = constant and (- - - -) $k = k_1 + k_2 X + k_2 X^2$.

Keywords: leather, tanning agents, DSC
Topic: Suitable Integration of life sciences & engineering

Abstract

Traditionally, quality, cost and yield are the three main concerns of leather manufacturers. However, the issue of environmental impact is now a worldwide concern. This environmental concern, combined with consumer preference, particularly in the European market, for chromium-free leather now makes the development of new tanning methods.

It is well known that collagen cross-linked with various cross-linking agents such as metal ions and aldehydes is made resistant against the degradation by collagenase and also that the thermal stability of collagen is increase owing to the cross-links formation. This cross-linking is the main objective of tanning, a process that converts raw hide/skin into leather. Understanding the effect of them on the dimensional stability of collagen will also aid in understanding the process of tanning.

The thermal stability of collagen has been investigated by measuring the hydrothermal shrinkage of collagen fibres, the characteristic temperature at which collagen fibre shrinks to one-third its original length and by differential scanning calorimetric (DSC) measurements. DSC allows the study of enthalpy changes, which are associated with the denaturation of collagen.

In this work the effect of different tanning agents in the stabilization of collagen was evaluated by DSC. The alternative agents selected were: mimosa extract, acrylic resin, glutaraldehyde, genipin. Chromium at 7% as been also tested as tanning agent, in the same scale, to be used as a reference.

The leather tanned with 7% of cromium was undoubtely the best results about themodynamic stability but several tanning agents can be choosed for and a good themodynamic stability was achieved. The DSC data of leather thermodynamic stability were correlated with test of leather shrinking temperature described in ISO 3380.

1 Introduction

The collagen molecule consist of a triple helix held together mainly by hydrogen bonds. Denaturation is simply a term which implies the physical change of the hydrated collagen complex. It is commonly defined as the transition from the triple helix to a randomly coiled form that has been caused by any one of the many deterioration agents that could affect leather. Collagen molecules are assembled into fibers stabilized by various cross-links between the molecules. When saturated with water and heated, the hydrogen bonds are broken, and the linear structure of the collagen molecules is transformed into a disorder structure. The temperature, at which the structure transforms, depends on the number and nature of the cross-links between the collagen molecules. The methods of tannage, as well as the degree of deterioration influence the stability of the collagen molecules, and this stability may vary

* Corresponding author. Tel + 351-228340500. E-mail:vfd@isep.ipp.pt

considerably from molecule to molecule. The change in structure is easily recognized, and the changes observed range from a small bending to a complete coiling of a fiber – the fiber shrink (Larsen et al., 1993). Our present understanding is that denaturation is the result of the loss of collagen's higher structural features due to disruption of the hydrogen bonding and other secondary forces that hold the molecule together. The temperature at which fully hydrated collagen or leather shrinks under defined conditions is called the shrinkage temperature (Ts).

Part of the benefit of tanning and lubricating leather is the ability to resist fiber sticking upon drying. Of the changes in appearance and properties that are a consequence of tanning, one of the more important is increase in hydrothermal stability (Kite and Thomson, 2005).

The Ts of undeteriorated mature collagen is around 65ºC but it can be as low as 30ºC in deteriorated collagen. The Ts for new vegetable-tanned leather is from 70 to 90ºC depending. In chrome-tanned leather the weak hydrogen bonds keeping the collagen polypeptides together are replaced by strong covalent chromium chemical bonds, thus the shrinkage temperature is around 100ºC (Young, 1998), (Chahine, 2000).

There's a chrome-free movement in several industry to answers to environmental and health concerning. Market demand has always been a main impetus for technological development and innovation, and now legislation demands careful environmental considerations as well.

Some vegetable extracts has been tried as tanning agent the mimosa extract and genipin. The application of Mimosa extract (from *Acacia negra* and *Acacia molíssima*) is very common worldwide and it can be modified by mixing with other types of tanning materials to adopt its characteristics to the specific leather type in re-tanning. Particularly suitable for the re-tanning of chrome leather where fullness, buff ability and good printing and plating properties are required. The combination with other anionic tanning agents such as resins and polymers is common practice to enhance the finishing of the leather. In general, Mimosa extract is now the favorite natural tanning agent in the use of fast modern tanning systems in pits or drums.

Genipin is a hydrolytic product of geniposide, which is found in the fruit of *Gardenia jasminoides Ellis*. The structure of genipin was discovered in the 1960's (Djerassi et al., 1961), Fig. 1. Because it is a naturally occurring, biodegradable molecule with low cytotoxicity, genipin has recently been investigated as a crosslinking material. The most common crosslinking agent has been glutaraldehyde, but because of concerns about its toxicity new methods are being tested like genipin. The tanning effect of genipin was found to be similar to that of glutaraldehyde, an organic tanning agent currently being used to produce chrome-free leather (Vaandering, 2006).

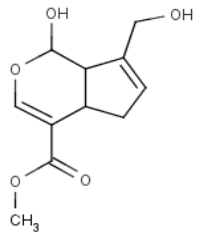

Figure 1. Structure of Genipin

One of the more important consequences of tanning is increasing the hydrothermal stability. The evaluation of the thermal behavior in the different leather samples obtained with the different tanning agents can be measured by different methods: by direct observation or under a microscope of the hydrothermal shrinkage temperature, by using the isometric tension test, or by differential scanning calorimetry (DSC). The latter allows the study of enthalpy changes which are associated with the denaturation of collagen, of which shrinkage is the macroscopic manifestation (Chahine, 2000).

In the present investigation, an attempt has been made to achieve different tanning agents and get high thermostability leather.

2 Experimental

2.1 Materials and reagents

Pickled bovine pelt was kindly supplied by NEIC and Curtumes Aveneda. Genipin was purchased from Wako Chemicals GmbH. Glutaraldehyde (Drasil GL) from Cognis, chromium sulphate with 25% Cr_2O_3 and 33% basicity (Cromosalt B) from Bayer, Plenatol HBE from Cromogénia Units SA, mimosa extract from Seta and the acrylic resin was developed by Indinor. The brine solution (6ºBe) was prepared using

commercial sodium chloride. The pH adjust was performed with sulfuric acid, formic acid or sodium carbonate and magnesium oxide from Riedel-de Haën.

2.2 Apparatus

Reactions with hide powder were carried out in a thermostated shaking bath, SBS30, with temperature controlled and assure uniform mixing. The skin powder was obtained using a laboratory cutting mill, Pulverisette 15 from Fritsch. The pH was controlled using a pHmeter GLP22 from Crison. Laboratory drums, Mathis CH-8155, were used to prepare the leather samples with the different tanning agents to perform the tests of leather shrinking temperature described in ISO 3380.

The measurements were performed using a Netzsch DSC 204 differential scanning calorimeter equipped with a controlled TASC 414/3A. It was calibrated for temperature and heat flow using Bismuth (Bi), Indium(In), Potassium nitrate (KNO_3), Tin (Sn) and Zinc (Zn) as standards (obtained from Netzsch).

2.3 Sample preparation

The tanning procedures were the same for the tests carried out in a thermostated shaking bath, with hide powder, and in the laboratory drums, with skin pieces. The hide were weighted and immersed in NaCl solution (6ºBe), then the first pH adjust was done. The tanning agents are added and the reaction occurs with temperature controlled and a uniform mixing. In the end of the reaction a second pH adjusts is made. All the samples are washed with distilled water; the tanned leather obtained in the laboratory drums is tested for shrinkage temperature. And the tanned hide powder obtained in the thermostated shaking bath is soaked in distilled water overnight, filtered in vacuum and dried in a desiccator and, finally analyzed in DSC for thermal stability.

However for each tanning agent the amount of the agent, pH conditions, time of reaction and temperature were different. In Table 1 are described the steps for the tanning procedures for chromium, mimosa extract, glutaraldehyde, genipin and acrylic resin.

Table 1. Tanning agents, percentage, time, temperature and pH conditions for hide tanning.

(*) % of the pickled pelt amount used

The tanned hide powder samples were filtered and maintained in a desiccator with silica gel at least 5 days.
The thermal stability of collagen has been investigated by measuring the hydrothermal shrinkage of the collagen fibers, the characteristic temperature at which collagen fiber shrinks to one-third its original length and by differential scanning calorimetric (DSC) measurements.

2.4 Differential scanning calorimetric analysis

The heating rate was maintained constant at 10ºC/min in the temperature range of 25 to 175ºC under continuous flow of dry nitrogen gas (20 mL/min). The samples were weighed (around 3 mg) and placed in aluminum crucibles with a pierced lid. An empty aluminum pan was used as reference.

2.5 Thermal properties

The hydrothermal shrinkage temperatures of the leathers were tested with total immersion in a water bath.

A piece of leather samples (around 8 cm^2) was held in water with controlled temperature in a period up to 3 minutes. The tested temperatures were between 30ºC to 95ºC with a variation of 5ºC each. Experiments using a Standards method, ISO 3380, were executed.

3 Results and discussion

To establish a basis for evaluating the tanning effects on temperature shrinking two tests were done: ISO 3380 in a Certified laboratory and an immersion in a water bath. The hydrothermal shrinkage temperatures of native and leather treat with several tanning agents are given in Table 2.

This high increase in hydrothermal stability on treatment with chromium when compared to others is due to the fact that chromium forms co-ordinate covalent linkages with the carboxyl group of the collagen and increases the long range ordering of collagen by forming a larger number of cross-links (Fathima et al., 2004).

Preliminary tests in DSC with pieces of leather showed a high standard deviation (28%). However studies with hide powder revealed a lowers standard deviation (6%).

Improvements in thermal stability of a hide, hide powder, or even collagen are often cited as evidence of the tanning potential of the process that resulted in increased thermal stability of collagen (Ding et al., 2006). The transition of protein from a native to a denatured conformation is accompanied by the rupture of inter- and intra-molecular bonds, and the process has to occur in a cooperative manner to be discerned by DSC (Ma et al., 1991). Analysis of a DSC thermogram enables the determination of an important parameter; the enthalpy of denaturation (ΔH).

Table 2. Shrinkage temperature analyses by two methods and enthalpy of denaturation obtained for hide powder tanned with different agents.

Tanning agent	Ts (℃) ISO 3380	Ts (℃) Water bath	ΔH(J/g)
Native	40	40-45	
Chromium 7%	95	90-95	336
Mimosa extract 25%	77	75-80	316
Glutaradehyde 6%	72	70-75	229
Genipin 5%	59	70-75	231
Acrilic Resin 8%	58	60-65	264

The thermal stability of collagen is considered as the marker of the reaction. Thermally induced structural transitions in the fibrous collagenous network leads to shrinkage. The enthalpy of denaturation of native and various samples of hide powder treated with different tanning agents are given in Table 2. It could be seen that the denaturation temperature measured using DSC follows the same trend as the hydrothermal shrinkage temperature as described by other authors (Fathima et al., 2004).

Both methods are based on the principle that when heated in water, the collagen will deform to randomly disordered chains over a distinct temperature interval (Larsen et al., 1993).

The Fig. 2 shows the thermograms obtained with the same tanning agents in hide powder.

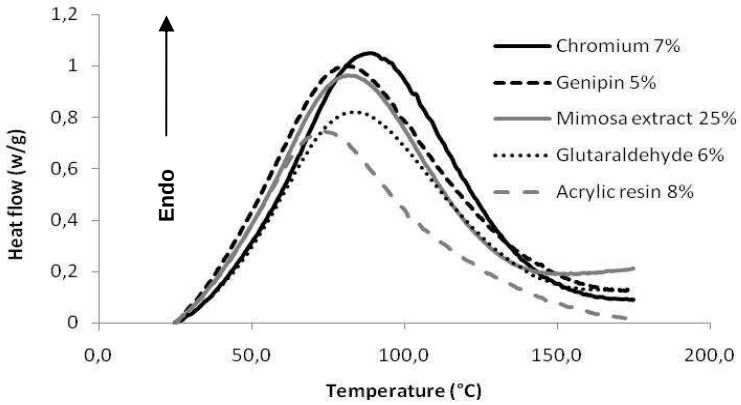

Figure 2 - Thermal absorption recording of denaturation of tanned leather with: chromium 7%, mimosa extract 25%, glutaraldehyde 6%, genipin 5% and acrylic resin 8%

It is an endothermic process in which a phase transition takes place involving changes in the lattice and long-range order. An increase in thermal stability could be related to the increase in the number of cross-links because they decrease the entropy of transition (Privalov and Tiktopul.Ei, 1970). However, the thermal stability measured using DSC is not the some phenomena measured by the water bath and ISO 3380. The collagen fibers were kept in the presence of water during the hydrothermal shrinkage measurements and in the absence of water during DSC measurements. And it is known that the thermal helix-coil transition depends on the degree of hydration (Pineri et al., 1978). It could also be seen from Fig 2 that the enthalpy of the endothermic peaks has increased for the chromium-treated collagen. ΔH is the amount of heat energy required to bring about the transition. An increase in ΔH indicates that cross-linking has occurred, which then requires more energy to undergo the helix-coil transition.

The chromium tanning shows a higher endothermic process than the others as expected. The studies of thermal stability of hide powder of chromium, mimosa extract and glutaraldehyde are identical as the results obtained for the hydrothermal shrinkage temperature by water bath and ISO 3380 (Table 2). However leather genipine tanning shows differences between the values of the thermal stability obtained by DSC analysis and the shrinkage temperature tests (with water bath and by ISO 3380).

Although the genipin data from DSC with hide powder are comparable with the results from chromium tanned, the Ts tests (with water bath and by ISO 3380) achieved lower Ts (70-75ºC and 59ºC). Those differences between these data shows different information which can be explained by the leather samples size used in tanning process. While DSC samples were tanned as hide powder the samples for Ts testes were tanned as hide pieces. The penetration and reaction of genipin is easier on hide powder, more difficult with hide pieces and even more complicated in bigger amount of leather obtained in the laboratory drums for the ISO 3380 determination.

4 Conclusions

Improvements in thermal stability (generally reported as shrinkage temperature) of a hide, hide powder, or even collagen are often cited as evidence of the tanning potential of the process that resulted in increased thermal stability of collagen.

The results of this study show that other tanning agents can be effective at increasing the thermal stability of hide powder.

Optimization of procedures for applying the agents studied to hides as a tanning agent or a component of a combination tannage is under development.

The results so far obtained support the assumption that genipin can act as a new type of crosslinking reagent of natural origin, with many potential applications.

Effect of Isooctane on Vapor-Liquid Equilibria of Water and TEG Solution

A. Khosravanipour Mostafazadeh, M. R. Rahimpour*, A. Shariati
Chemical and Petroleum Engineering Department, School of Engineering, Shiraz University, Shiraz 71345, Iran

Keywords: Experimental data; Activity Coefficient; NRTL; UNIQUAC

Abstract
In this study, vapor-liquid equilibria for systems water-triethylene glycol (TEG) and water-TEG-isooctane were measured experimentally. The VLE data were determined in a modified Othmer still which is the continuous-distillation still that recirculates the vapor phase and the samples were analyzed using gas chromatography and titration method. NRTL and UNIQUAC models were correlated for liquid phase behavior. It was observed that the correlations can provide good agreement with experimental data. The results of multi-component VLE demonstrate the enhancement of volatility of water in water-TEG solutions and increasing the purity of the dehydrated TEG by the addition of isooctane (2,2,4 trimethyl pentane).

1. Introduction

The natural gas dehydration is an important operation in the gas processing and conditioning industry. The standard method for natural gas dehydration is by absorption of water using TEG. TEG is used in about 95% of the glycol dehydration units for natural gas streams. Glycol dehydration units conventionally consist of a contactor, and a regenerator. An alternate approach for the enhancement of reconcentrator performance is the use of stripping agent. In this approach a volatile hydrocarbon liquid is added into the glycol regeneration system. The hydrocarbon increases the volatility of water in the solution of water-TEG. Smith and Skiff (1990) reported that this type of process can achieves concentrations of over 99.99% with triethylene glycol, resulting in potential dry gas with the water dew points range in -100 to -140°F. Isooctane (2,2,4 trimethyl pentane) are used as entrainers in the stripping column of natural gas dehydration unit (Francis S. Manning, Richard E. 1992, A. Ryba, 2005). Knowledge of vapor-liquid equilibrium (VLE) data is necessary for accurate design and simulation of stripping columns. Therefore, vapor-liquid equilibria for water-TEG and water-TEG with addition of isooctane (as stripping agents) have been studied in this work. Morrison et al. (1990) investigated the salt effect in vapor-liquid equilibrium of water-ethanol system and they showed the relative volatility of ethanol is increased by the addition of salt. Herskowitz and Gottlieb (1984) determined the activity coefficient of water in a water-triethylene glycol solution using an isopiestic method. Gupta et al. (1989) determined isobaric vapor-liquid equilibria for the systems TEG-benzene, toluene-TEG and benzene-N-Methylpyrrolidone. Scauzillo (1961) presented equilibrium ratios and activity coefficients of water in the systems water-TEG-natural gas. Chorng et al. (2005) developed an advanced EoS for prediction of triethylene glycol and water system. In this work, experimental procedure was done in order to determine vapor-liquid equiliria data for binary water-TEG and ternary water-TEG-isooctane systems. Modified Othmer still was used for taking samples and they were analyzed by gas chromatography (GC) and titration method. The results were used to optimization the interaction parameters of the NRTL and UNIQUAC equations.

2. Experiments

2.1. Materials

The materials were used from commercial sources. They were obtained from Merck with nominal purities that are tabulated in Table 1.

Table 1 Materials used in this study

chemical	purity	water content	density gr/cm^3	supplier
triethylene glycol	> 99 %	< 0.3 %	1.123	Merck
isooctane	> 99.5 %	< 0.01 %	0.691	Merck
distillated water	-	-	1.00	Shiraz University

2.2. Apparatus and experiments

The VLE data were determined at atmospheric pressure in a modified Othmer still which is the continuous-distillation still that recirculates the vapor phase. The modified Othmer still provides accurate vapor-liquid equilibrium data in a relatively short experimental time. The still comprises a distillation flask, a reflux condenser and condensate return. The detail description has been reported in that paper. In this research, the all seal glass recirculating still with two magnetic homogenizers was used. The still was slightly modified by providing a magnetic stirrer in condensate and liquid sections. Also, the vacuum was performed by a vacuum pump before any experiments and then the atmospheric pressure was applied. Thermocouple model was Pt 100 and the digital temperature detector within ±0.1 K accuracy was used. The schematic procedure of experiments is shown in Fig. 1.

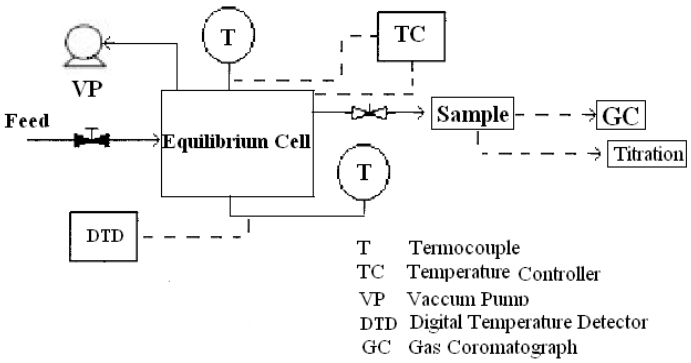

Fig. 1. Schematic procedure of vapor-liquid equilibrium measurement

2.3. Sample analysis

At steady state condition the samples were taken. Only the vapor (condensate) sample need be analyzed. Incidentally this method also possesses the advantages of producing experimental data rapidly and of giving liquid composition on a single phase directly. Analysis of samples was carried out by gas chromatography (GC) on a Varian coupled with a personal computer by use of relative program. The GC apparatus equipped with 2m×1/4in column packed with Propack Q. Helium was used as a carrier gas. Two different detectors were used to analyze the amounts of components in this work. Flame ionization detector (FID) was applied to obtain the concentration of isooctane and thermal conductivity detector (TCD) was chosen to detect the water content. The temperatures of the injector and detector were maintained at 300 ^{o}C, the column temperature was controlled by programming the temperature. The concentration of TEG was determined using titration method. This method contains the acetylation of hydroxyl group by acetic anhydride with perchloric acid (Fritz and Schenk, 1959). Liquid compositions throughout the experiment are calculated by overall material balance based on that of initial mixture.

3. Correlation

The liquid-phase activity coefficients of the components in the mixtures were calculated from UNIQUAC (Abrams and Prausnitz, 1975) and NRTL (Renon and Prausnitz, 1968) equations. The general equation of the activity coefficient for component *i* in a mixture with *n* components is given by Abrams and Prausnitz (1975):

$$\ln \gamma_i = \ln \frac{\varphi_i}{x_i} + \frac{z}{2} q_i \ln \frac{\theta_i}{\phi_i} + l_i - \frac{\varphi_i}{x_i} \sum_j x_j l_j - q_i \ln \left[\sum_j \theta_j \tau_{ji} \right] \quad (1)$$

$$+ q_i - q_i \sum_j \frac{\theta_j \tau_{ij}}{\sum_k \theta_k \tau_{kj}}$$

$$\tau_{ij} = \exp(A_{ij} / T) \quad (2)$$

NRTL equation was also applied on liquid phase for calculation of activity coefficients. The activity coefficients are calculated from the NRTL model as follows:

$$\ln \gamma_i = \frac{\sum_j x_j \tau_{ji} G_{ji}}{\sum_k x_k G_{ki}} + \sum_j \frac{x_j G_{ij}}{\sum_k x_k G_{kj}} \left(\tau_{ij} - \frac{\sum_k x_k \tau_{kj} G_{kj}}{\sum_k x_k G_{kj}} \right) \quad (3)$$

$$G_{ij} = \exp(-\alpha_{ij} \tau_{ij}) \quad (4)$$

$$\tau_{ij} = \frac{A_{ij}}{T}$$

4. Results

Experimental data for system water and TEG is presented in Table 2. Since there is a high difference between the boiling points of TEG and water, the amount of water in the vapor phase was very small. Fig. 2 depicts *y-x* diagram of water in water-TEG solution. Also, the experimental vapor-liquid data for ternary system containing water, TEG, and isooctane is given by Table 3. From this table, the volatility of water increases in the presence of isooctane. Also the equilibrium temperature declines while isooctane is added to the mixture.

The relative volatility of water rather than TEG is shown in Fig. 3(a). In this figure, it is observed that the relative volatility increases by addition of isooctane and also Fig. 3(b) shows the temperature declines by addition of isooctane and water volatility increases with decreasing temperature.

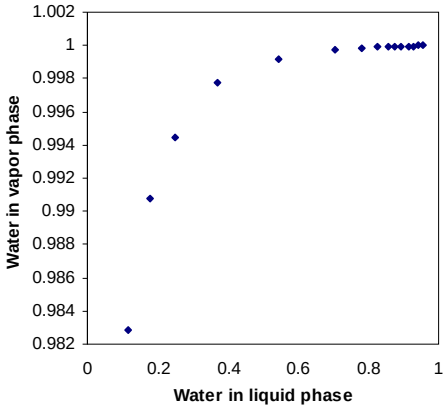

Fig 2 *x-y* diagram for water in water-TEG solution at P=638 mmHg

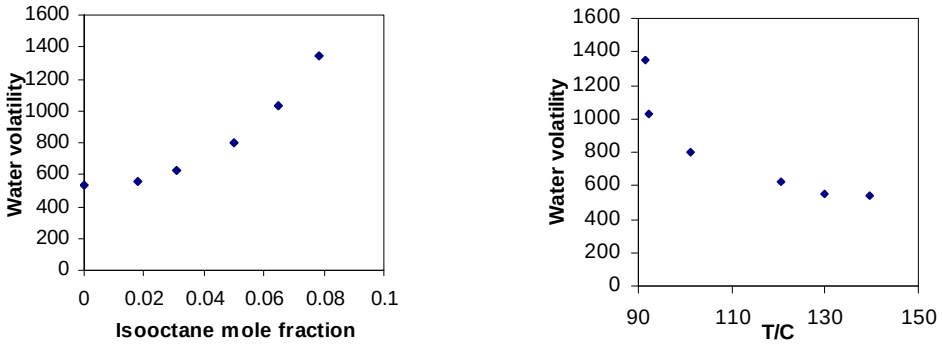

(a) (b)

Fig. 3 Relative volatility of water in water-TEG solution with addition of isooctane, (a) as a function of Isooctane mole fraction, (b) as a function of temperature

The experimental data of the water-TEG and water-TEG- -isooctane systems were correlated using UNIQUAC and NRTL equations. Estimation of the binary interactions of these models was based on minimization of the objective function O*F* in terms of calculated and experimental activity coefficient values. The function O*F* used in this work can be expressed as:

$$OF = Min\sum_{i=1}^{n}\sum_{j=1}^{m}\left(\gamma_{\exp} - \gamma_{cal}\right)^2 \tag{5}$$

where γ_{exp} and γ_{cal} are the experimental and calculated activity coefficients, respectively. The subscripts *i, j* denote the component and data, respectively. The binary interaction parameters in UNIQUAC and NRTL equations between TEG-water and TEG-water-isooctane are listed in Table 4. Good agreements are observed between model results and experimental data.

Table 4 Binary interaction parameters between water (1)-isooctane (2)-TEG (3)

	Interaction Parameters (UNIQUAC)		Interaction Parameters (NRTL)		
Water+TEG					
Water-TEG	A_{13}=-428.627	A_{31}=331.663	A_{13}=248.949	A_{31}=-172.965	α_{13}=2.366
Water+TEG+Isooctane					
Water- Isooctane	A_{12}=-647.140	A_{21}=-464.858	A_{12}=-72.078	A_{21}=314.051	α_{12}=-2.060
Water-TEG	A_{13}=-99.311	A_{31}=151.290	A_{13}=-155.068	A_{31}=-67.819	α_{13}=-4.103
Isooctane-TEG	A_{23}=-608.41	A_{32}=52.198	A_{23}=1081.279	A_{32}=1181.917	α_{23}=0.501

Root mean square deviation (RMSD) in activity coefficients are shown in Table 5. The errors are acceptable for applying theses correlations.

Table 5 Root mean square deviation[1] (RMSD)

Comp in the mix	NRTL	UNIQUAC
Water	0.037	0.027
TEG	0.013	0.001
Isooctane	0.101	0.033

1- $RMSD = \left\{\sum_i^n \left\{\gamma_i^{\exp} - \gamma_i^{calc}\right\}^2 / n\right\}^{0.5}$

5. Conclusions

Isobaric vapor-liquid equilibria of water-triethylene glycol (TEG) and the effect of isooctane on this solution have been investigated experimentally. The experimental data of the binary (water+TEG) and ternary systems (water+TEG+isooctane) were tuned using UNIQUAC and NRTL activity coefficients models. Good agreements were obtained. The results demonstrate the volatility of water increases in water-triethylene glycol solution by the addition of isooctane and decreasing equilibrium temperature. By use of this approach, the separation of TEG and water is done with higher performance in a stripping column of natural gas dehydration unit.

Keywords: Monte Carlo, Alkanes, Xenon, Vapour-liquid equilibria, Force field
Topic: Advancing the chemical and biological engineering fundamentals (thermodynamics)

Abstract

Although TraPPE-UA is able to predict vapour-liquid coexistence curves and vaporization enthalpies for many linear alkanes at wide temperature ranges, this is not so for vapour pressures of the shortest alkanes at low temperatures. In view of this fact, we did an optimization of non-bonded parameters of typical units of TraPPE force field so that experimental and calculated liquid density and vapour pressure match for ethane and propane. Using the new optimized parameters, vapour pressures and orthobaric liquid densities of butane at low to moderately high temperatures were calculated by Monte Carlo (Gibbs ensemble) simulation as well as vapour-liquid diagrams for systems xenon+ethane, xenon+propane and xenon+butane at cryogenic temperatures. The calculation results presented excellent agreement with experimental ones and the optimized parameter sets proved to be transferable.

1. Introduction

Our research team has dedicated a lot of work on thermodynamic properties of liquid mixtures involving noble gases (in particular, xenon) and the lightest alkanes (except methane). As stated elsewhere, xenon, being a structureless spherical particle, is an ideal component to use as reference when the liquid structure and intermolecular interactions of the other component of a binary mixture has to be assessed. Linear alkanes constitute a chemical family whose thermodynamic properties usually presents pronounced regularities, varying gradually with the number of carbon atoms in the molecule. This fact implies that it is possible to predict, with reasonable accuracy, one given thermodynamic property for a specific alkane based on values for the same property (at corresponding conditions) previously obtained for other alkanes by simple extrapolation. This behaviour extends also to mixtures of alkanes by applying theoretical or phenomenological approaches such as segment theories (Blas, 2000) or congruence principle (Weiguo *et al.*, 1990). Despite the effort that has been made to integrate the thermodynamic behaviour of all the akanes under the same united scheme, the lightest alkanes hardly follow some of the regularities encountered among the longer ones, probably due to the absence of a fully developed angle-type molecular structure.

Among the force fields that have been proposed recently, TraPPE-UA was one of the most successfully in describing the vapour-liquid equilibria of hydrocarbons, while keeping a simple form which allow the calculations to be made with low computational cost. TraPPE-UA was able to predict the vapour-liquid coexistence curves from methane do dodecane, but failed to reproduce the vapour pressure curves for the lightest alkanes, in particular at low temperatures (Martin and Siepmann, 1998).

We have recently reported Monte Carlo computer simulations of excess enthalpies and excess volumes for the binary systems of xenon with ethane, propane and butane at low

temperatures (Carvalho *et al.*, 2007). Simulation results presented an excellent agreement with experimental ones for xenon+ethane, whereas for the remaining systems, some deviations were observed, which became progressively more significant as the alkane chain length increased. For these systems it is also important to obtain VLE simulation results. In the paper aforesaid, the TraPPE-UA force field was chosen to model all the alkanes studied because, among other tested force fields, was the one that was found to give the best agreement between calculated and experimental liquid density of pure components. However, TraPPE-UA was unable to predict vapour pressures of the lightest alkanes at cryogenic temperatures, which prevents the prediction of VLE of mixtures involving such components. On the other hand, the Lennard-Jones potential from Bohn *et al*. (1985) didn't give the best prediction of the vapour pressure curve of xenon. For this reason, we did a reparameterization of both force fields in order to match the results of Gibbs ensemble simulations of vapour-liquid equilibrium to experimental data specifically for the lightest alkanes and xenon at temperatures between 150 K and 350 K. In the case of alkanes, we found that there is no a unique set of non-bonded (Lennard-Jones) parameters that can predict the entire vapour pressure curve as a function of temperature. Two sets of parameters for each alkane were obtained, one for low temperatures and the other for not too low or higher temperatures. With these sets of parameters, a better prediction of vapour-liquid equilibrium for systems involving xenon and the alkanes ethane, propane and butane has been accomplished.

2. Simulation Details

The computer simulations both for pure liquids and liquid mixtures were done by Monte Carlo method, using MCCCS Towhee Monte Carlo molecular simulation package, version 5.2.12. We start the calculation by the optimization of the non-bonded Lennard-Jones parameters of both used force fields. For xenon, the optimization of ε and σ, was done simultaneously, by trial and error, in order to obtain the best fit of orthobaric liquid densities and vapour pressure as a function of temperature in the range 160-200 K, using the Bohn *et al.* potential as a starting point. In the case of short alkanes studied, a stepwise procedure was attempted. Starting from TraPPE-UA force field and keeping its structure and all of its intramolecular parameters, a trial and error optimization of the CH_3 Lennard-Jones parameters was done by trying to fit orthobaric liquid density and vapour pressure curves for ethane. Since, as stated above, no unique set of non-bonded parameters was obtained, the ethane liquid range was divided in two portions: 150-200 K and 205-305 K. For each one, the optimization was possible and a set of parameters was found that fit orthobaric liquid density and vapour pressure curves for ethane. Then, following TraPPE philosophy, the transferability of CH_3 was assumed and the Lennard-Jones parameters for CH_2 were also optimized by the same trial and error procedure, matching simulation and experimental results for orthobaric liquid densities and vapour pressures of propane. As for ethane, two sets of non-bonded parameters were obtained, one for each temperature range considered, 160-210 K and 215-350 K. The optimized parameters were then used to predict the vapour pressure and orthobaric liquid density curves for pure butane and vapour pressures of xenon+ethane, xenon+propane and xenon+butane mixtures for a series of predefined total compositions at temperatures for which experimental results exist.

The computer simulations were carried out in the *NVT* Gibbs ensemble. For pure components, each simulation consisted of a total of 500 molecules, distributed to each cubic simulation box so that the "liquid" box have side lengths of about 30-40 Å. The simulations were done in large temperature ranges at intervals of 5 or 10 K. Mixtures were "prepared" by varying the proportions of molecules of each component, being the total number of molecules between 500 and 1000 molecules, observing the same criteria as above to fill the simulation boxes. The simulations were carried out at temperatures for which experimental results exist to allow comparison between simulation and experience.

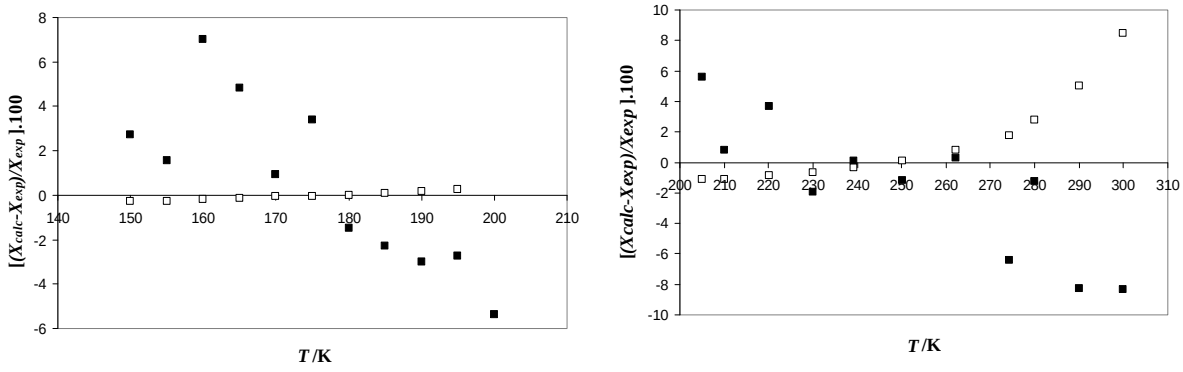
In each simulation, a preliminary equilibration run of between 20 000 and 50 000 steps (in which each step is in fact a MC cycle, consisting of an amount of moves equal to the number of molecules in the system) was done, followed by a production run for the calculation of averages, consisting of another 100000 to 200000 steps, which were divided into 20 blocks in order to estimate errors. The Monte Carlo moves consisted simulation box volume exchanges, coupled-decoupled configurational-bias regrowths, translations and of the centre of mass, rotations about the centre of mass, configurational-bias molecule reinsertions in the same simulation box and aggregation volume-bias and configurational-bias molecules exchanges between boxes.

3. Results and Discussion

In table 1 the non-bonded parameters for CH_3 and CH_2 obtained from trial and error optimization are presented. For comparison, the original TraPPE-UA parameters are also shown. The fitting results for ethane and propane at low and high temperatures are shown in figures 1 and 2. Those are the best fittings that it was possible for each temperature range with just one set of parameters per range per compound. For xenon, ε/k_B = 226.3 K and σ = 3.948 Å were found.

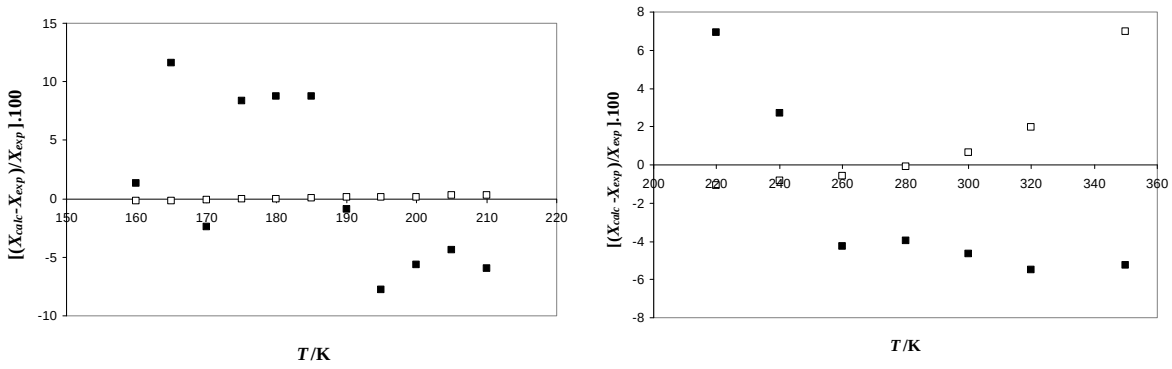
Table 1. Optimized TraPPE-UA non-bonded parameters for two sets considered and comparison with the corresponding original parameters

	"Low temperature"		"High temperature"		Original TraPPE-UA	
unit	ε/k_B [K]	σ [Å]	ε/k_B [K]	σ [Å]	ε/k_B [K]	σ [Å]
CH_3	102.2	3.773	100.75	3.787	98	3.75
CH_2	48.55	4.01	47.2	4.03	46	3.95



a) b)

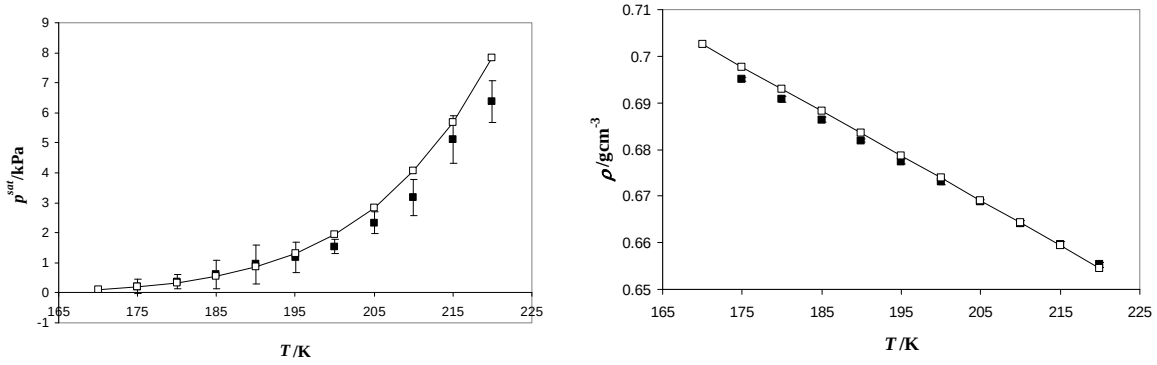
Figure 1. Relative deviations between calculated and experimental values of saturated liquid densities (empty squares) and vapour pressures (filled squares) for ethane with low [a)] and high [b)] temperature sets.



a) b)

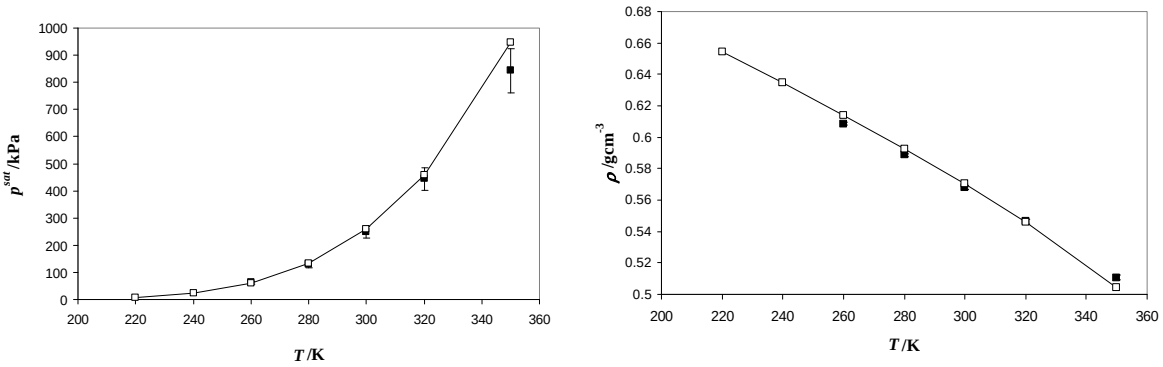
Figure 2. Relative deviations between calculated and experimental values of saturated liquid densities (empty squares) and vapour pressures (filled squares) for propane with low [a)] and high [b)] temperature sets.

Using both sets of parameters for each unit, vapour pressure and orthobaric liquid density of pure butane were obtained by simulation and presented in figures 3 and 4. The agreement is very good, except in the high temperature region of "low temperature" set, where the calculations probably were extended outside the temperature range of the fitting procedure. The results show that the parameters so obtained are reasonably transferable.



a) b)

Figure 3. Vapour pressures [a)] saturated liquid densities [b)] as a function of temperature for butane in the low temperature parameter set. Filled squares: simulation results; empty squares: experimental results (NIST).



a) b)

Figure 4. Vapour pressures [a)] saturated liquid densities [b)] as a function of temperature for butane in the high temperature parameter set. Filled squares: simulation results; empty squares: experimental results (NIST).

Finally, as the main goal of this work, vapour-liquid phase diagrams of binary systems of xenon with ethane, propane and butane were calculated at two (fixed) temperatures, for which experimental results have already been reported. In figure 5 phase diagrams of

xenon+ethane system at temperatures between 161.40 K and 230.05 K are shown. The vapour-liquid equilibria of xenon+propane and xenon+butane are presented, respectively, in figures 7 and 8. For all the cases, the agreement between simulation and experiment is excellent, the experimental results lying within the error bars of the simulation results. The new TraPPE-UA parameters can predict phase diagrams of mixtures involving xenon and light alkanes by computer simulation without any fit to mixture properties.

3. Conclusions

We have optimized the non-bonded parameters from TraPPE-UA force field for alkanes by matching Monte Carlo simulations and experimental orthobaric liquid densities and vapour pressures for ethane and propane (for CH_3 and CH_2 parameters). We also optimize the Bohn *et al.* potential for xenon at low temperatures. The parameters proved to be transferable to butane and, with them, we were able to predict vapour-liquid phase diagrams of binary systems involving the alkanes from ethane to butane and xenon.

Keywords: Capillary viscosimetry, Concentration, Temperature, Modeling.
Topic: Rheology.

Abstract

Kinematic viscosity of ternary aqueous solutions of ethanol and glycerol were determined at several temperatures (from 20 up to 45 ºC) and different molar fractions of component (up to 0.75 of ethanol and 0.60 of glycerol) covering a wide range of experimental conditions. A capillary viscosimeter was employed as equipment.

Experimental data of kinematic viscosity showed non-ideal behaviour and were modelled employing previous proposed correlations for aqueous ethanol solutions modified with an additional exponential term where is taken into account the influence the presence of glycerol. The final model reproduces the experimental data of kinematic viscosity of ternary solutions of glycerol, ethanol and water with deviations less than 6% in the range of concentrations and temperatures tested.

1. Introduction

Viscosity is an important transport property for equipments design and for evaluation of operational costs. Glycerol is very employed in the pharmaceutical and food industries because is nontoxic and can be considered as good solvent for organic and inorganic compounds. Aqueous solutions of glycerol with presence of alcohols are also frequently found in several industrial processes. Nowadays, these systems have also specially importance in the production of biofuels from vegetal oils and ethanol where glycerol is a by-product (Ito et al., 2005).

Several approaches with theoretical or semi-theoretical bases have been proposed in the literature for estimating viscosity of pure (electrolytic and non-electrolytic) liquids, but well understood theories have not been developed (Poling et al., 2001; Viswanath et al., 2007). The estimation of viscosity of mixture fluids can usually carried out by extension of pure component methods by semi-theoretical methods or by application of mixing rules to experimental data or values calculated by means of a model for pure component. There are a lot of proposed equations for systems with specific chemical properties (Viswanath et al., 2007).

One of the aims of this work is to determine experimentally the kinematic viscosity of glycerol/ethanol/water ternary solutions. Viscosity of the corresponding ethanol/water and glycerol/water binary solutions are already studied in wide range of temperatures and concentrations. High non-ideal behaviour of kinematic viscosity of binary ethanol-water solutions was reported (Pemberton et al., 1978) with maximum values of kinematic viscosity varying with concentration and temperature. In this way, the maximum was determined at 0.25 ethanol molar fraction at 293.1 K and at 0.35 at 318.1 K (Moreira et al., 2007). These last authors modelled the kinematic viscosity employing Redlich-Kister equation (Redlich and

* Corresponding author. Tel + 34-981-563100. E-mail:eqmoncho@usc.es

Kister, 1948) for the concentration effect and, for the dependence on temperature, empirical Vogel-Fulcher-Tamman (Cocchi et al., 1999) relation was selected. The model is given by:

$$\upsilon_{eth/water} = x\upsilon_{eth} + (1-x)\upsilon_{water} + x(1-x)\left[\exp\left(\frac{3255}{T} - 9.41\right) + \exp\left(\frac{-3917}{T} + 11.44\right)(1-2x) + \exp\left(\frac{5113}{T} - 16.06\right)(1-2x)^2\right] \quad (1)$$

where $\nu_{eth/water}$ (m^2/s) is the kinematic viscosity of ethanol/water binary solutions, x is the molar fraction of ethanol, T (K) the absolute temperature, ν_{eth} and ν_{water} (m^2/s) are the kinematic viscosity of pure ethanol and water, respectively.

Aqueous glycerol solutions were also studied in different ranges of temperatures and concentrations (Chenlo et al., 2004; Cheng, 2008). These solutions show a strong dependency of kinematic viscosity on glycerol concentration at high glycerol concentrations. In general, viscosity modelling is carried out by means of exponential relationships with temperature and concentration as variables.

2. Materials and Methods

The solutions were prepared by weight, with a Mettler AJ150 balance with a precision of ± 0.0001 g using degassed distilled water, commercial ethanol (Panreac, 96% v/v) and glycerol (Merck > 99%).

Kinematic viscosities were determined by using a Schott-Gerate AVS 350 automatic Ubbelohde viscosimeter with the procedure previously described (Vázquez et al., 1994). All measurements were made at least in five replicates. Temperature control was assured by inserting the capillary viscosimeter into a water thermostatic bath with a Selecta Digiterm heating system (precision of ± 0.1ºC). The temperature was varied from 20 ºC up to 45 ºC by steps of 5 ºC. Upper temperature was limited by the presence of ethanol. The uncertainty in the measurements was within $\pm 10^{-9}$ m^2/s and capillaries were periodically calibrated by determination of tri-distilled water at several temperatures.

In terms of concentration, the ternary system was generated from ethanol/water binary solutions with concentrations ranged from 0.05 up to 0.75 molar fraction adding different amounts of glycerol in order to obtain 0.05, 0.1, 0.2, 0.3, 0.45, and 0.60 molar fraction of this component. In this way, ternary mixtures were created maintaining the ethanol/water ratio constant. Table 1 shows the initial binary solutions of ethanol and water and the corresponding ethanol/water averaged ratios and standard deviation of ternary solutions with glycerol.

Table 1. Initial ethanol/water solutions and experimental ethanol/water ratios of ternary solutions.

Molar fraction of ethanol of aqueous solutions	Water/ethanol ratio in ethanol/glycerol/water solutions
0.05	19.245 ± 0.290
0.15	5.746 ± 0.096
0.25	3.048 ± 0.058
0.35	1.891± 0.041
0.45	1.249 ± 0.032
0.60	0.687 ± 0.024
0.75	0.349 ± 0.019

Statistical analysis of experimental data, non-linear fittings and parametric optimization, were carried out using the program TableCurve 3D®.

3. Results and discussion

Figure 1 shows the changes of kinematic viscosity of glycerol/ethanol/water mixtures at a fixed molar fraction of glycerol. At low molar fraction of glycerol, at all assayed temperatures, a maximum value of kinematic viscosity can be observed around 0.23 molar fraction of ethanol (Fig. 1a). This maximum value of viscosity is also presented at higher concentrations of glycerol, but at lower concentrations of ethanol and the curves are more smoothed. In fact, at the highest glycerol concentration tested in this work (0.6 molar fraction, Fig. 1b), the maximum value is around 0.06 molar fraction of ethanol and viscosity values of solutions from this concentration up to 0.14 molar fraction of ethanol are closed. On the other hand, as it was expected, the kinematic viscosity of ternary solutions decreases with temperature and increases with glycerol concentration in all mixtures.

These results indicate that the presence of glycerol at high concentrations moves the typical maximum of aqueous solutions of ethanol towards lower ethanol concentrations because in the limit case of aqueous solutions of glycerol (ethanol concentration equal to zero) there is not a maximum value at intermedeate concentrations (Weast, 1983). Different molecular interactions associations between the components can explain these results that reveal strong deviations from the ideal behaviour.

Taking into account the previous comments and the non-ideal behaviour of the systems, the modelling of kinematic viscosity of the ternary systems can not be simple as mixing rule models, and interactions must be included.

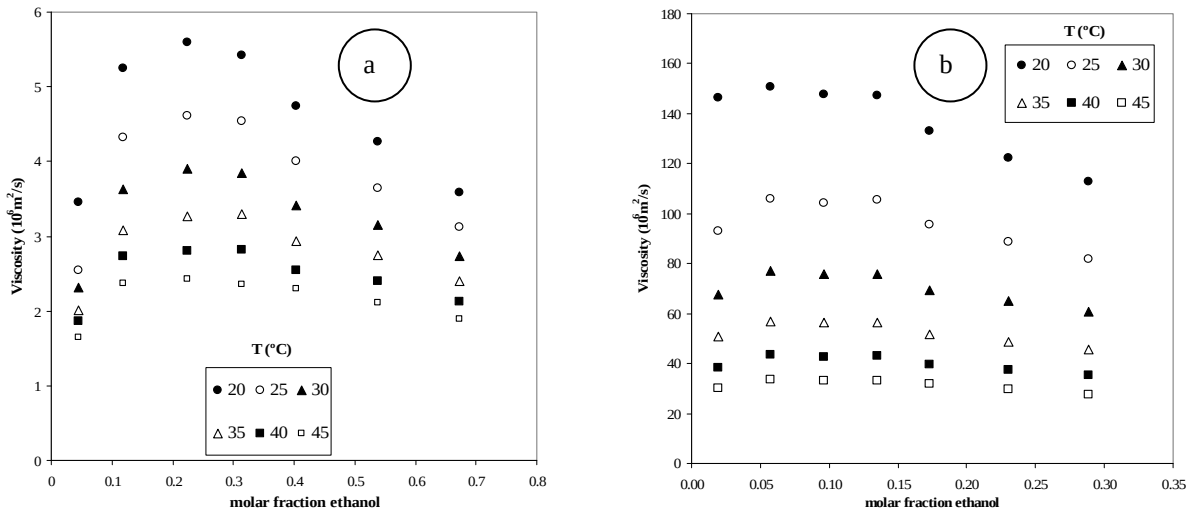

Fig. 1. Kinematic viscosity of glycerol/ethanol/water mixtures at a fixed molar fraction of glycerol: a) 0.1 and b) 0.6.

The modelling of kinematic viscosities, ν (m^2/s), corresponding to the ternary solutions was carried out applied the following equation which is a modification from the originally proposed by Torok et al., (1993):

$$\nu = \nu_{eth/water} + a\left[\exp(bx_{gly}) - 1\right] \quad (2)$$

where $\nu_{eth/water}$ (m^2/s) is given by the Eq. (1), x_{gly} is the molar fraction of glycerol in ternary solution, a (m^2/s) and b are parameters of fitting.

Parameter *a* was correlated by means of non-linear fittings simultaneously to *T* and *x* (ethanol concentration corresponding to binary system after removal glycerol), obtaining the following expression:

$$a = 1.39 + 5.64\left[\exp(-T/62.03)\right] + \left[3.56 - \frac{89.18}{T^{1.5}}\right] x - 8.80\,x^2 + 5.91\,x^3 \qquad (3)$$

Parameter *b* showed only dependence on temperature according to:

$$b = 4.11 + 5.54\left[\exp(-T/25.03)\right] \qquad (4)$$

Figure 2 shows experimental data of kinematic viscosity of ternary solutions at two different water/glycerol ratios, as examples. One more time, it can be observed as viscosity increases with glycerol concentration at a fixed water/ethanol ratio and the strong influence of temperature on viscosity. Comparing Figs 2a and 2b it can be also observed kinematic viscosity values decrease when ethanol concentration increases (lower values of water/ethanol ratio). In Figs. 2a and 2b are also plotted the proposed model, involving the Eqs 1 to 4, and a good agreement between experimental data and predicted values can be observed.

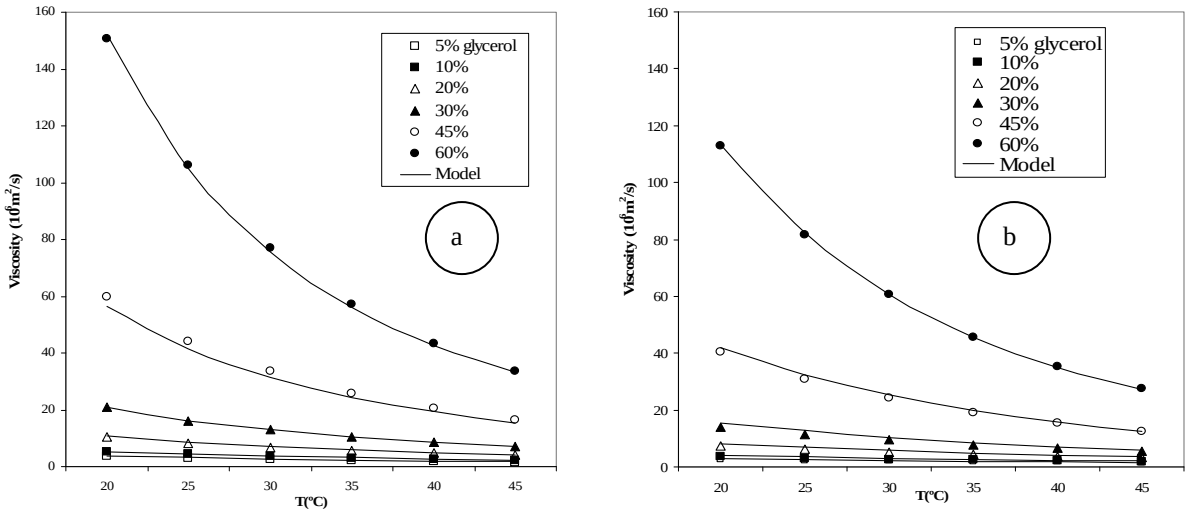

Fig. 2. Experimental data (dots) and modelled values (lines) by means of Eqs (1 to 4) of glycerol/ethanol/water mixtures at fixed ethanol/water ratios: a) 5.746 and b) 0.349.

Using the model is possible to reproduce successfully the kinematic viscosity of ternary solutions of glycerol, ethanol and water in the range of concentrations and temperatures tested with deviations less than 6%. Fig. 3 shows the good agreement between the experimental data and calculated values for all tested conditions of concentration and temperature.

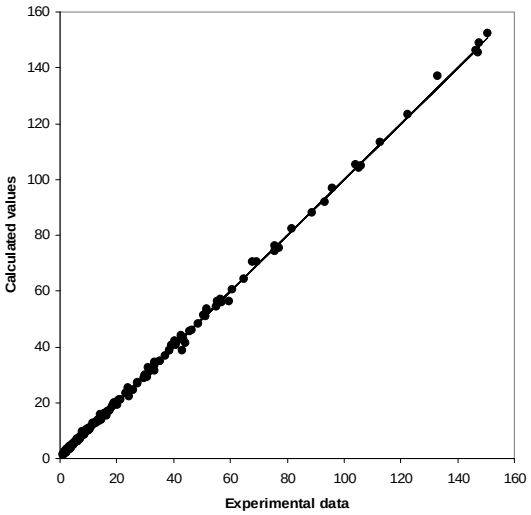

Fig. 3. Calculated kinematic viscosities (10^6 m^2/s) in comparison with experimental data.

4. Conclusions

Kinematic viscosity for Newtonian ternary systems, consisting in a mixture of ethanol, glycerol, and water was determined using a capillary viscosimeter showing a strongly non-ideal behaviour due to typical water/ethanol interactions. In this way, maximum values of kinematic viscosity was detected at determined ethanol concentration and being modified by the presence of glycerol in the ternary system. Higher glycerol concentrations increases kinematic viscosity values. In all cases, as it was expected, temperature decreases the kinematic viscosity.

In spite of the commented behaviour, a model to correlate the kinematic viscosity with temperature and component concentration is proposed and satisfactorily tested by statistical analysis.

Topic: Advancing the chemical and biological engineering fundamentals.

Abstract

The main goal of this study is to determine Aqueous Biphasic Systems (ABS) phase diagrams at 298.15 K to evaluate the salting-in *versus* salting-out strength of ionic liquids (ILs) ions. The separation of both aqueous phases was achieved between the inorganic salt K_3PO_4 and hydrophilic ILs addition. The selected ILs combination allowed the study of the cation alkyl chain length and the type of functional groups at the cation impact in their water-structuring ability. The coexistence curves were determined using an empirical mathematical description from relationships from volume and density data collected for each aqueous phase (Merchuk et al.,1998).

1. Introduction

The efficiency of any fermentation process depends largely on downstream processing which ensures the purity and quality of the biochemicals and represents about 60-90 % of the cost of the biological processes (Kula et al., 1982). Nevertheless, many biomolecules have narrow tolerance limits of pH, temperature, osmotic pressure and surface charges, and the extraction and isolation techniques should be specific and compatible to the product (Banik et al. 2003). The conventional techniques used for product recovery, are not only expensive but also result in lower yields. Keeping this problem in mind, the industrial community has carrying a large effort in the use of cost-effective ecofriendly simple separation techniques: the aqueous biphasic systems (ABS). These systems consist in two mutually incompatible solutes such as polymers/polymer, polymer/salt or salt/salt dissolved in water. Above critical concentrations of these components the spontaneous phase separation takes place.
Environmental concerns about volatile organic compounds have increased in the last few years and there is a growing interest nowadays in finding ‘‘greener’’ replacement solvents for extractions and liquid-liquid separations. In this context, ionic liquids (ILs) have aroused as a new class of organic solvents with high potential as “green” solvents. It is essentially their specific characteristic of negligible vapor pressure (Freemantle, 1998; Anderson et al., 2002) that make of them suitable “green” candidates for a large range of applications.
The first publication of ABS with ILs was reported by Rogers and his co-workers (Gutowski et al., 2003). In this paper, the authors have demonstrated that the addition of K_3PO_4 to an aqueous solution of an hydrophilic IL produces a salting-out effect and promotes the separation of phases. On the other hand, the extraction of different organic compounds by ILs was reported by a larger number of authors. Li and his co- workers (He et al., 2005; Li et al., 2005) have studied the extraction of biochemical compounds and drugs such as, testosterone, epitestosterone and opium alkaloids. The extraction of metals ions (Dietz, et al., 2003), and organic molecules, such as penicillin (Liu, et al., 2006), antibiotics (Cull et al.,

* Corresponding author.Tel +351-234-370200. E-mail: jcoutinho@ua.pt

2000), alcohols (Fadeev et al., 2001) and acids (Matsumoto et al., 2004) were also described in literature. Nevertheless, there are still many gaps in what concerns the IL impact in promoting ABS.
The main goal of this study is to determine the impact of different characteristics of the IL cation, such as the presence of a long or short alkyl chain length, the presence of a double bond or an hydroxyl group in generating ABS. The results show that the cation structural differences have an important influence in the binodal curves behavior and in the formation of ABS. The cation alkyl chain length increase decrease the IL affinity for water and this facilitates the phases separation. In general, ILs with a smaller solubility in water have a higher ability to promote a salting-out effect, resulting in a binodal curve closest to the origin and indicating that less inorganic salt is needed to form the ABS.
The present work shows different phase diagrams (binodal curves and tie-lines) for selected systems of hydrophilic ILs + K_3PO_4 + water. The binodal curves were fitted to a three-parameter equation and the tie-lines are determined for a mathematical method well described by Merchuck et al. (Merchuk et al.,1998).

2. Materials and Methods

The K_3PO_4 (purity level > 98 %) was from Sigma-Aldrich. The ILs 1,3-dimethylimidazolium chloride, [C_1mim]Cl, with a purity level > 98 %, 1-ethyl-3-methyl-imidaziolium chloride, [C_2mim]Cl, with a purity level > 98 %, 1-butyl-3-methyl-imidaziolium chloride, [C_4mim]Cl, with a purity level > 99 %, 1-hexyl-3-methyl-imidaziolium chloride, [C_6mim]Cl, with a purity level > 98 %, 1-allyl-3-methyl-imidaziolium chloride, [amim]Cl, with a purity level > 98 %, 1-hydroxyethyl-3-methyl-imidaziolium chloride and [hydemim]Cl, with a purity level > 99 %, were acquired at Iolitec. Prior to the experimental measurements all the ILs samples were dried under vacuum and at moderate temperature (353 K) for at least 48 h.
The liquid-liquid phase separation inducing measurements between the aqueous solutions of K_3PO_4 and ILs were carried out at atmospheric pressure and 298 K. The binodal curves were determined through the visual cloud point titration method. For each system studied (water + IL + K_3PO_4) at least one tie-line (TL) was determined by a simple gravimetric method. The TLs were determined by application of the lever arm rule to the relationship between the mass phase composition and the overall system composition (Merchuk et al.,1998).

3. Results and Discussion

The experimental binodal data obtained are shown in Figure 1.

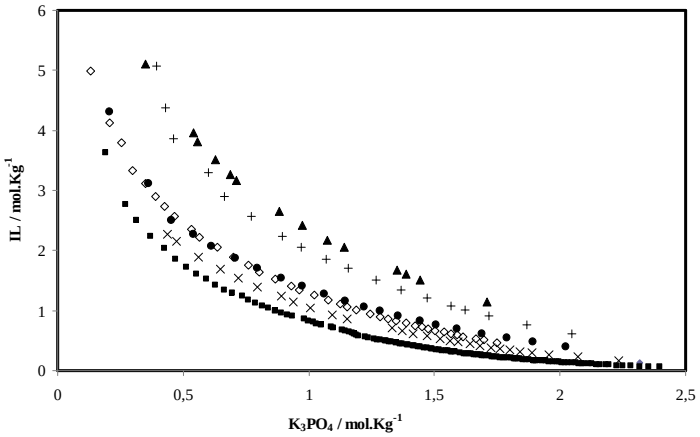

Figure 1. Experimental binodal curves for the IL and K_3PO_4 aqueous systems studied for the following ILs: ■, [C_6mim]Cl; ×, [C_4mim]Cl; ●, [C_2mim]Cl; +, [C_1mim]Cl; ◊, [amim]Cl; ▲, [hydemim]Cl.

Figure 1 presents the binodal curve for the different ILs studied. Perusal of Figure 1 indicates that the increase in the alkyl chain length of the IL cation promotes phase separation. The higher the IL alkyl chain length less inorganic salt is needed to promote ABS. On the other hand, the presence of a double bond at the alkyl chain length of the imidazolium cation or the presence of an hydroxyl group decreases the IL salting-out inducing capacity. This arises from the IL affinity for water increase (or IL hydrophilic nature increase) by the presence of double bonds or hydroxyl groups.

In general, ILs with a higher ability to promote a salting-out effect, indicate that less salt is needed to promote the phase separation, which results in a binodal curve closer to the origin and in a higher biphasic region. It can be seen from Figure 1 that the phase-forming ability of the ILs follows the order: [C_6mim]Cl > [C_4mim]Cl > [C_2mim]Cl > [amim]Cl > [C_1mim]Cl > [hydemim]Cl.

Tie-lines for these cloud point curves were fitted by a least-squares method. Figures 2 and 3 present two examples of a complete phase diagram for [C_2mim]Cl and [C_6mim]Cl + K_3PO_4 + H_2O systems, respectively.

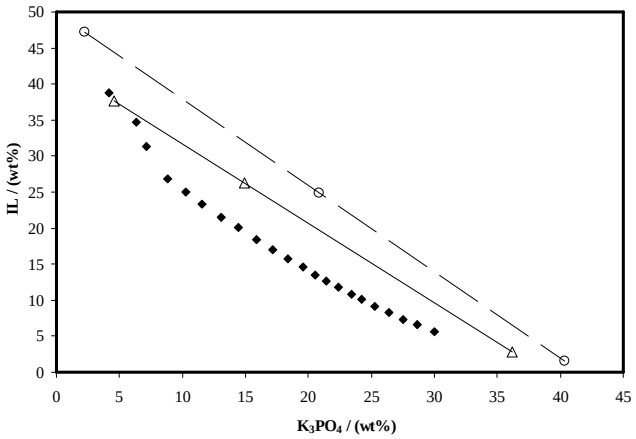

Figure 2. Experimental coexistence binodal curve (♦) for the aqueous systems [C_2mim]Cl + K_3PO_4 and respective tie-lines.

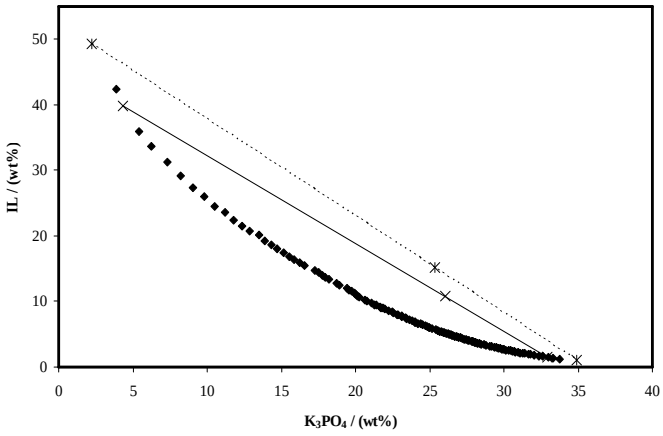

Figure 3. Experimental coexistence binodal curve (♦) for the aqueous systems [C_6mim]Cl + K_3PO_4 and respective tie-lines.

A phase diagram provides information about the concentration of phase-forming components required to form two aqueous phases, the concentration of the phase components at the top and bottom phases (given by the tie-lines) and finally, information about the ratio of the phase volumes**.**

Conclusion

The ability to form salt-salt ABS allows for hydrophilic ILs to be used in aqueous separation systems. Phase equilibrium experimental data were determined for systems involving hydrophilic ILs + K_3PO_4 + water, at atmospheric pressure and 298 K. Binodal data were fitted according to the empirical relationship of Merchuk (Merchuk et al.,1998) and the parameters for this equation were determined by a least-squares regression of the cloud point data.
The results show that aqueous biphasic systems can be obtained over a large range of concentrations both for ILs and the inorganic salt. The IL cation alkyl side chain length increase facilitates the phase separation formation. On the other hand, the inclusion of double bond or hydroxyl groups decreases the ability of phases separation. In this context, the ILs capacity for phase separation follows the order: $[C_6mim]Cl > [C_4mim]Cl > [C_2mim]Cl >$ [amim]Cl > $[C_1mim]Cl >$ [hydemim]Cl.

Abstract

In this work a systematic study of the mutual solubilites between hydrophobic ionic liquids (ILs) and water from (288.15 to 318.15) K and at atmospheric pressure was conducted for imidazolium, pyridinium and pyrrolidinium-based cations and bis(trifluoromethylsulfonyl)imide and hexafluorophosphate-based anions ILs. The main goal of this work is to determine the impact of several IL structural modifications in their liquid-liquid phase behaviour with water keeping the possibility to design a solvent for a specific application, in this case to fine-tune a particular IL with known mutual solubilities with water. Moreover, from the experimental results the ILs hydrophobic tendency, and thus their toxicity impact, was predicted. The predictive capability of COSMO-RS, a model based on unimolecular quantum chemistry calculations, was evaluated for the description of the binary systems investigated providing an acceptable agreement between the model predictions and experimental data both with the temperature dependence and the ILs structural variations.

1. Introduction

In recent years ionic liquids (ILs) have gathered special attention from the scientific community and an exponential increase of studies involving different features, properties and applications of ILs have been presented in literature. Their particular physicochemical characteristics such as high solvation ability and coordination properties, non flammability, wide liquidus range, wide electrochemical window, high thermal stability and negligible vapor pressures make of them suitable candidates for a large range of applications (Earle et al., 2006). Moreover, the possibility of controlling their polar/apolar characteristics by correctly choosing the cation and/or the anion allows them to present selective solubilities for particular components in fluid mixtures. This characteristic, coupled with their negligible vapor pressures, has transformed ILs into excellent alternatives as potential green solvents with an obviously high industrial interest.

Besides the many possible applications already reported in literature such as solvents for electrochemical applications (Seddon, 1997), recyclable alternatives to aprotic solvents or catalysts for organic or organometallic synthesis and as media for analytical chemistry (Armstrong et al., 1999), ILs are very promising solvents for separation processes where they could serve as media for clean liquid-liquid extraction or absorption processes (Bosmann et al., 2001). Nevertheless, for the extraction of organic products from chemical reactions that proceed in aqueous media and for liquid-liquid extractions from aqueous phases, ionic liquids with lower solubility in water are preferred.

While ILs cannot contribute to air pollution due to their negligible vapour pressures, they may have in fact a significant solubility in water (even the ones known as “hydrophobics”) and, as a result, this is the most likely medium through which ILs will enter and pollute the environment (Freire et al., 2007a and Freire et al., 2008a). In addition, their release to aquatic environments could cause water contamination because of their potential toxicity and limited biodegrability. The ILs toxicity is directly related and mainly controlled by their lipophilicity (Ranke et al., 2006). This kind of studies have demonstrated that the ILs toxicity is primordially determined by the cation nature and it is essentially driven by the cation alkyl side chain length (Ranke et al., 2006). Therefore, the ILs bioaccumulation is directly proportional to their hydrophobicity and thus, the knowledge of their water solubility can be a way of predicting the toxicity and bioaccumulation impact of an ionic liquid in the ecosystem.

Some contributions dealing with experimental solubilities between ILs and water have already been reported (Freire et al., 2007c). However, careful and methodical studies of the cation and anion influence in a common series and in a wide range of temperature, which thus allow the calculation of derived properties, are still scarce.

Traditional approaches to predict fluid properties or phase equilibria require an extense data bank of vapor-liquid (VLE) and liquid-liquid equilibrium (LLE) experimental measurements. COSMO-RS (Klamt and Eckert, 2000) is a predictive method based on unimolecular quantum chemical calculations of the individual molecules, which has already proved to be a promising approach to model phase equilibria for ionic liquids (Freire et al., 2007d and Freire et al., 2008b). The performance of this predictive method is here analyzed in the prediction of the water-IL binary systems which have also been experimentally measured.

2. Materials and Methods

The ILs 1-alkyl-3-methylimidazolium bis(trifluoromethylsulfonyl)imide (with the alkyl group ranging from methyl to octyl), $[C_n mim][Tf_2N]$, 1-butyl-3-methylimidazolium hexafluorophosphate, $[C_4 mim][PF_6]$, 3-methyl-1-propylpyridinium bis(trifluoromethylsulfonyl)imide, $[C_3 mpy][Tf_2N]$ and 1-methyl-1-propylpyrrolidinium bis(trifluoromethylsulfonyl)imide, $[C_3 mpyr][Tf_2N]$, were acquired at IoLiTec with purity levels > 99 % for all samples. In order to improve the ILs purity level and reduce the water content and volatile compounds to negligible values, the ILs individual samples were dried under constant agitation at vacuum and moderate temperature for a minimum of 48 h. The water used for equilibration was ultra-pure water, double distilled, passed by a reverse osmosis system and further treated with a Milli-Q plus 185 water purification apparatus.

The mutual solubilities measurements were performed at temperatures from (288.15 to 318.15) K and at atmospheric pressure. The two phases were vigorously agitated and allowed to reach equilibrium for a minimum of 48 h. The vials were thermostated on an aluminum block, immersed in an isolated air bath, and capable of maintaining the temperature within ± 0.01 K by means of a PID temperature controller driven by a calibrated Pt100 (class 1/10) temperature sensor inserted into the aluminum block. In order to achieve temperatures below the room temperature, a Julabo circulator, model F25-HD, is coupled to the overall oven system allowing the passage of a thermostatized fluid flux around the aluminum block.

The solubility of water in the IL-rich phase was determined with a Metrohm 831 Karl-Fischer (KF) coulometer. IL-rich phase samples of ≈ (0.1 to 0.2) g were taken from the equilibrium vials using a glass syringe maintained in dry and warm conditions. The solubility of ILs in the water-rich phase was determined by UV-spectroscopy using a SHIMADZU UV-1700, Pharma-Spec Spectrometer. Samples of ≈ (0.3 to 1.0) g were taken from the water-rich phase by means of a glass syringe and diluted by a factor ranging from (1:50 to 1:1000) (v:v) in pure water, depending on the IL solubility under study, and in order to read values of

absorbance in an adequate range. The solubility results at each temperature were determined as the average of at least five independent measurements.

3. Results and Discussion

Figure 1 presents both the experimental and COSMO-RS predictions of the liquid-liquid phase diagram between the [C_2-C_8mim][Tf2N] ILs series and water.

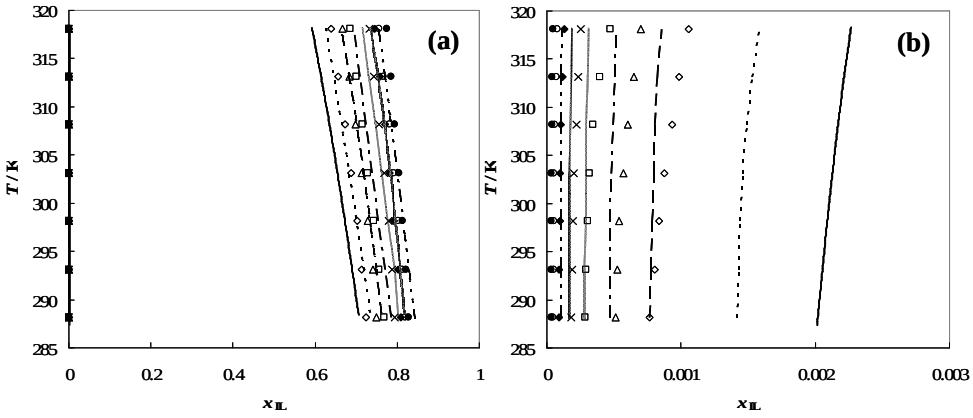

Figure 1. Complete liquid-liquid phase diagram for water and ILs (a) and water-rich phase side (b): (◊) (————) [C_2mim][Tf_2N]; (□) (- - - - - - -) [C_3mim][Tf_2N]; (□) (—— ——) [C_4mim][Tf_2N]; (×) (— - —) [C_5mim][Tf_2N]; (♦) (▪▪▪▪▪▪▪▪▪▪▪▪) [C_6mim][Tf_2N]; (○) (▪▪▪▪▪▪▪▪▪▪▪▪) [C_7mim][Tf_2N]; (●) (— - - —) [C_8mim][Tf_2N]. The single symbols and the lines represent respectively the experimental data and the COSMO-RS predictions.

It should be noted, for instance, the asymmetrical behavior of these binary systems (involving ILs and usual molecular solvents) when adopting the mole fraction basis. Experimentally, there is an increase in the IL hydrophobic nature with the alkyl chain length increase (decreasing therefore the mutual solubilities values). The results obtained from COSMO-RS calculations show an acceptable agreement with the experimental data and follow the same hydrophobic tendency, depicting the good qualitative prediction capability of this model when dealing with the alkyl chain length impact in these mutual solubilities. Nevertheless, higher relative deviations were observed at the water-rich phase, probably due to the low solubility of the studied ILs in water.

Figure 2 depicts the experimental results obtained and the COSMO-RS prediction values for the cation family impact in the mutual solubilities with water maintaining the [Tf_2N] anion in common for imidazolium, pyridinium and pyrrolidinium-based ILs.

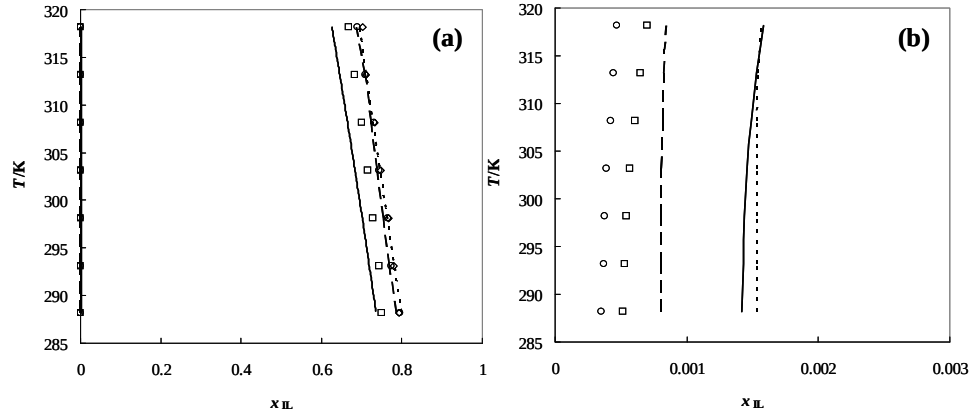

Figure 2. Complete liquid-liquid phase diagram for water and ILs (a) and water-rich phase side (b): (□) (————) [C_3mim][Tf_2N]; (○) (—— ——) [C_3py][Tf_2N]; (◊) (- - - - - - -) [C_3pyr][Tf_2N]. The single symbols and the lines represent respectively the experimental data and the COSMO-RS predictions.

The hydrophobic tendency increase derived from the cation class family follows the order: [C_3mim] < [C_3mpy] < [C_3mpyr]. The overall trend is shown to be well predicted by COSMO-RS. Besides the qualitative description, the predictions also provide a good quantitative description of the experimental data. For the water-rich phase the predictive hydrophobic tendency is also well described.

Figure 3 shows the comparison between the experimental data and COSMO-RS predictions for the liquid-liquid phase behaviour of the [C_4mim] cation in combination with the anions [PF_6] and [Tf_2N].

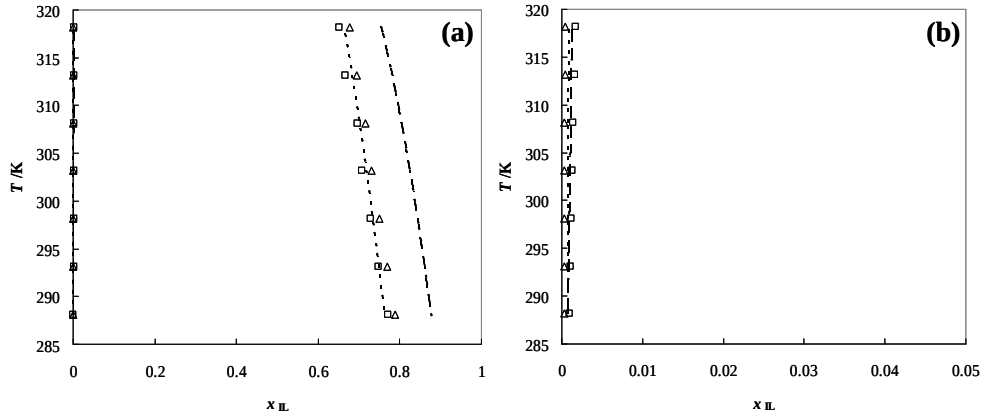

Figure 3. Complete liquid-liquid phase diagram for water and ILs (a) and water-rich phase side (b): (□) (—— ——) [C_4mim][PF_6]; (Δ) (- - - - - - -) [C_4mim][Tf_2N]. The single symbols and the lines represent respectively the experimental data and the COSMO-RS predictions.

The solubility of ILs and water decreases from the [PF_6] to the [Tf_2N] anion. At the water-rich phase, COSMO-RS proved to predict the increase in the IL hydrophobicity nature due to the anion identity following the experimental mutual solubilities results. However, in the IL-rich phase the hydrophobic tendency between [PF_6] and [Tf_2N] is not well described when compared to the experimental data. COSMO-RS predicts a higher solubility of water in [C_4mim][Tf_2N] than in [C_4mim][PF_6]. Clearly the phase behavior is the result of several competing interactions in the solution and all types of interactions should be considered.

4. Conclusions

Experimental data for mutual solubilities between water and hydrophobic imidazolium, pyridinium and pyrrolidinium-based cations in combination with bis(trifluoromethylsulfonyl)imide and hexafluorophosphate anions in the temperature range between (288.15 and 318.15) K and at atmospheric pressure were presented. The hydrophobic tendency of the cation family increases from imidazolium to pyridinium to pyrrolidinium-based ILs and with the alkyl chain length increase within the same cation family. On the other hand, the anion hydrophobic tendency increases from hexafluorophosphate to bis(trifluoromethylsulfonyl)imide-based anions ILs. In addition, the results depicting the ILs amphiphilic character can be used to fine tune the ILs mutual solubilities with water and to manage their ecotoxicity impact. COSMO-RS showed to be an *a priori* method of selection for the IL-water binary systems phase behavior qualitative prediction, which may be of considerable value for the design of suitable ILs for practical applications and with expected mutual solubilities.

Introduction

Recently, a class of *neoteric* solvents composed of large organic cations and organic or inorganic anions, that cannot form an ordered crystal and thus remain liquid at or near room temperature, have become one of the fastest growing "green" media for chemists and engineers. Ionic liquids (ILs) outstanding tunable properties through the combination of cations and anions, place them on a green and sustainable level where more efficient and renewable processes and products can be developed by minimizing wastes and avoiding the use of toxic and/or hazard solvents and reagents. Among the several applications foreseeable for ionic liquids such as solvents in organic synthesis [1, 2], homogeneous and biphasic transfer catalysts [3-5], separation processes [6-9] their use in processes with supercritical gases is one of the most exciting.

Several authors [9-12] described potential applications for ILs systems + supercritical fluids, demonstrating the possibility of solute extraction from an IL without any contamination of the extracted solute and solving one of the shortcoming of the use of ILs in solvent extraction processes: the recovery of the compounds from the IL media, by phase separation induction.

Muldoon et al. [13] and Lopez-Castillo [14] reported that the solubility of gases, that typically present low solubilities, could be enhanced by the presence of CO_2, even at low partial pressures. Solinas et al. [15] reported that inducing CO_2 pressure improves the activation, tuning, and immobilization of chiral iridium catalysts in IL/CO_2 for the enantioselective hydrogenation reaction of imines. High-pressure NMR showed that the CO_2 presence increases the amount of H_2 dissolved in the IL, lowering the system viscosity, and thus allows the catalyst, known to be sensitive to the H_2 availability, to operate more effectively [15].

Task-specific ILs are also becoming usual, Bates et al. [6] reported amine functionalized ILs while Yuan et al. [16] and Sun et al. [17] presented hydroxyl-functionalized ILs as novel efficient catalyst for chemical fixation of CO_2. Yu et al [18] and Huang et al. [19] presented guanidinium based ILs, where the electron-donating groups attaching to -NH_2 coupled with the intramolecular hydrogen bonds and associated with H atom on -NH_2 raises the strength of the donor-acceptor interactions energy on -NH_2 and consequently enhance the interactions between -NH_2 and CO_2.

However, the successful development of separation methods based on supercritical fluids depends on the adequate knowledge of the phase behavior of the systems. Several authors, such as Brennecke [11, 20, 21], Peters [22-24] Noble [25], Lim [26], Baltus [27], Outcalt [28], Yokozeki [29] and Majer [30] have been reporting supercritical carbon dioxide solubility in common ILs, but few have focused their studies on the Tf_2N anion based ionic liquids [22, 24-28].

In this work, a new apparatus was developed to investigate the high pressure phase

behavior of gas + ionic liquid systems. Two ionic liquids based on the Tf_2N anion were selected for this study to try to contribute for a better understanding of the solubility of supercritical CO_2 on these fluids. The system of CO_2 + 1-ethyl-3-methyl-imidazolium bis(trifluoromethylsulfonyl)imide ([C_2mim][Tf_2N]) was chosen because it allows the evaluation of the quality of the measurements by comparison with literature data [24] and the CO_2 + 1-methyl-3-pentyl-imidazolium bis(trifluoromethylsulfonyl)imide ([C_5mim][Tf_2N]) system was studied to investigate the effect of the alkyl chain length on the CO_2 solubility in ionic liquids. Both systems were measured in temperatures up to 363 K and pressures of 50 MPa.

Experimental Section

Materials: Two imidazolium based ILs, 1-ethyl-3-methyl-imidazolium bis(trifluoromethylsulfonyl)imide, [C_2mim][Tf_2N] and 3-methyl-1-pentyl-imidazolium bis(trifluoromethylsulfonyl)imide, [C_5mim][Tf_2N], were used on this study. All compounds were acquired at IoLiTec with mass fraction purities > 99 % and bromide impurity mass fraction < 10^{-4}. The purities stated by the supplier, of each ionic liquid, were checked by ^{1}H NMR, ^{13}C NMR and ^{19}F NMR.

It is well established that IL physical properties are influenced by their water content [31-34]. To reduce to negligible values both water and volatile compounds, vacuum (0.1 Pa), stirring and moderate temperature (353 K), for a period of at least 48 hours, were applied prior to the measurements. The final IL water content was determined with a Metrohm 831 Karl Fischer coulometer, indicating a water mass fraction of (42 and 20)•10^{-6} for [C_2mim][Tf_2N] and [C_5mim][Tf_2N] respectively.

The CO_2 used was from Air Liquide with a purity of ≥ 99.998 % and H_2O, O_2, C_nH_m, N_2 and H_2 impurities volume fractions lower than (3, 2, 2, 8 and 0.5)•10^{-6}, respectively.

Experimental measurements: The high pressure equilibrium cell developed on this work is based on the synthetic method and is sketched in Figure 1. The cell, based on the design of Daridon et al. [35-39], consists of a horizontal hollow stainless-steel cylinder, closed at one end by a movable piston and at the other end by a sapphire window. This window, along with a second window on the cell wall through which an optical fiber lights the cell chamber, allow the operator to follow the behavior of the sample with pressure and temperature. The orthogonal positioning of the sapphire windows minimizes the parasitic reflections and improves the observation in comparison to axial lighting.

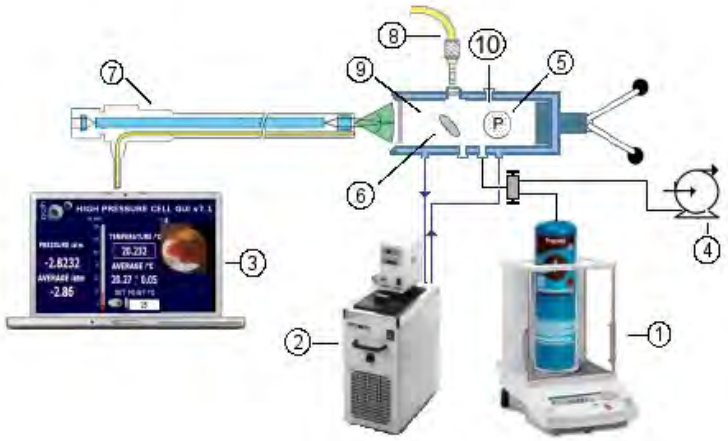

Figure. 1. Schematic apparatus: 1 – Analytical balance; 2 – Thermostatized bath circulator; 3 – Computer to data and video acquisition; 4 – Vacuum pump; 5 – Piezoresistive pressure transducer; 6 – Magnetic bar; 7 – Endoscope plus a video camera; 8 – Light source with optical fiber cable; 9 – High-pressure variable-volume cell; 10 – Temperature probe.

A small magnetic bar placed inside the cell allows the homogenization of the mixture by means of an external magnetic stirrer. The presence of the magnetic stirrer as well and the sapphire window on the cell wall limit the minimum internal volume of the cell to 8 cm^3, while the maximum value is set to 30 cm^3. The cell reduced volume helps to minimize the inertia and temperature gradients within the sample.

The cell is thermostatized by circulating a heat-carrier fluid through three flow lines directly managed into the cell. The heat-carrier fluid is thermo-regulated with a temperature stability of ±0.01 K by means of a thermostat bath circulator (Julabo MC). The temperature is measured with a high precision thermometer, Model PN 5207 with an accuracy of 0.01 K connected to a calibrated platinum resistance inserted inside the cell close to the sample. The pressure is measured by a piezoresistive silicon pressure transducer (Kulite) fixed directly inside the cell to reduce dead volumes, that was previously calibrated and certified by an independent laboratory with IPAC accreditation, following the EN 837-1 standard and with accuracy better than 0.2%. The accuracy of the transducer in the experimental range studied is 0.2 MPa.

Due to the high viscosities of the ionic liquids, a fixed amount of ILs was introduced directly inside the cell. The exact mass of the samples was determined by weighting, using a high weight/high precision balance with an accuracy of 1 mg (Sartorius). In order to avoid any interference of atmospheric gases during the manipulation, after placing the IL inside the cell this was kept under vacuum overnight, while stirring and heating at 353 K.

The CO_2 was introduced under pressure from an aluminum reservoir tank. Its quantity was measured on the precision balance and introduced into the measuring cell by means of a flexible high pressure capillary.

After preparation of a mixture of known composition, this was allowed to reach the desired temperature at low pressure; the pressure was then slowly increased at constant temperature until the system becomes monophasic. The pressure at which the last bubble disappears represents the equilibrium pressure for the fixed temperature.

The purity of the IL is checked again by NMR at the end of the study to confirm that no degradation of the IL takes place during the measurements.

Results and Discussion

Although measurements were previously carried by us and other in similar apparatuses [35-39], to validate the methodology and experimental procedure adopted in this work, [C_2mim][Tf_2N] was selected and compared against data from Schilderman et al. [24]. High pressure binary vapor-liquid mixtures data, of CO_2 in ILs, are scarce and significant discrepancies among data from different authors [24, 26, 28] are common in literature, since previous authors where not aware to the influence of water as well as other impurities or even degradation products on ILs physical properties and phase equilibria. The identification of the data with the highest quality available in the literature was carried using a thermodynamic consistency test. Valderrama and Àlvarez [40], proposed a thermodynamic consistency test for systems with incomplete *PTxy* data and based on the Gibbs-Duhem equation that was recently extended by Àlvarez and Aznar [41] to systems of supercritical fluid + IL systems. Their work allows the identification of the more reliable phase equilibrium data for supercritical fluids in ionic liquids. The most reliable data identified y Àlvarez and Aznar [41] was the Schilderman et al. [24] data for the system CO_2 + [C_2mim][Tf_2N], where the isotherms at 313 K, 323 K e 363 K were found thermodynamically consistent. For this reason this system was here chosen to validate the measurements on the new high pressure cell developed on this work. A comparison of the data here measured with the data by Schilderman et al. [24] is presented in Figure 2 showing very good agreement.

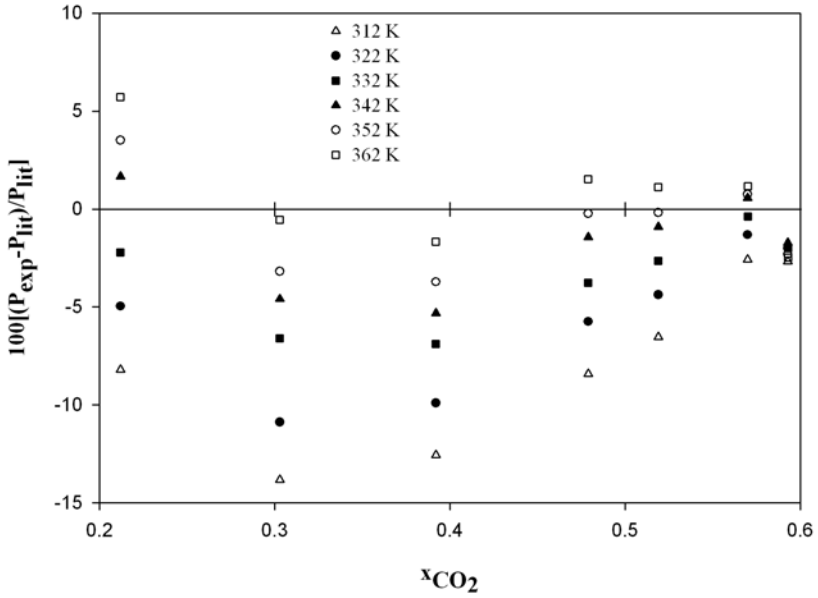

Figure 2. Percent average deviations between the experimental data of this work and those reported by Schilderman et al. [24] for the system CO_2/[C_2mim][Tf_2N].

The solubility of carbon dioxide in the ILs studied was measured for mole fractions from (0.2 to 0.8), in the temperature range (293 to 363) K and pressures from (0.6 to 50) MPa, are depicted in Figures 3 a and 3b.

The temperature increase leads to an increase on the equilibrium pressure and by increasing CO_2 concentration, the equilibrium pressures increase gradually, at first, and rapidly for higher CO_2 contents.

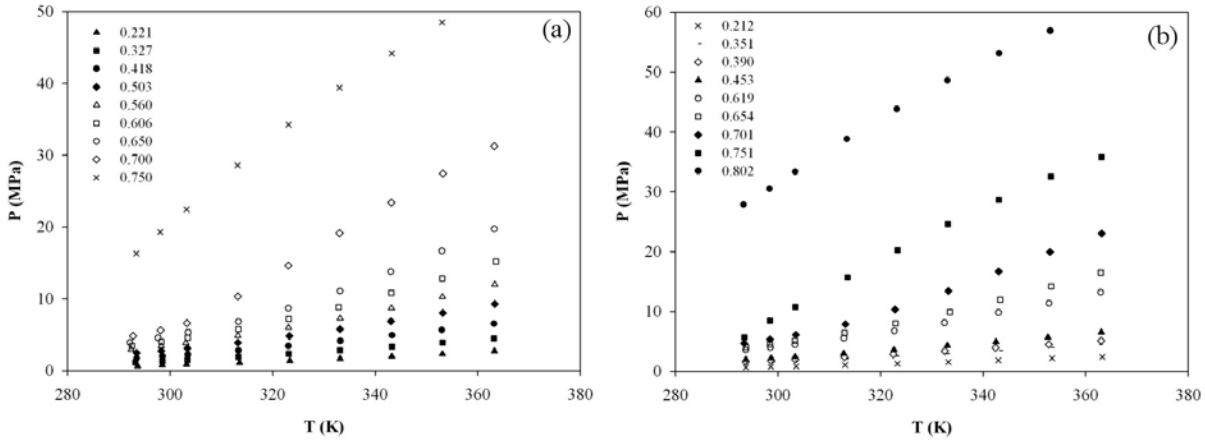

Figure 3. Pressure – temperature diagram of the binary systems (a) CO_2 + [C_5mim][Tf_2N] and (b) CO_2 + [C_2mim][Tf_2N].

It is well established that Tf_2N anion based ILs, due to the presence of fluoroalkyl groups which are known to be "*CO_2-philic*", present higher CO_2 solubilities than other common ILs. In fact, results show that Tf_2N anion based ILs exhibit considerable low equilibrium pressures for higher mole fractions, as can be seen in Figure 3. This behavior, yet poorly understood, is related to the interaction between the negative fluorine atoms and the positive charge on the carbon of the CO_2 molecule [20, 21].

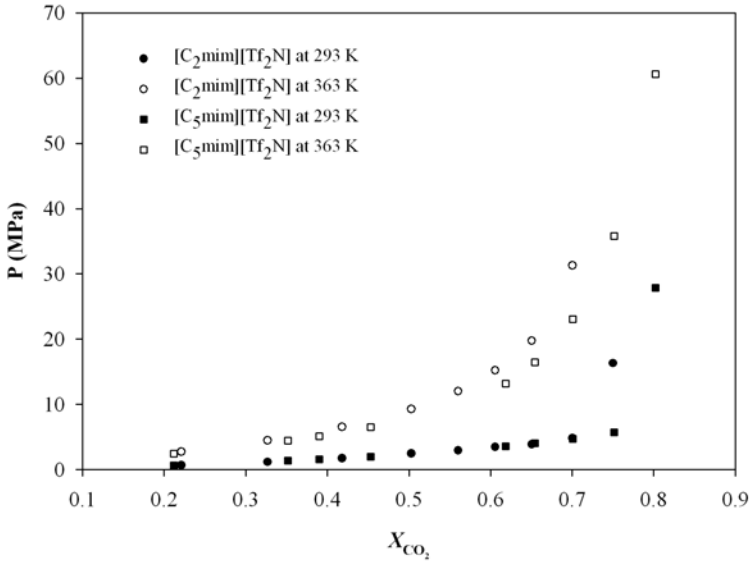

Figure 4. Pressure – composition diagram of CO_2 in [C$_n$mim][Tf_2N].

It is well established that the substituents on the imidazolium ring can affect the ILs properties [22, 23, 31, 34, 42-45]. For CO_2 solubility an slight increase can be seen with the alkyl chain length increase, for all pressures [11, 20, 22, 24]. Nonetheless, Tf_2N anion based ILs present lower alkyl chain length influence on the solubility than other ILs, even for higher CO_2 concentrations, as can be seen in Figure 4 [20, 24]. Kazarian et al. [46], using ATR–IR spectroscopy, reported that the solubility is not related to any specific interactions between the CO_2 and the cation, furthermore, the high solubility of CO_2 in ILs is not either related to the interaction with the most acidic hydrogen on the C_2 position of the imidazolium ring or with the nitrogens in the imidazolium or pyridinium rings [46, 47]. Shariati et al. [22] and Aki et al. [20] explained this entropic rather enthalpic behavior due to the decrease of the compounds densities, with the increase of the alkyl chain length, and by its turn, to a greater free volume in the ILs.

Conclusions

A new high pressure cell to measure supercritical fluid + liquid phase behaviour was developed and tested. The 1-ethyl-3-methyl-imidazolium bis(trifluoromethylsulfonyl)imide was choosed to validate both the apparatus because high quality data for this systems by Schilderman et al. [24] Was available. It is shown that the data measured is in good agreement with the data by these authors.

New experimental data are reported for CO_2 solubility in 3-methyl-1-pentyl-imidazolium bis(trifluoromethylsulfonyl)imide in a wide range of temperature, pressure and carbon dioxide mole fractions.

As commonly observed, the increase of the temperature leads to a decrease on the solubility, while the opposite behavior can be observed by increasing the pressure. As the CO_2 mole fraction increases, the equilibrium pressure starts to increase gradually, for low concentrations, and ends increasing rapidly for higher CO_2 contents. While CO_2 solubility increases marginally when increasing the alkyl chain length, on the imidazolium ring, the Tf_2N anion based ILs present a lower influence than other common ILs, even for higher CO_2 concentrations. This behavior can be explained by the fact that the pentyl group impose a bulkier behavior, in the [C_5mim][Tf_2N], than the ethyl group in the [C_2mim][Tf_2N]. Nonetheless, since the density decreases with the alkyl chain length increase, leading to a greater free volume in the ILs, an increase of the solubility with the alkyl chain length increase is expected and can be understood as a entropic behavior.

Aknowledgments

The authors are thankful for financial support from Fundação para a Ciência e a Tecnologia (Project POCI/EQU/58152/2004) and Ph.D. grant (SFRH/BD/41562/2007) of Pedro J. Carvalho

Keywords: Contact Angle, PCA, PLS, Printing quality, Profilometry, Surface sizing
Topic: Interfacial & colloidal phenomena and/or Product design & innovation

Abstract

At present, there is an increasing demand concerning the quality of printing and writing paper grades. Printing quality strongly depends on the properties of the fibrous matrix and on the characteristics of the paper surface, which are influenced by the quality of the pulp fibers and by all the operations of the papermaking process, which include the surface treatments, such as calendering and/or coating and surface sizing. Regarding surface sizing, typically only starch is used as sizing agent, but there is an increasing tendency for combining this compound with synthetic polymers.

The present study aims at correlating the surface properties and the printing quality of printing and writing papers, prepared with different surface sizing formulations. The samples were characterized by using profilometry and contact angle measurements. A mask was printed onto the paper samples, by inkjet printing, and optical densities, Gamut areas and line quality were computed. The results were analyzed using Principal Component Analysis (PCA) and Partial Least Squares (PLS).

1 Introduction

The increasing demand from costumers and the competition from other information media challenge the papermaking industry to increase its know-how and improve the quality of all paper grades. The printing and writing papers performance depends on the properties of the fibrous matrix and on the characteristics of the paper surface, which are influenced by the quality of the pulp fibers, the refining process, the chemicals added in the preparation of the furnish, the operations at the paper machine and the modifications of the paper surface (Koskela, 2003; Carceller, 2004). Surface modifications include calendering and/or chemical treatments such as coating and surface sizing (Koskela, 2003). Today, chemical modifications of paper surface for improving printing quality is a common practice in papermaking and, as a consequence, there is a large increase in the production of new chemicals that meet specific end-use paper requirements.

For surface sizing, cationic starch alone or mixed with a synthetic polymer are used to control the hydrophilic character of paper surface, preventing excessive absorption of liquids and inks. A thin film is formed at paper surface, reducing the number and size of pores as well as paper roughness, and modifying paper surface energy, so that not only liquid penetration but also liquid spreading is attenuated (Koskela, 2003).

For selecting the most appropriate surface sizing agent for a specific paper grade it is essential to evaluate surface energy, porosity and roughness, which largely influence ink spreading, penetration and drying. Furthermore, it is also crucial to study the effect of surface sizing on printing quality. Optical density, raggedness, sharpness, mottling, bleeding, line and dot quality and Gamut area are some of the relevant properties that should be taken into account when printing processes are involved (Koskela, 2003).

This study aims at correlating the surface properties and the printing quality of UWF (Uncoated Wood Free) printing and writing papers, prepared with different surface sizing formulations. For that, and considering the large quantity of samples and the resulting large amount of data, PCA (Principal Components Analysis) and PLS (Partial Least Squares) were used.

2 Materials and Methods

A calendered uncoated base paper produced with an Eucalyptus globulus Kraft pulp was surface sized using a series of distinct surface sizing formulations. These formulations were produced by the combination of cationic starch with different synthetic polymers. A sample surface sized with cationic starch alone was produced has reference (Table 1).

The polymers were selected considering the current trends in the papermaking industry. So, mostly commercial products were selected. As for the cationic starch, it was collected immediately before the size press of a paper machine, in order to be as close as possible to the industrial practice. All the additives introduced before the size press are presented in the starch suspension.

Table 1 - Polymers used in the production of the surface sizing formulations.

Compound	Ref.	Compound	Ref.
Cationic starch collected at the paper	St	Methylated Melamine	S6
Co-styrene-acrylate	S1	Co-styrene-dimethylaminopropylamine	S7
Co-styrene-maleic anhydride	S2	Co-styrene-butyl acrylate	S8
Co-acrylonitrile-acrylate	S3	Co-styrene-acrylate	S9
Co-styrene-maleic anhydride	S4	Co-styrene-acrylate	S10
Quaternary ditallow methyl epoxypropyl	S5		

The surface sizing formulations were prepared with a synthetic sizing agent content of 5, 10 or 20% (w/w) and, accordingly, a starch content of 95, 90 and 80% (w/w) (Table 2). Then they were applied on the surface of the base paper using a Mathis laboratory device, SVA-IR-B. A 0.15 mm roll was used and its velocity adjusted to 6m/min. The drying process was performed with an IR drier followed by air drying. The total surface sizing pick-up was 3.5 ± 0.3 g/m^2. The surface sized samples were no further calendered.

The physical characterization of the samples surface was performed by optical profilometry using the AltiMet perfilometer Altisurf 500 and the PaperMap software. For each sample, pieces of 4x4 mm^2 were scanned with a scanning resolution of 2 μm. From the 2000 profiles obtained for each piece, several relevant surface texture parameters were computed (Cohen, n.d.; Stout, 1994): average roughness (Sa, μm); root mean square roughness (Sq, μm); maximum peak height (Sp, μm); maximum valley depth (Sv, μm); total height of the surface (St, μm); skewness of the 3D surface texture (Ssk); root-mean-square slope of the surface (Sdq); texture aspect ratio of the surface (Str); arithmetic mean summit curvature of the surface (Ssc) and developed interfacial ratio (Sdr, %).

For the evaluation of the surface energetics of the paper samples, contact angle measurements were performed with the DataPhysics equipment OCA20, using the sessile drop method (Brigs, 1989). The initial contact angle using water was measured to evaluate the ability of the paper surface to interact with the water based inks. The total, as well as the dispersive and polar components of the solid surface energy were determined by measuring on the same sample the initial contact angle with other different liquids whose surface tension components are known (Diodomethane, Ethileneglycol, Formamide, and Propileneglycol). For that, the WORK method was applied. The theory behind this method and the surface tension values of the liquid probes used are presented elsewhere (Brigs, 1989). For each paper sample, pieces from at least three different sheets were used and for each liquid probe a minimum of 10 drops were measured.

Inkjet printing quality was evaluated by measuring the optical density (OD), Gamut area and some line quality parameters in a specified mask printed on the paper samples. The OD and the Gamut area, defined elsewhere (Moutinho, 2007) were chosen since they correlate well with the end users perception. The former was determined in a gretag 19C spectrophotometer. The CIE lab color coordinates necessary to compute the Gamut area were obtained by using the AvaMouse spectrophotometer (Avantes). The line quality parameters, image area, borderlenght and roughness, which are commonly used in many paper mills, were determined using the image analysis system PIA BASF – 8042319.

Table 2 - Sample description.

Sample	Surface Sizing Formulation (% w/w)	Sample	Surface Sizing Formulation (% w/w)	Sample	Surface Sizing Formulation (% w/w)

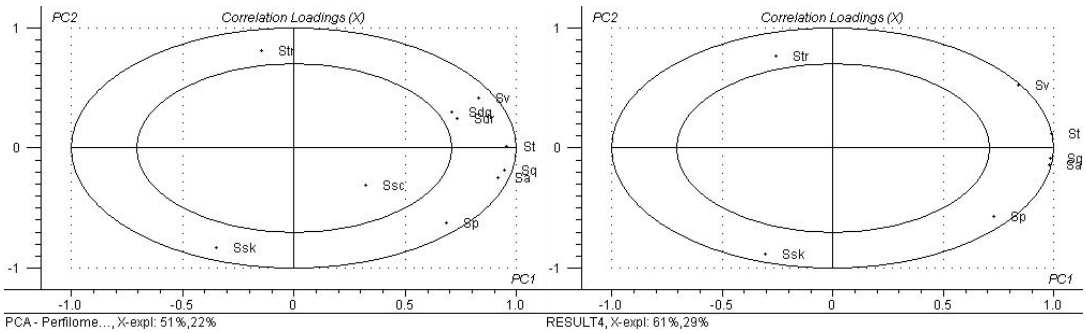
3 Results and Discussion

PCA was used to choose the best set of topographic parameters that describe all the paper samples. The ten variables that were measured, plotted in Figure 1a, describe 73% of the results variability (51% 1st component; 22% 2nd component). According to the correlation loadings, the variables Ssc, Sdq and Sdr can be eliminated from the set. The resulting PCA analysis, which includes the seven variables Sa, Sq, Sp, Sv, St, Ssk and Str, is presented in Figure 1b. A higher degree of explanation (90%: 61% 1st component; 29% 2nd component) is now achieved. Therefore, these seven parameters are enough to adequately describe and analyze the effect of surface sizing in the topography of all the paper samples.



(a) (b)

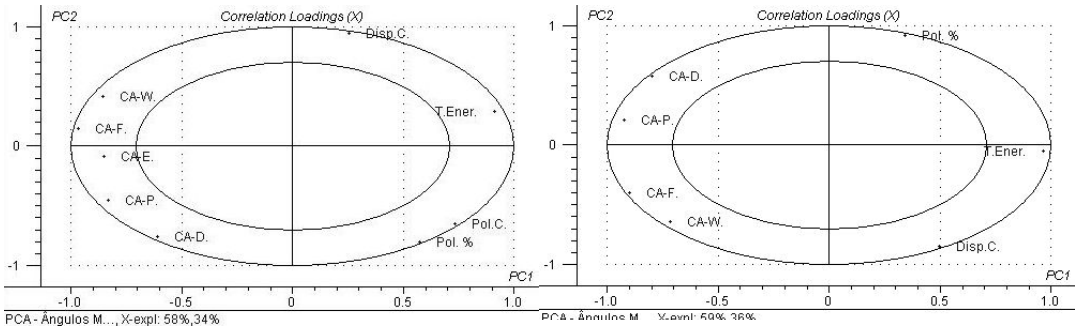
Figure 1 - PCA analysis (a) using the descriptive variables obtained by profilometry; (b) using 7 descriptive variables.

The ANOVA results corresponding to the seven topographic parameters selected after the PCA analysis are listed in Table 3. Has can be seen, the results are statistically significant ($p << 0.05$ and $F > F_{critical}$) and reveal that the major contribution to the variability of the results is due to the differences among the samples. However, the variability due to the measurements within each sample is not negligible.

Table 3 – ANOVA analysis results for the most important profilometry variables, resolute by PCA analysis.

Variable	Contribution to total variation (%)		Reproducibility Factor	p	F	Fcritical
	Among Samples	Within Samples				
Sa	56.72	43.28	0.40	1.7E-14	6.25	1.54
Sq	63.57	36.43	0.45	1.3E-15	7.16	1.55
Sp	53.49	46.51	1.39	9.2E-09	4.29	1.56
Sv	60.53	39.47	1.87	5.7E-17	7.31	1.54
St	57.53	42.47	2.65	5.4E-15	6.46	1.54
Ssk	62.64	37.36	0.23	2.5E-14	6.65	1.56
Str	57.32	42.68	0.22	3.7E-08	4.25	1.58

The values of the contact angle with the five distinct liquids, as well as the total surface energy, its dispersive and polar components and the polar character, were analyzed by PCA (Figure 2a). The two components with the nine variables describe 73% of the variability of the data (51% 1st component; 22% 2nd component). After discarding the polar component of the surface energy, which is redundant relatively to the polar character, and the contact angle with ethileneglycol, which has the smaller correlation loading, and new PCA with seven variables was performed (Figure 2b). A higher degree of explanation was now obtained (95%: 59% 1st component, 36% 2nd component).



(a) (b)

Figure 2 – PCA analysis (a) for all variables computed from the contact angle variables; (b) using 7 variables achieved through contact angle measurements.

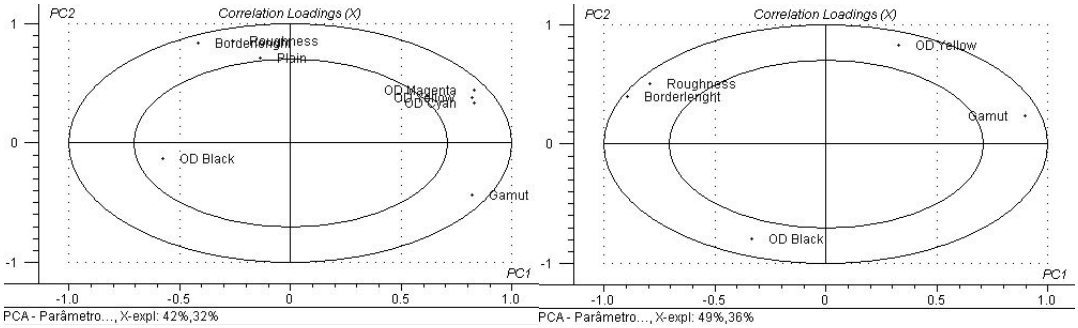
ANOVA was also applied to the results of the contact angle measurements performed with each one of the five aforementioned different liquid probes. The results, listed in Table 4 are once again statistically significant and show that the variability is mostly due to the differences between the 31 paper samples. This indicates that the contact angle results, and those of the properties derived from them (the total surface energy and its dispersive and polar components) clearly distinguish samples, contrary to the Profilometry results. Thus, it is legitimate to conclude that the use of different surface sizing agents has a predominant effect on the surface energetics and a reduced impact on the surface texture.

Table 4 - ANOVA Analysis of the contact angle values.

Variables (Contact Angles)*	Contribution to total variation (%)		Reproducibility Factor	p	F	Fcritical
	Among Samples	Within Samples				
Diodomethane	96.81	3.19	3.57	3.5E-263	382.95	1.49
Propileneglycol	97.82	2.18	4.06	7.2E-223	434.52	1.50
Ethileneglycol	98.59	1.41	3.75	1.7E-276	743.27	1.49
Formamide	98.93	1.07	3.69	0.0E+00	1029.46	1.49
Water	98.88	1.12	4.01	0.0E+00	1099.36	1.49

* ANOVA Analysis performed using the measured values for the contact angle with the different liquids tested, since all the calculations are based in these values.

PCA was also used with the following printing quality parameters: optical densities for black, cyan, magenta and yellow, gamut area, image area and contour perimeter and roughness (Figure 3a). From this set of eight variables, the cyan and magenta optical densities were removed for further analysis since, in the graph these are close to the yellow OD. For the same reason, the image area was also discarded. The remaining five variables (black and yellow Optical densities, Gamut area and contour perimeter and roughness) were used in a new PCA analysis (Figure 3b) and, as can be seen, it was possible to increase th explanation from 74% (42% 1st component; 32% 2nd component) up to 85% explanation (49% 1st component, 36% 2nd component).



(a) (b)

Figure 3 – PCA analysis (a) for all the printing quality parameters; (b) using 5 printing quality parameters.

The corresponding ANOVA results for these 5 variables are presented in Table 5. The quality of the ANOVA analysis is once again ensured by the good values of the parameters P, F and Fcritical.

Table 5 – ANOVA analysis results for the most important printing quality variables.

Variable	Contribution to total variation (%)		Reproducibility Factor	p	F	Fcritical
	Among Samples	Within Samples				
OD Black	67.58	32.42	0.21	4.0E-25	10.84	1.53
OD Yellow	64.90	35.10	0.07	1.7E-22	9.55	1.53
Gamut Area	73.00	27.00	952.59	1.4E-03	2.97	1.81
Borderlenght	57.53	42.47	0.90	8.7E-17	7.00	1.53
Roughness	49.12	50.88	0.02	1.2E-11	4.99	1.53

From this table, it is possible to conclude that OD and Gamut area are significantly different from sample to sample, whereas for the line quality parameters the variations between samples or within the same sample have similar relevance. These findings indicate that caution must be taken in the interpretation of the line quality parameters, and they must always be analyzed in combination with other printing quality parameters in order to avoid misleading conclusions.

Next, in this study, PLS models were computed in order to determine whether the physical and/or the chemical surface parameters previously described can explain the printing performance of the distinct sized papers, as evaluated by the printing quality in terms of optical densities, Gamut area and line quality parameters.

Three different sets were created: one with the seven independent topographic variables (Figure 1b), assigned as “Physical”; another with the seven independent chemical variables evaluated by the contact angle measurements (Figure 2b), assigned as “Chemical”; and another with these 14 variables all together, assigned as “Total”. The above five printing quality variables (Figure 3b) were used as the “dependent” variables, either isolated or grouped as follows: all dependent; OD (OD black + OD yellow); line quality (borderlenght + roughness). Thus, 24 models were considered. Table 6 presents the results of the resultant models with a degree of explanation superior to 10%.

Table 6 – Results achieved by PLS models.

Independent Variables Set (xx)	Dependent Variables Set (yy)	Explanation %*	Correlation Coeficcient
Total	All Printing Variables	17% (11; 6)	0.43
Total	Optical Densities	20% (13; 7)	0.47
Chemical	Optical Densities	15% (5; 10)	0.29
Total	Line Quality	23% (21; 2)	0.42
Physical	Line Quality	14% (13; 1)	0.28
Total	Gamut Area	22% (13; 9)	0.36
Chemical	Gamut Area	26% (8; 18)	0.28
Total	OD - Black	25% (20; 5)	0.45
Physical	OD - Black	15% (12; 3)	0.35
Chemical	OD - Black	10% (12; 3)	0.28
Total	OD - Yellow	32% (15; 17)	0.70
Chemical	OD - Yellow	41% (8 ; 2)	0.67
Total	Borderlenght	20% (16; 4)	0.40
Total	Roughness	29% (27; 2)	0.54
Physical	Roughness	20% (18; 2)	0.45

* Total% (1st component; 2nd Component)

The explanation percentages as well as the coefficients of correlation are in general small. This means that other paper surface properties than those measured is this study and used in the PLS analysis are also necessary to explain the printing quality parameters that were assessed in the distinct samples. Nonetheless, some interesting features are clear in Table 6: the optical densities and gamut area are more affected by the chemical properties, while the line quality variables are more related to the physical structure of the paper surface. In other words, the paper topography mostly affects the printed image contours while the chemical properties of the surface have a more pronounced influence on the color related properties.

4 Conclusions

The mathematical tools applied in this work proved to be most useful in the treatment of the large amount of information achieved. Using PCA it was possible to identify the most relevant parameters regarding paper surface characterization (physical and chemical) and printing quality evaluation. The ANOVA analysis demonstrated that surface sizing operation influences more significantly the chemical rather than the physical properties of the paper surface, while from the PLS analysis it was possible to conclude that the topography is more important in the explanation of the printing properties related to the definition of the contours while the chemical properties achieved from contact angle measurements are more useful in the explanation of the printing quality variables related to the colour.

Keywords: Aragonit, Precipitation, Ultrasonic field, Size distribution
Topic: Advancing the chemical and biological engineering fundamentals.

Abstract

Aragonite with sub-micron size particles was synthesized in a liquid-liquid reaction by the controlled double jet precipitation method. The reaction medium was an ethanol-water solution. The precipitation process depends on supersaturation, pH, temperature, reaction time, agitation specific energy, feeding order of the reacting solutions, the nature, and the presence/absence of the additives. This parameters influence the final solid phase morphology and also the particle sizes. All samples were characterized by FT-IR spectroscopy, XRD, optical and electron microscopy, particle size distribution by laser granulometer and microscopic measurements methods. The results proved that a very small amount of the precipitated particles were agglomerated.

The population balance equation describing the precipitation process was integrated using the method of classes (Marshal P. et al, 1988). The kinetic parameters were estimated using a random search optimization method. The results obtained were in good agreement with experimental data and proved that in the present working conditions nucleation and growth are the main mechanisms while agglomeration is inhibited.

1 Introduction

Nano calcium carbonate finds applications in advanced materials like composites and biomaterials. The controlled double-jet precipitation method allows the production of colloidal particles with a good control of their monodispersity .The precipitation of calcium carbonate (PCC) by liquid-liquid reaction usually provides a mixture of polymorphs since calcium carbonate has at least three stable polymorphs: calcite, aragonite and vaterite. In order to induce the crystallization of aragonite, the high pressure polymorph, the precipitation conditions, such as supersaturation, temperature, pH, feeding order, stirring, additives, must be carefully controlled.

This paper reports the synthesis of aragonite by the double jet precipitation method. The reaction medium was either bi-distilled water or a solution of bi-distilled water and ethanol. The influence of ultrasonic agitation on the particle size distribution was investigated in comparison with magnetic stirrer.

The final PSD, measured in a mass base system, on a laser beam particle size analyzer (PSA) was used for the kinetic parameter estimation considering that the final shape of the PSD is the result of overlapping primary and secondary crystallization mechanisms such as nucleation, growth and agglomeration.

* Corresponding author. Tel + 4072265848. E-mail:ralucaisopescu@yahoo.com

The parameters were estimated by fitting the experimental PSD to the computed values obtained by solving the population balance equation as defined in a large number of publications.

2 Experimental

Aragonite was synthesized by liquid-liquid reaction using 0.1 M solutions in bi-distilled water of analytical grade, calcium nitrate tetrahydrate (Riedel-de Haen) and potassium carbonate (Sigma-Aldrich). The reagents were introduced into a glass reactor by means of peristaltic pumps at the same flow rate of 10 ml/min. The reaction medium was either 50 cm^3 of bi-distilled water or a mixture of water and ethanol 1:1 in volumes. The reaction temperature was kept constant at 50°C by means of a thermostate.
In a first set of experiments a magnetic stirrer performed the agitation into the reaction medium. In a second set of experiments the glass reactor was placed into an ultrasonic bath and agitation was resumed to the influence of ultrasonic field. The experiments were set up in absence and in presence of polyelectrolyte type additive: *polyoxyethilene sorbitan monolaureate* (Tween 20) at two different concentrations. The precipitate was aged for 1hour, then filtered and washed several times with bi-distilled water and dried at 100°C.

Phase composition was established by FT-IR spectroscopy using a Perkin-Elmer spectrophotometer. PCC samples were dispersed in spectral grade KBr and pressed. Using powder X-ray diffraction (diffractometer Bruker D8 Advantage) quantitative phase composition was established and particles mean size was calculated with Debye-Scherrer formula. Particle size distribution was also investigated using a laser beam particle size analyzer (Analysette 22 Micro Tech). TEM was performed using a JEOL 200CX electron microscope. Samples were deposited on carbon coated 3 mm diameter copper electron microscope grids.

3 Results and discussion

FT-IR spectroscopy of PCC proved to be mainly aragonite. The other two anhydrous polymorphs (calcite and vaterite) are present in various ratios (table 1). XRD measurements confirmed the conclusions drawn on the basis of FT-IR spectra.

Table 1. Experimental results

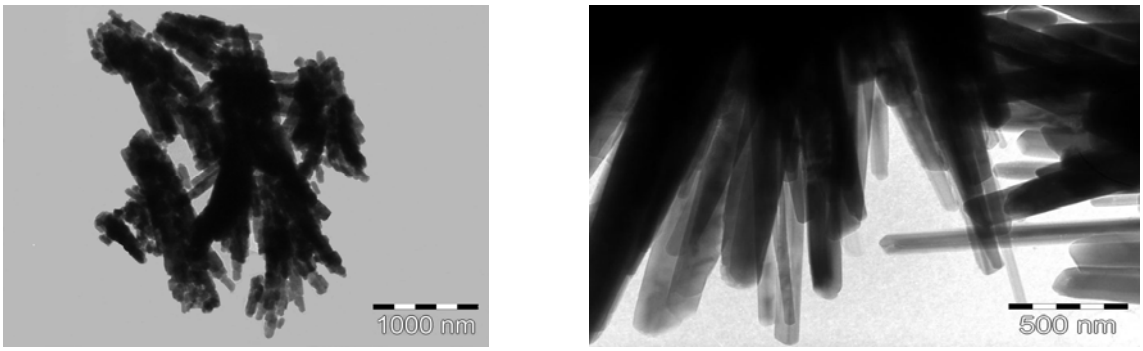
Sample no	Agitation mode	Reaction medium	Composition	Mean diameter PSA [µm]	XRD Mean diameter [nm]
1	magnetic	50 cm^3 bi-distilled water	65.05% aragonite; 2.78% calcite; 32.17% vaterite	15.314	102.0 190.0 60.7
2	magnetic	50 cm^3 ethanol – water ratio 1:1	98.76 % aragonite; 1.24 % calcite;	1.457	25.4 33.3
3	US 50 kHz;	50 cm^3 bi-distilled water	71.48% aragonite; 20.99% calcite; 7.53% vaterite	13.282	57.5 570.0 47.9
4	US 50 kHz;	50 cm^3 ethanol – water ratio 1:1	98.18 % aragonite; 1.82 % calcite	1.075	18.2 21.2
5	magnetic	50 cm^3 bi-distilled water with TWEEN 20 1.2 10^{-4} mmol/l	65.05% aragonite; 2.78% calcite; 32.17% vaterite	12.54	-
6	US 50 kHz	50 cm^3 bi-distilled water with TWEEN 20 1.2 10^{-4} mmol/l	71.48% aragonite; 20.99% calcite; 7.53% vaterite	1.12	-

The reaction medium proved to have a significant influence on the composition of the precipitate and on the particle size distribution. When the reagents are dropped and react in bi-distilled water, the proportion of the other stable polymorphs of $CaCO_3$ is significant, PCC is a mixture of the three polymorphs, aragonite being still the dominant phase with a percentage of 65-70 %. When the reaction medium is a solution of 1:1 ethanol and bi-distilled water, the phase composition determined both by FT-IR spectrometry and XRD measurements, shows that aragonite is only slightly impurified with calcite (1.24-1.28 %). The temperature of 50 °C is reported to be specific for aragonite development but from our experiments the reaction medium is in fact more important. The presence of alcohol – water clusters, at 50°C proved to be favorable to aragonite development

The PSD diagram registered by means of a particle size analyzer shows that when the reaction medium was a mixture of ethanol and bi-distilled water 1:1 in volumes, a diminishing of the particles size by one order of magnitude appears. The PSA (laser beam analyzer) measures in fact not the individual crystallites size but the size of agglomerates and it registers a mass base distribution, emphasizing the contribution of agglomerates. The diminishing of the dimensions when additives are used proves that additives prevent the aggregates formations (figure 3).

From XRD spectra, using the Debye-Scherrer formula, the crystallites size was estimated using the most intensive maxima for each phase. These measurements proved that using the double jet precipitation method nanoparticles of PCC develop. In the presence of ethanol solution aragonite dimensions dropped to 25 nm.

TEM images reveal the presence of nanometric particles gathered in agglomerates of micrometric dimensions (figure 1a) in the case when ethanol is present in the reaction medium. When bi-distilled water is used as reaction medium longer aragonite needels of several microns form and gather in bunches (figure 1b).



(a) (b)

Figure 1. TEM images of PCC. (a) sample 4; (b) sample 3.

Figure 2 presents SEM images of the PCC obtained in the two experimental runs. The images show a significant contribution of spherical vaterite and calcite in sample 1 (figure 2b) while in sample 2 (figure 2a) mainly rod and needle like aragonite are present.

4 Kinetic parameters estimation

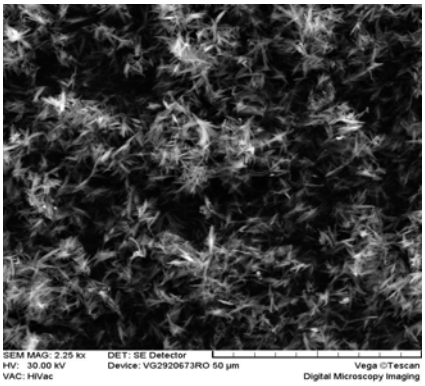
The kinetic parameters estimation relays on mathematical modelling of the precipitation process considering the mechanisms assumed according to the analyses of experimental PSD data. These mechanisms are: nucleation, non-ideal crystal growth and agglomeration.

The PBE for a batch crystalliser is generally represented by an integro-partial differential equation. Considering nucleation, growth and agglomeration as main mechanisms and adopting a discretisation of the particle size range as defined by Marshal et all (1998), the PBE can be transformed in a system of differential equation. Considering Ni the number of particles in unit volume of slurry in class i (according to the method of classes first defined in

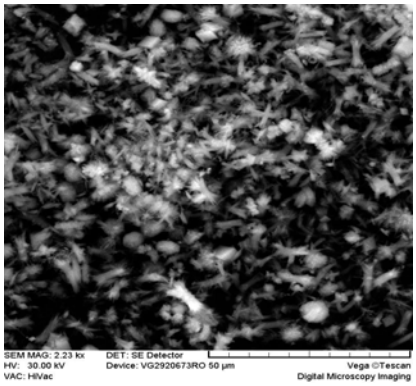
(Marshal et all 1998) the PBE for class i becomes:

$$\frac{dN_i}{dt} + \frac{1}{V}\frac{dV}{dt}N_i + [G(d_i) * n(d_i) - G(d_{i-1}) * n(d_{i-1})] = B_i + r_{A,i} \quad (1)$$

where V is the volume of suspension, B_i is the nucleation contribution in class i, $r_{A,i}$ the agglomeration term. G(d) stands for the size dependent crystal growth rate and n(d) is the population density function.



(a)



(b)

Reaction without TWEEN	Reaction with TWEEN 20
	PSD at the end of reaction	
	PSD for 40 minutes aging period.	

Figure.3. The PSD dynamic for calcium carbonate precipitation.

Further, we consider that nucleation occurs only in the first class at the nuclei size, so B_i is termed B^0 for this class and is null for all other classes. The agglomeration term is calculated considering the equation derived by Hounslow et all (1988):

$$r_{A,i} = N_{i-1}\sum_{j=1}^{i-2} 2^{j-i+1}\beta_{i-1,j}N_j + \frac{1}{2}\beta_{i-1,i-1}N^2_{i-1} - N_i\sum_{j=1}^{i-1} 2^{j-i}\beta_{i,j}N_j - N_i\sum_{j=i}^{Nc}\beta_{ij}N_j \quad (2)$$

The kinetics G, B^0 and $\beta_{i,j}$ depend on the nature of the system and operating condition. As revealed by experimental data analysis, a non-ideal crystal growth can be assumed. For the definition of G(d) the ASL model was selected. As concerning the agglomeration rate, a size independent kernel was assumed: $\beta_{i,j}=\beta$. Deriving equation (1) for all classes, a system of differential equations is formed and solved by a standard numerical method. The kinetic parameters (B^0, G_0, a, b, β) were estimated by minimising a least squares criterion.

$$F = \sum_{i=1}^{Nc}[\ln(N_{i,\exp}) - \ln(N_{i,comp})]^2 \quad (3)$$

where N_c is the number of classes in accordance with experimental data.

The use of logarithm in equation (3) assures the same contribution of all classes in the definition of the minimisation criterion. The minimisation was performed using a random adaptive search method recommended for multimodal objective functions, which is generally the case in kinetic parameters estimation.

The solution found by solving the PBE and fitting the results to experimental data are presented in table 2, together with the best value of the least squares criterion. The kinetic parameters were identified for the first 15 minutes of the precipitation process.

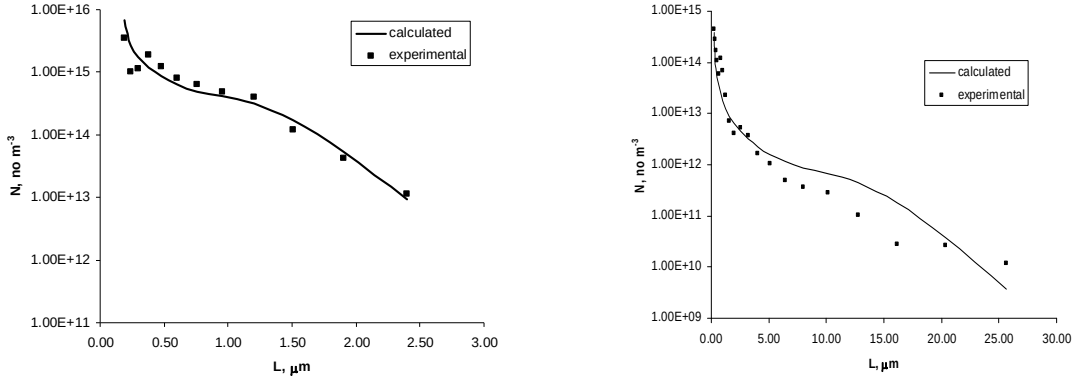
Table 2. Estimated kinetic parameters

Run	B^0, no·m^{-3}s^{-1}	G_0, m·s^{-1}	a, m	b	β, m^3·s^{-1}	F_{min}
1	$1.8625\cdot10^{14}$	$1.3297\cdot10^{-11}$	$3.91\cdot10^{7}$	0.278	$4.4159\cdot10^{-15}$	12.20
2	$4.0002\cdot10^{14}$	$1.1597\cdot10^{-10}$	$2.45\cdot10^{5}$	0.098	$1.0578\cdot10^{-17}$	3.67
3	$6.2148\cdot10^{14}$	2.167810^{-10}	$2.74\cdot10^{7}$	0.470	$2.1678\cdot10^{-15}$	16.40
4	$4.0789\cdot10^{14}$	$2.3600\cdot10^{-10}$	$4.89\cdot10^{7}$	0.017	$3.2700\cdot10^{-18}$	2.35
5	$1.9600\cdot10^{8}$	$1.9700\cdot10^{-13}$	$4.84\cdot10^{7}$	0.790	$3.2700\cdot10^{-18}$	4.57
6	$3.1000\cdot10^{9}$	$2.8000\cdot10^{-10}$	$3.37\cdot10^{7}$	0.680	$3.2700\cdot10^{-18}$	1.39

It may be noticed from the data in table 2 that the mathematical model gives more reliable results in the case of ethanol-water precipitation medium where few agglomerates are formed. In this case the constant mean shape factor considered from the transformation of mass based PSD into number based distribution introduces lower errors. On the other hand when large agglomerates are formed, the constant kernel agglomeration model might not be enough accurate to capture the complexity of the process. Figure 4 presents calculated and experimental PSD data for 1 and 2 runs.

The data in table 2 confirm that nucleation is the dominant mechanism in all experimental runs. The ultrasonic filed slightly increases the nucleation rate, more evident for bi-distilled water medium than for ethanol-water mixture and decreases the agglomeration. The linear crystal growth rate, G_0 is affected by the US waves as expected, increasing the crystal growth rate probably by an enhanced mass transfer close to the crystal surface. In the case of bi-distilled water, where larger agglomerates are formed, a size dependent crystal growth was revealed, as the values of parameters “a” and “b” show (table 2). The effect of the precipitation medium is even more important on the mechanisms involved than the presence of ultrasonic field. The agglomeration rate is drastically reduced in ethanol water mixture. The

newborn particles seem to grow mainly by linear growth mechanism while efficient particle collisions leading to agglomerates are very rare.



(a) (b)

Figure 4 Experimental and computed PSD, N_i for sample 4 (a) and sample 3 (b).

The presence of several polymorphs may also increase the agglomeration rate by creating a larger free surface of the solid phase capable to attach other solid particles. The polymorphic transformation that probably occurred when the precipitation took place in bi-distilled water may also be responsible for the shape of PSD and a reason for a poorer data fitting with the model based on nucleation, growth and agglomeration.

5 Conclusions

PCC was synthesized by the double jet precipitation method using two mixing systems, either ultrasonic waves or magnetic mixer, in a reaction medium of bi-distilled water or ethanol-water solution.

The presence of ethanol in the reaction medium and aditives had an important influence on the final solid phase properties both from morphological point of view and particle size distribution.

The mathematical model derived and the values of estimated kinetic parameters confirm that nucleation is the dominant mechanism in all experimental runs. The agglomeration process is significantly decreased when precipitation takes place in ethanol-water medium.

The double-jet calcium carbonate precipitation in ethanol-water mixtures may be a challenging solution to obtain pure polymorphic phase and submicron size particles.

Change on rheological properties of mushroom cream due to freezing process

E. Álvarez*, M. A. Cancela, N. Delgado-Bastidas, R. Maceiras

Keywords: Rheological properties, activation energy, mushroom cream, freeze-thaw treatment.
Topic: Advancing the chemical and biological engineering fundamentals

Abstract

The effect of the freeze-thaw treatment on rheological behaviour and activation energy in mushroom cream has been investigated. Freeze-thaw treatment was made at different times of frozen storage; it was within a range of 0 to 6 weeks. For each freezing cycle, the sample was submitted to rheological measurements within a range of temperature between 20 and 40°C. Mushroom cream exhibited pseudo plasticity following the Ostwald Waele model in all cases. This model described very well the flow behaviour of analyzed samples, for each temperature and time of frozen storage (R^2 > 0.999). Furthermore, it was observed that sample viscosity increased with freeze-thaw treatment respect to the not treated sample. Finally, an equation type Arrhenius was used to determine and quantify the temperature effect on the consistency index during the heating and shearing program; moreover, activation energy values were obtained.

1. Introduction

The increasing social and economic importance of food production, together with the complexity of production technology, processing, handling and acceptance of these highly perishable and fragile food materials requires a more extensive knowledge of their physical properties; because of this, the viscoelastic properties play an important role in the handling and quality attributes of both minimally processed foods, such as fruits and vegetables, and fabricated foods such as sauces and creams (Rao and Steffe, 1992). In the alimentary industry the foods undergo a lot of transformations during their processing therefore there is a significant relationship between industrial practice and research studies on properties of foods.

Most foods are subjected to variations in their temperature during production, transport, storage, preparation and consumption, e.g., pasteurization, sterilization, evaporation, cooking, freezing, chilling etc. Temperature changes cause alterations in the physical and chemical properties of food components which influence the overall properties of the final product, e.g., taste, appearance, texture and stability. Chemical reactions, such as hydrolysis, oxidation or reduction, may be promoted or physical changes, such as evaporation, melting, crystallization, aggregation or gelation, may occur. A better understanding of the influence of temperature on the properties of foods enables food manufacturers to optimize processing conditions and improve product quality (Osborne and Voogt, 1986).

An important factor in the studies on the flow properties is the effect on rheological behaviour of thawing conditions. Works have been carried out to determine the effect of freeze-thawed cycles on the apparent viscosity of commercial and natural purees (Alvarez and Canet, 2001a, b;

* Corresponding author. Tel + 34-986-812213. E-mail: ealvarez@uvigo.es

Downey, 2003). They observed that time of frozen storage plays an important role on the apparent viscosity and others rheological parameters, whose negative effect is more significant for commercial creams. This effect is related to ice crystal growth caused by fluctuations when time increases. It maybe causes a break in the cell structure of the fluid, and it originates a greater fluid loss (Alvarez *et al.*, 2004). These factors indicated that freezing treatment causes a greater structural damage in commercial purees, due to retrogradation of gelatinized starch and operation conditions during the manufacturing process.

The objective of this work was to evaluate the effect of the freeze-thaw treatment on rheological behaviour and on activation energy in a commercial mushroom cream.

2. Materials and Methods

Sample Preparation

Mushroom puree was prepared according the maker instructions, weighing 18.375 g with a balance Mettler AJ150 with a precision of ±0.1 mg, and they were dissolved in 250 ml of warm water. The ingredients of mushroom cream was: vegetal fat, starch, milky solids, wheat flour, salt, flavour enhancer (E-621), animal fat, mushroom (3.4 mass %), sucrose, aroma, spices and antioxidants (E-304/E-307).

Frozen Storage and Conditions of Freeze-Thaw Treatment

Freeze-thaw treatments were performed by storing in a refrigerator for 16 h at 4ºC, followed by freezing at -24ºC in a freezer. Samples of each system were subjected to 0, 1, 2, 3, 4, 5 and 6 weeks of frozen storage. Afterwards, all samples were thawed at room temperature of 20ºC for 14 h to ensure them same conditions of thaw before realizing the experiments. Each testing date was repeated twice.

Rheological Measurement

A rotation viscometer, Viscotester VT550 (Haake, Germany), equipped with SV1 rotor (bob length = 61.4 mm, bob diameter = 20.2 mm, gap width = 1.45 mm) in a concentric cylindrical cup assembly interfaced to a computer for control and data acquisitions was used for rheological measurements. The viscometer was operated in controlled shear rate mode, where the shear rate (γ) was set and the resultant shear stress was measured (τ). The sample compartment was maintained at a constant temperature using a water/bath circulator and it was varied from 20 to 40 ºC.

For each test, the filled sample cup and spindle were temperature equilibrated for about 10 min and the samples were subjected to shear changes from 17.8 and 445 s^{-1}. The rheograms were evaluated using the Ostwald Waele model (Eq. 1) and the apparent viscosity was computed as the ratio of shear stress to shear rate ($\eta = \tau/\gamma$).

$$\tau = K\gamma^{n} \quad (1)$$

where τ is the shear stress (Pa), γ is the shear rate (s^{-1}), *K* is the consistency index ($Pa \cdot s^{n}$) and *n* is the flow behaviour index (dimensionless).

Model fitting was carried out using Origin 7.0. The model parameters were varied simultaneously to achieve the minimum residual square error between the predicted and the actual flow curves data.

3. Results and Discussion

Rheological Properties

All test samples of mushroom cream exhibited shear-thinning behaviour at different temperatures and different frozen storage times. The viscosity decreased with temperature for the same frozen storage time (Figure 1). This behaviour was observed in starchy foods and reported by Alvarez and Canet (2004).

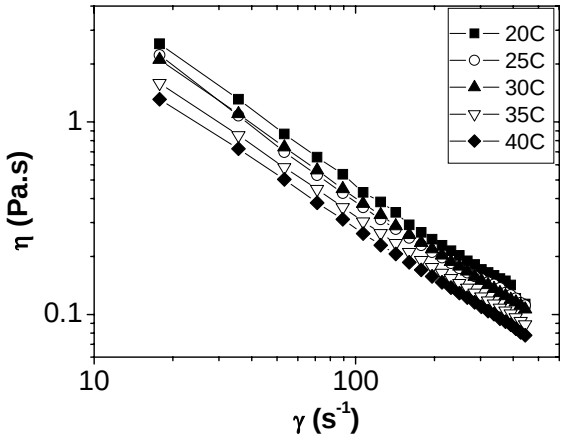

Figure 1. Viscosity vs. shear rate for 6th week, at all temperatures.

Figure 2 shows rheograms at different frozen storage time of mushroom cream samples. In these rheograms, it can be observed that viscosity increases with time frozen storage in all cases. Our results show a clear tendency to increase viscosity with respect to time of frozen storage, despite of possible structural damage caused by freeze-thaw treatment. Analyzed frozen cream was more affected by the starch behaviour as a swelling agent that by breakdown of the cell structures caused by freeze-thaw treatment. The cell structures were destroyed progressively under the effect of shear rate; this can be seen in Figure 2.

The crystallization on cooling and frozen storage is the cause of that frozen storage stability decreases. In this study, one of the reasons, that viscosity did not diminished with the frozen storage time, was the use of cryoprotectants and other hydrocolloids, such as thickness, starches and sugars. The water binding ability (high but relatively weak) of hydrocolloids can provide body and texture to foodstuffs, this is main reason for using starches as an additive in commercials creams, moreover they are claimed to offer temperature resistance, shear and storage stability and smooth texture.

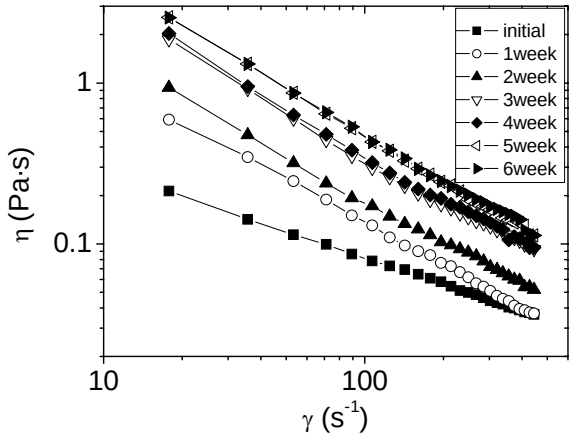

Figure 2. Viscosity vs. shear rate at all time of frozen storage and 30 ºC.

The causes of the viscosity increase with frozen storage time are possibly related to the transformation of the starch into a sponge-like material after freezing (Eliasson and Kim, 1992). During frozen process, cell walls are broken due to crystallization of water and association of amylose molecules, as well as a redistribution of amylopectin in swollen starch granules (Vermeylen et al., 2004; Van Hung et al., 2006). In addition, a growth of ice crystals happens during frozen treatment. The dissolution of ice crystals happens and it promotes differences in local concentration of amylose and amylopectin. The increase of the local concentration of amylose and amylopectin could be cause by the formation of aggregated; it leads to shrinkage and disruption of swollen starch granules (Alvarez and Canet, 1999). It is important to mention that the growths of intercellular ice crystals, as well as their dissolution, are related to the time of frozen storage. Because of this, it is possible to find relationship between experimental evidences defined by others authors with the experimental results obtained in this work.

Once obtained viscosity values, these data were fitted to Ostwald Waele model, since this model described very well the flow behaviour of analyzed samples, for each temperature and time of frozen storage. For all cases, R^2 values were greater that 0.999.

Figure 3 was plotted to describe the influence of temperature and time of frozen storage on the consistency and flow index in all analyzed cases. It can be observed that *n* has a value less than unity in all cases. It indicates a pseudoplastic behaviour of analyzed samples. In relation with the dependence of flow index with temperature, it was observed a strong detrimental effect on flow index values when samples were submitted to freeze-thaw treatment. On the other hand, consistency index values experimented a diminution with respect to temperature, although these values shown an ascending trend with respect to time of frozen storage. These values presented a linear trend with temperature and with the time of frozen storage.

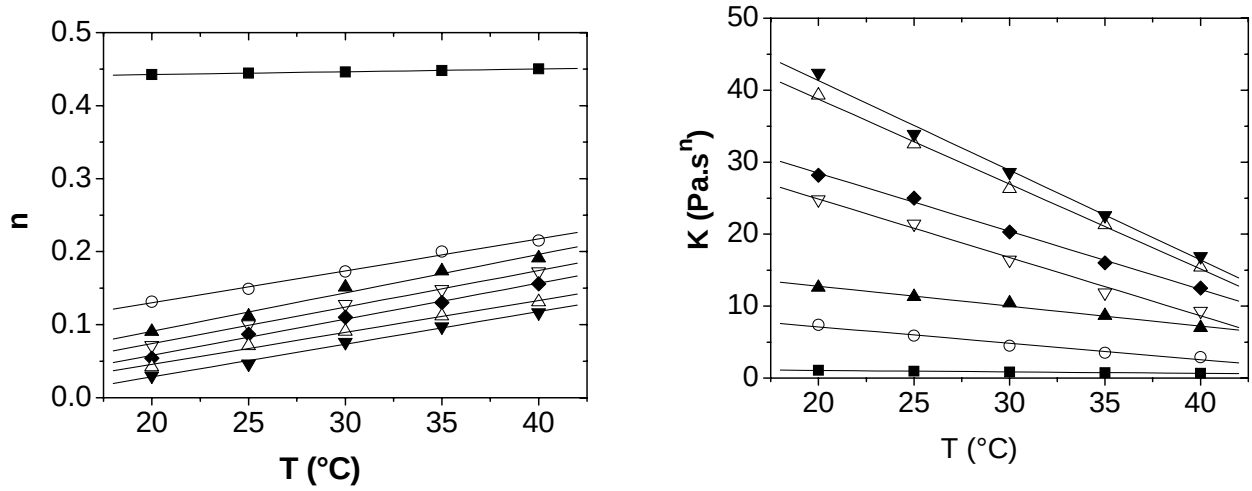

Figure 3. Flow and consistency index at different time of frozen storage: (■) 0 Week, (○) 1st Week, (▲) 2nd Week, (▽) 3rd Week, (◆) 4th Week, (△) 5th Week, (▼) 6th Week

Activation Energy

In the literature, the Arrhenius model has been most widely used to describe the effects of temperature. Therefore, an equation type Arrhenius (Eq. 2) was used to determine and quantify the temperature effect on the consistency index during the heating and shearing program.

$$K = K_T \, e^{\left(\frac{E_A}{RT}\right)} \tag{2}$$

where K is the consistency coefficient (Pa.s^n), K_T is Arrhenius constant (Pa.s^n), E_A is the activation energy (KJ/mol), R is the gas constant and T is the temperature (K). Constants of the Arrhenius model are displayed in Table 1.

Table 1. Parameters of Arrhenius Model.

Time of frozen storage (weeks)	E_A (KJ/mol)	R_T (Pa.s^n)
0	19	$5.4 \cdot 10^{-4}$
1	37	$2.2 \cdot 10^{-6}$
2	22	$1.6 \cdot 10^{-3}$
3	39	$3.1 \cdot 10^{-6}$
4	27	$5.2 \cdot 10^{-4}$
5	33	$4.5 \cdot 10^{-5}$
6	34	$4.5 \cdot 10^{-5}$

From the results, it can be concluded that the effect of temperature is lightly significant in all studied cases.

4. Conclusions

The Ostwald Waele model was effective to describe the rheological behaviour of mushroom cream behaved as a pseudoplastic fluid. The samples exhibited a reduction viscosity when these were suffered a shearing and heating program, when the used temperature was always smaller to the gelatinization temperature of starches. Furthermore, viscosity increased in all cases when they were exposed to freeze-thaw treatment with respect to not treated samples.

The consistency index presented a downward linear trend with respect to temperature and increased linearly with the time of frozen storage. On the other hand, the flow index increased linearly with temperature and presented a clear downwards trend with the time of frozen storage. Finally, Arrhenius model was used to describe the effects of temperature on the consistency index, observing a high dependence with respect to the temperature.

The Effect of operating conditions on styrene bulk polymerization in a spinning disk reactor

S.Mohammadi, M.Alavi [1], M.R.Moghbeli
Chemical engineering Department, Iran university of Science and Technology(IUST), Farjam Str., Tehran, Iran

Abstract: in this paper the influence of operating parameters on performance of spinning disk reactor (SDR) in styrene bulk (without solution) polymerization by 2, 2-azobisisobutyronitrile (AIBN) as an initiator has been studied. The parameters that used for this study are temperature initiator, disk speed and pre-polymer conversion. The results are compared to those observed in a stirred batch reactor. It is believed that centrifugal and shear conditions on rotating disk are the reasons of enhancements in the rate of free radical polymerization.

Key words: bulk polymerization, polystyrene, spinning disk reactor, stirred batch reactor

Introduction

Free radical polymerization technique is widely used by industry for polymerization of styrene. Industrial polymerization process has been traditionally carried out in large stirred tanks. In the market world quality is one of the most important parameters of competition. SDR reactor technology uses centrifugal accelerations to create thin highly sheared films on rotating surfaces so it provides good mixing as well as high mass and heat transfer [1,2]. These characteristics can solve problems of bulk process significantly in high polymer concentration and viscosity during polymerization and we can have uniformity in the mixture. Excellent mixing as well as plug flow characteristics should aid in producing polymer products characterized by narrow molecular weight distribution [3,4]. In the application of the spinning disk technology time scale is the other benefits in polymerization process.

2. Experimental

2.1. Material

Styrene monomer and 2, 2-azobisisobutyronitrile (AIBN) as initiator from Merck Co are being used for experiments.

2.2.Apparatus

Stirred tank reactor

The apparatus used for this study, consisted of a batch reactor and a spinning disk reactor (SDR). The batch consisted of 250 ml capacity volume Pyrex flat glass .the reactor stood in water bath in the center of a magnetic plate which together with a magnetic stirrer in the reaction mixture was used to provide uniform temperature and polymer melt. a thermometer was inserted in the water bath.

SDR

[1] Corresponding author. Tel +982173912716. E-mail:alavi.m@iust.ac.ir

It consists of a chamber enclosed in water cooled housing; the chamber is located on a double pipe rotating shaft driven by an electric motor. The rotating disk system is made of stainless steel 316 and was 20 mm in diameter. The surface of disk is smooth. The disk is rotated by an electromotor positioned on the central shaft, which supported double disk arrangement. The speed of disk is variable by inverter system that is connected to the rotating shaft. The system can used to vary the disk speed in the range 0-3000 rpm. Several copper coils are around the out side of reactor for preventing further polymerization and cooling the product. The temperature of disk is controlled by continues flow of water through a narrow channel underneath it. The water is pumped from a temperature – controlled water bath up the central shaft pipe and is returned to the bath through the outlet shaft pipe. Performance of heating cooling system is shown in figure1

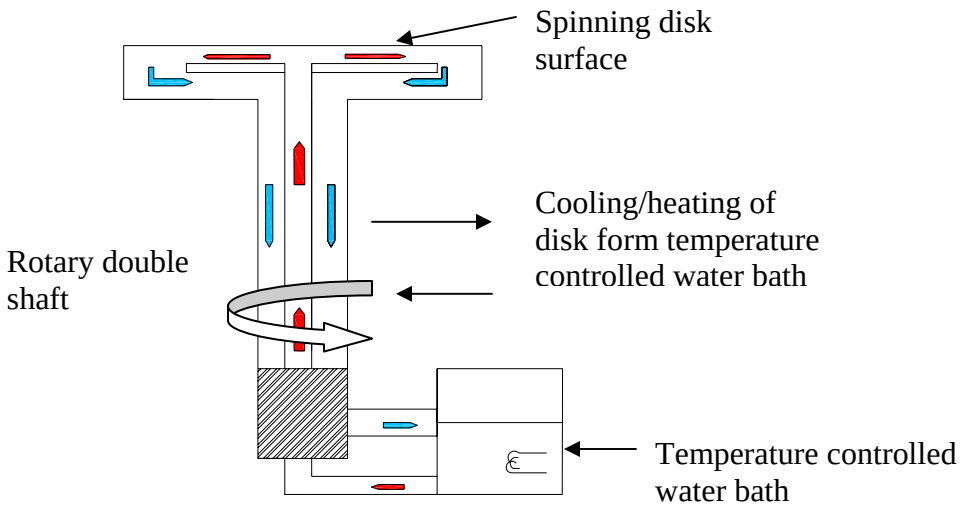

Figure1. internal heat transfer system of SDR

Various parameters for flow on the spinning disk surface have been derived on the basis of centrifugal model.[5] The SDR parameters of interest in this study are the disc residence time t_{res} and the average shear rate $\dot{\gamma}_{ave}$ as expressed in eqs (1),(2)respectively.[5,6]

$$t_{res} = \left(\frac{81\pi^2\nu}{16\omega^2 Q^2}\right)^{1/3}\left(r_o^{4/3} - r_i^{4/3}\right) \quad (1)$$

$$\dot{\gamma}_{ave} = 1.5\left(\frac{Q\omega^4 r}{18\pi\upsilon^2}\right)^{1/3} \quad (2)$$

The mean residence time represents the contact time between the various
Reacting species on the rotating disc while the average shear rate characterizes the degree of mixing achieved in the reacting film.

3.3. Polymerization procedure

3.3.1. Polymerization in batch reactor

Tests were carried out to investigate the effectiveness of the spinning disk on bulk polymerization of styrene. 200 ml styrene polymerized with (0.5-1.5 %) w/w AIBN as initiator at (70-90) °C. Samples were taken every 20 minutes for determining the conversion.

3.3.2 Polymerization in SDR.

Polymerization in SDR consists of 2 stages 1-pre-polymerization in batch as described above and SDR polymerization. The pre-polymer mixture containing monomer polymer and initiator was fed to the center of disk by feeder. Centrifugal forces created by disk rotation force the liquid to flow over the disk surface in the form of a very thin film, after reaching the edge of disk, the product gets thrown off the surface, hits the cold walls and collect for analysis.
The disk temperature (70, 80, 90°C), pre-polymer conversion (32-61%) initiator (0.5, 1, 1.5%w/w) and the disk speed (400-1500rpm) were varied.

4. Results and discussion

4.2 Spinning disk reactor

4.2.1. Effect of pre-polymer feed conversion

The conversion results of runs in SDR can be seen in fig 2. In this experiment different feed conversions are led to disk and as it has shown by increasing feed conversion, there is an increase in product conversion. As we know by proceeding polymerization the viscosity of mixture will be increased so at fixed rotating speed the residence time will be increased so the liquid has higher time exposure on disk and polymerization proceed to higher conversions.[5] The batch time means the time that need to reach to the same conversion in the batch.

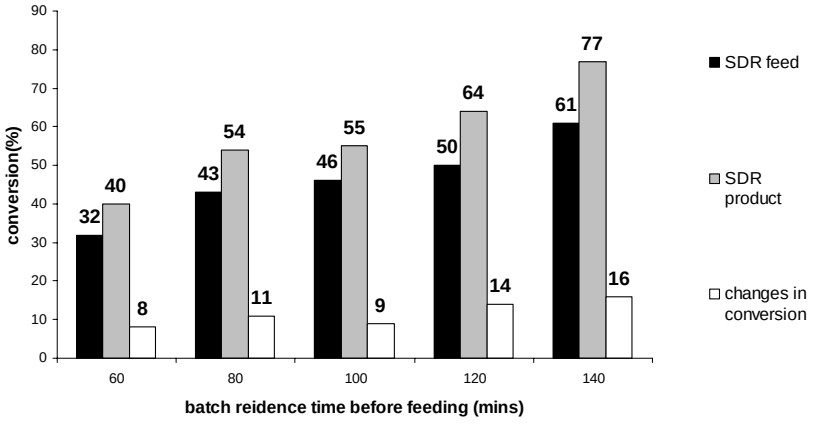

Figure2. Effect of pre-polymer conversion at fixed speed of 1500rpm in SDR

4.2.2. Effect of disk speed

The changes in conversion of the polymer collected from spinning disk surface at disk rotational speeds in the range 400-1500 rpm and fixed SDR feed conversion of 61% can be seen in figure 3. The maximum increase in conversion of 19.6% can be obtained at disk speed of 1500 rpm. By increasing the speed the residence time will be decreased but shear will increase and the shear has more influential role for increasing the conversion.

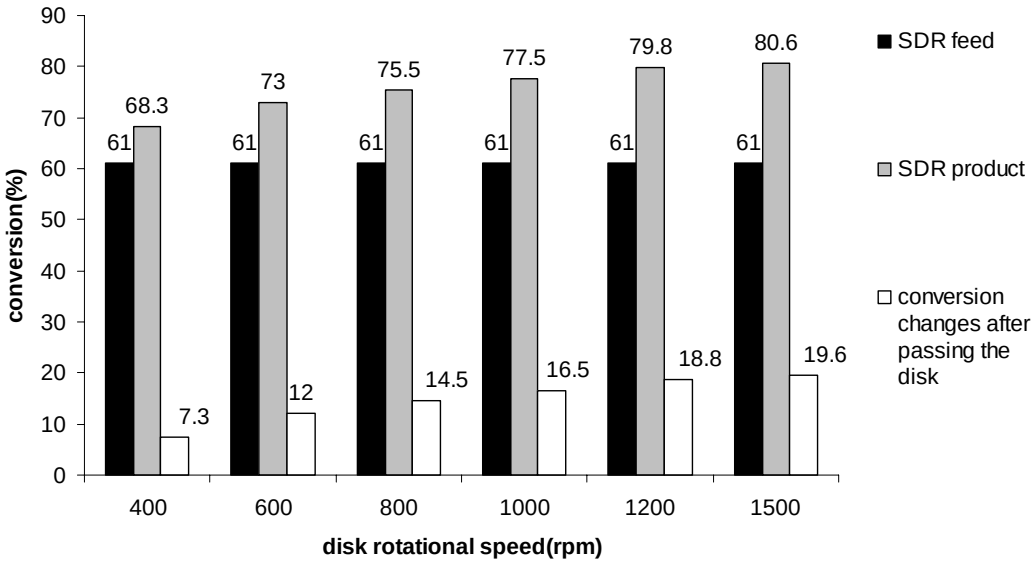

Figure3. Effect of disk speed at fixed pre-polymer conversion of 61%in SDR

For finding disk optimum speed in fixed pre-polymer conversion of 50% led to disk at different disk speed from 400-2000 rpm and the result is shown in figure4.

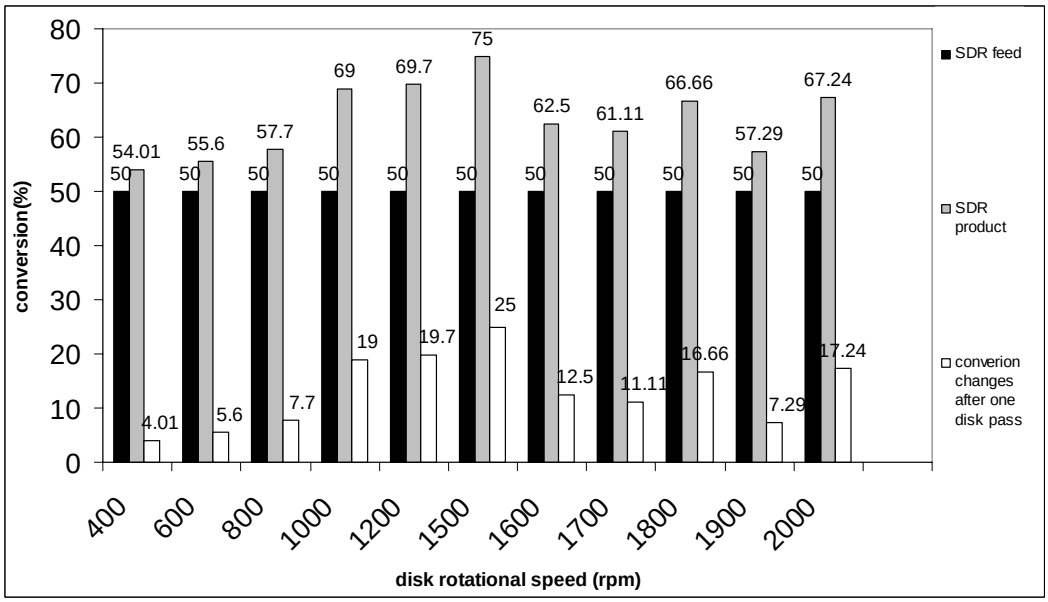

Figure4. Effect of speed on conversion in SDR at fixed pre-polymer conversion of 50%

As we can see after speed of 1500 rpm the conversion will be decreased and residence time is more influential than shear.

For finding an optimum pre-polymer conversion, We have done several tests with different pre-polymer conversion at different disk speed at fixed initiator concentration of 1% and fixed disk temperature 0f 70°C. The results are shown in figure5. As we can see the conversion of 50% has the most changes in one disk pass.

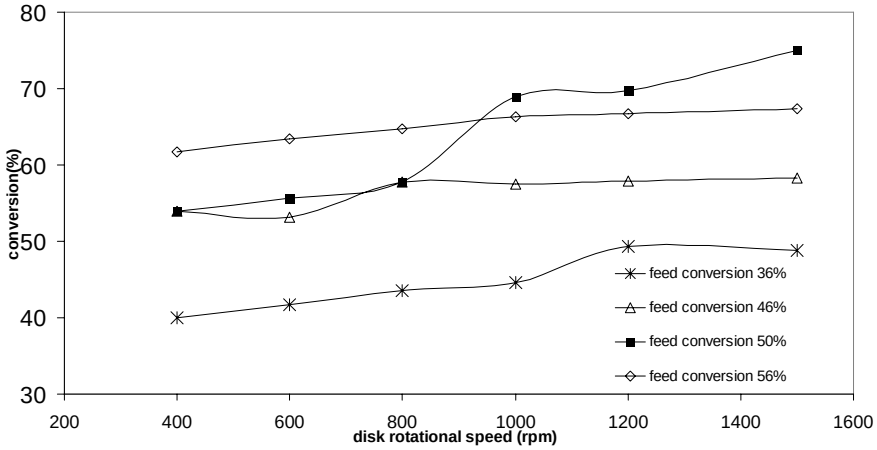

Figure5.effect of pre-polymer at different disk speed in SDR

4.2.3. Effect of temperature

For study the effect of temperature several tests have been carried out that the results are shown in figure 6. as we expected by increasing disk temperature at fixed pre-polymer conversion of 46% and fixed initiator concentration of 1%(w/w) the polymerization rate will be increased, so the conversion will increase.

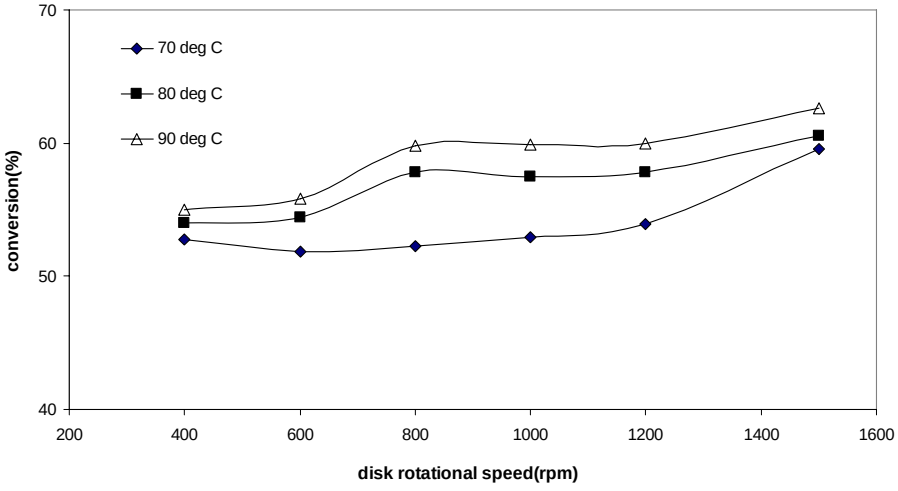

Figure6.Effect of disk temperature on conversion changes at fixed pre-polymer 46% in SDR

5. Conclusion

This work was carried out in an attempt to gain the optimum operating condition in SDR to have the highest changes in conversion of product of SDR at one disk pass. it is hoped that the finding of the effect of parameters, the work will forward our understanding the mechanism of SDR in bulk polymerization.

Topic: Advancing the Chemical and Biological Engineering Fundamentals

Abstract

Vinyl chloride (VC)/difunctional derivative copolymerization was carried out in the suspension process for preparing chemically crosslinked poly(vinyl chloride) (PVC). Effects of concentration of the divinyl monomer on the structure of crosslinked PVC (such as the gel fraction, polymerization degree of sol and crosslinking density of gel) were investigated. We could observe that the yield of crosslinking was dependent on the type of crosslink agent. The crosslinking efficiency of diallyl maleate (DAM) was higher than ethylene glycol dimethyl acrylate (EGDMA) Moreover, for DAM, it was possible to achieve a slight increase in the glass transition temperature of the obtained copolymers.

Introduction

The world consumption of poly(vinyl chloride) (PVC) in 2007 was around 33.5 million of metric tons, being the second polymer, considering the different types of poly(ethylene) (Bryen, 2007). Although the vast majority of applications are linked directly with its excellent mechanical properties, compatibility with additives, recyclability and good cost to performance ratio, the major disadvantages comes from its lower heat stability and, consequently, a limited range of final applications (Beltran *et al*, 1998; Yong-Zhong *et al*, 1999). To overcome these deficiencies, the application of the copolymerization technique intends to incorporate a new monomer on the poly(vinyl chloride) growing chain, in order to provide new properties or improve the original ones (Burgess, 1982)

A particular type of copolymerization, consists in the application of a small percentage of a difunctional (divinyl or diallyl) monomer to prepare a chemically crosslinked PVC (Burgess, 1982). Besides other properties, this technique has been continuously studied and developed for the production of special polymers for matte surfaces in top coated finished products (Amano *et al*, 1992; Yong-Zhong *et al*, 1999; Koga *et al*, 1997).

The crosslinked polymer normally follows significant changes on the structure and final behaviour of the material. If previous soluble in the presence of a solvent, the crosslinked polymer swells as the solvent penetrates the network, producing a solvent-swollen crosslinked polymer so called a gel (Stevens, 1990).

The denominated crosslinking agents, such as divinylbenzene, glycol dimethyl acrylate, diallyl maleate or phthalate, have been reported on the literature as efficient gel promoters (Burgess, 1982).

The aim of this paper was to study the effect of new difunctional monomers, like diallyl maleate (DAM), ethylene glycol dimethyl acrylate (EGDMA), polyethylene glycol dimethyl acrylate (PEG Mn: 550) and the correspondent high molecular weight (PEG Mn: 750). Also, besides the study of the effect of co-monomer dosage on the obtained gel fraction, the study of the correspondent glass transition temperature (Tg), could give us a valuable information over the produced copolymer and potential market applications.

Experimental

Chemicals

Vinyl chloride monomer (VCM) from Shin Etsu B.V. (purity 99.99% (w/w) from chromatographic method). Deionized industrial water (conductivity < 10µS.m^{-1})
Dially Maleate, tech. (purity min. 93%) (DAM), Ethylene glycol dimethyl acrylate (purity min. 98%) (EGDMA), Polyethylene glycol dimethyl acrylate (PEG Mn: 550), Polyethylene glycol dimethyl acrylate (PEG Mn: 750) from Sigma Aldrich.
Suspending agents: Partially hydrolyzed poly(vinyl alcohol) with 72.5% (PVA 72.5) and 88% (PVA 88) hydrolysis degree (purity min. 95%) – commercial grades from Synthomer Ltd.
Initiator: Tert-butyl peroxydeodecanoate (purity min. 95%) – commercial grade from Akzo Nobel Polymer Chemicals BV.
Tetrahydrofuran (THF) (purity min. 99.9%) and Cyclohexanone (purity min. 99.5%) – chemically pure grades from Riedel-den Haën

Polymerization

The polymer samples studied in this work were prepared in a 150dm^3 pilot reactor equipped with a blade agitator and an external jacket. All standard procedures are described in the literature (Burgess, 1982; Butters, 1982).
The partially hydrolyzed poly(vinyl alcohol) grades were used as colloidal protectors and were dispersed in the deionized water during the reactor charge sequence.
The free radical generator was an organic peroxide (Tert-butyl peroxydeodecanoate), half life 3.9h at 53ºC, and it was charged after the vacuum operation into the reactor mixture.
The polymerization reactions were carried at constant temperature (53ºC), and the unreacted monomer was recovered when the reactor pressure reached 6.60 bar G.
The concentration on monomer (VCM) mass and absolute quantities of water and chemicals are shown in Table 1.

Table 1: Standard Recipe for the VCM polymerization with divinyl monomers.

Chemical	% (on VCM)	Mass, g
Vinyl chloride monomer	--	37000
Deionized water	190.0	70300
PVA 72.5	0.055	20.4
PVA 88	0.012	4.44
Initiator	Variable	
Divinyl monomer	Variable	

The amount of divinyl monomer was variable considering the initial mass concentration based on VCM.

Separation and structure characterization of the sol and gel

A dry sample of polymer was immersed in THF to swell at ambient temperature (20ºC) for 24h. After that, the swollen gel was centrifuged and weighed before the drying operation at 50ºC to obtain the sol. The gel fraction (w_g) of polymer is the ratio of the weight of the dry residue to that of the original resin. The molecular weight (M_c) between crosslinks was determined according to the Flory–Rehner equation (Flory, 1950), according to Eq. (1):

$$M_c = \frac{-\rho_{PVC} \cdot V_{THF} \cdot V_2^{1/3}}{\ln(1 - V_2) + V_2 + \chi \cdot V_2^2} \quad (1)$$

Where, ρ_{PVC} is the density of PVC (1310 kg.m^{-3}), V_{THF} is the molar volume of THF (0.0811 dm^3.mol^{-1}), χ is the polymer-solvent interaction parameter (0.14). The volume fraction of polymer in the swollen gel, V_2, was calculated according to Eq. (2):

$$V_2 = \frac{1}{1 + \frac{\rho_{PVC}}{\rho_{THF}} \cdot \frac{w_s - w_0}{w_0}} \quad (2)$$

Where, ρ_{THF} is the density of THF (0.889 kg.dm^{-3}), w_s is the weight of the swollen gel, and w_0 is the weight of PVC.

The crosslink density (ν) was determined from M_c (Eq. 1) as reported in Eq. (3):

$$\nu = \frac{\rho_{PVC}}{M_c} \quad (3)$$

The gel fraction (w_g) is calculated according to Eq. (4):

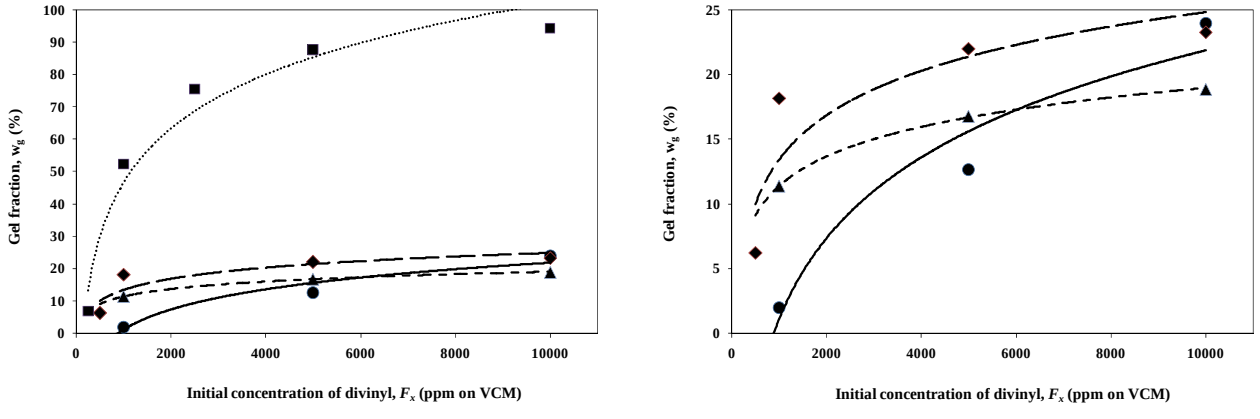
$$w_g = \frac{w_s}{w_0} \quad (4)$$

Following the industrial standards, the molecular weight distribution of PVC is estimated from the dilute solution viscosity measurements. According to a reduced viscosity method (ISO 1628-2), using cyclohexanone as the solvent based component for the polymer solution, the Fikentscher "K- value" was determined.

Results and Discussion

Crosslinking Efficiency of Different Divinyls

The polymerizations with a mixture of VCM and the selected divinyl monomers were carried out according to the stated recipe and procedure. After the reaction, the polymer samples were dried in a fluidized bed until a moisture content target lower than 1% (w/w) was reached. The effects of the initial concentration of each divinyl monomer F_x (mass concentration on VCM) on the obtained gel fraction of copolymer are shown in Fig. 1.



a) b)

Figure 1: Effect of the initial concentration (F_x) of each divinyl monomer on the obtained gel fraction (w_g): (●) VC/PEG Mn550; (♦) VC/PEG Mn750; (▲) VC/EGDMA; (■) VC/DAM.

From Fig. 1 it is possible to conclude that the gel fraction (w_g) increases with the dosage of divinyl co-monomer. Nevertheless, the curve behaviour is different for each divinyl, namely

the gel fraction of VC/DAM copolymer increases rapidly with F_x and a high gel fraction is achieved at a relatively low dosage. The gel fraction of VC/EGDMA copolymer increases slowly as F_x increases, but and it difficult to obtain a crosslinked polymer with a gel fraction higher than 19% (w/w). Also, it seems that the different types of EGDMA have a different behaviour at lower dosage. In fact, for F_x equal to 1000ppm, the PEG Mn550 produced the lower gel fraction (2%), followed by a steady increase in EGDMA (11%) and PEG Mn750 (18%). Although these relative differences are kept lower for higher F_x values, PEG Mn550 and Mn750 had a similar final performance (≈24%).

The different behaviour of the VC/Divinyls in the copolymerization and the different crosslinking efficiencies, are strictly correlated with the reactivity ratios of each pair of VC/Divinyl monomers. In the previous work of Yong-Zhong *et al* (2000), some of the reactivity ratios of VC/ Divinyl monomers were published following the Mayo-Lewis equation for a standard free radical copolymerization system (table 2).

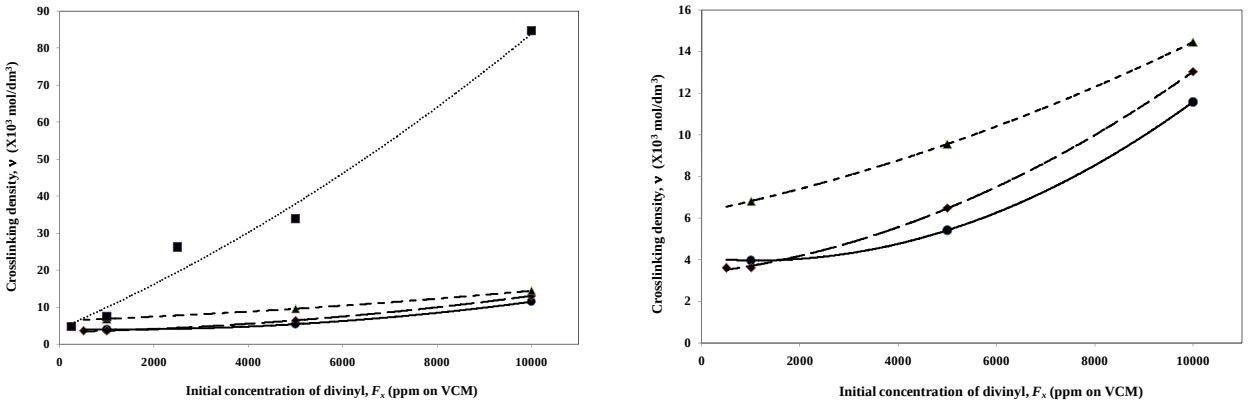
Table 2: Reactivity ratios of VC/crosslinking monomers at 45ºC (Yong-Zhong *et al*, 2000).

(second monomer-2)	DAM	EGDMA
r_1	0.425	0.844
r_2	0.480	23.1
r_1/r_2	0.885	0.0365

From the data in Table 2, It is possible to see that r_1, r_2 of VC/DAM are smaller than 1, showing is copolymerization tendencies. Also, r_1 of VC/EGDMA is smaller than 1, but r_2 much greater than 1, showing the strong tendency of EGDMA towards homopolymerization. Thus, the gel fraction of VC/EGDMA copolymer and the crosslinking efficiency of EGDMA are lower. Moreover, although the reactivity ratios are not published for VC\PEG Mn550 and VC\PEG Mn750, from the obtained results, it is possible to conclude that those reactivity ratios should be similar to the ones of VC\EGDMA system.

Crosslinking Density of Different Divinyls

From the stated calculation procedure (eq. 3), fig. 2 shows that the crosslinking density (ν) of the gel. Again, the major differences in the results of DAM are observed in Fig. 2a).



a) b)

Figure 2: Effect of the initial concentration of each divinyl monomer on the crosslinking density of the gel (ν). (●) VC/PEG Mn550; (♦) VC/PEG Mn750; (▲) VC/EGDMA; (■) VC/DAM.

The crosslinking density increases gradually with the increase of the gel fraction, nevertheless for EGDMA, PEG Mn550 and PEG Mn750, there is only a steady increase to 12~14 x10^3 mol.dm^{-3} (fig. 2b). For DAM, the gel fraction becomes noticeable higher for higher divinyl dosages. These results are in direct tune with the higher crosslinking efficiency of DAM.

K Value of Sol for Different Divinyls

The effect of the concentration of each divinyl monomer on the K value of sol is shown in Fig. 3.

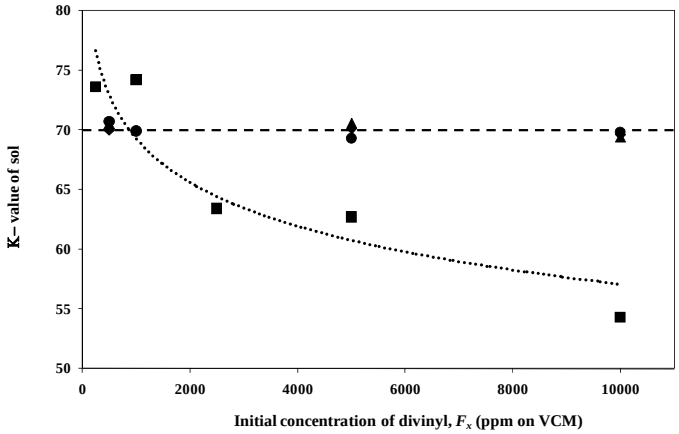


Figure 3: Effect of the initial concentration of each divinyl monomer on the K value of sol: (--) K value homopolymer; (●) VC/ PEG Mn550; (♦) VC/ PEG Mn750; (▲) VC/EGDMA; (■) VC/DAM.

Besides the known dependence of the reaction temperature, there is a sudden decrease in K value only for a concentration of DAM higher than 1000 ppm. That is, it seems that only for a very high gel fraction (>50%), there is a lowering effect of the K value of the sol. Thus, comparing with the homopolymer data, for an efficient gel promoter like DAM, the longer primary chains will have a higher probability of participating in the crosslinking reaction.

Glass transition (Tg) for Different Divinyls

The glass transition temperature was determined by Differential Scanning Calorimetry (DSC) according to a standard procedure for poly(vinyl chloride). In fig. 4 it is shown the Tg for each polymer sample.

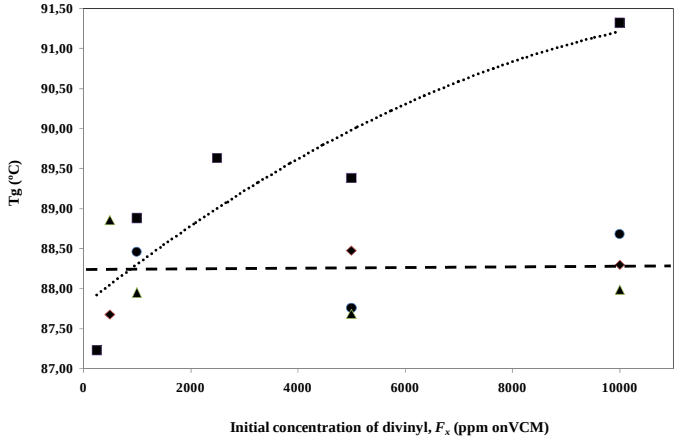

Figure 4: Effect of the initial concentration of each divinyl monomer on the Tg of the copolymer: (--) Tg homopolymer; (●) VC/PEG Mn550; (♦) VC/PEG Mn750; (▲) VC/EGDMA; (■) VC/DAM.

Although the data variation around the homopolymer target (88.48º), mainly related with the fluctuations from the polymer production process, it is possible to observe in Fig 4. an increase trend of Tg with the DAM dosage. This result it's in tune with the fundamentals of the Tg definition, mainly the modifications in the polymer chemical structure by a lower molecular free volume or rotational freedom, related with the crosslinking effects in the carbon chains.

Conclusions

Chemically crosslinked PVC can be obtained by VC/difunctional monomer suspension copolymerization. Its structure is influenced by the concentration of the difunctional monomer and the correspondent reactivity with VCM. The crosslinking efficiency of the divinyls changes in the following order of relative magnitude: DAM>>PEG Mn750>PEG Mn550>EGDMA. The crosslinking efficiency of EGDMA is very low due to its higher probability of homopolymerization. Also, the similar behaviour of PEG Mn750 and PEG Mn550, induces the fact that the correspondent reactivity ratios should be within the same range of the system VC\EGDMA. The crosslinking density of the gel increases as the concentration of the divinyls increases, but markedly for DAM rather than all the others. Also, for DAM, the K value of the sol of the copolymer decreases with the increase of the gel fraction. The opposite effect is observed for the glass transition temperature (Tg), with an abrupt increase of more than 2.5ºC, from the standard homopolymer, when the gel fraction reached over 90% (w/w).

Topic: Advancing the chemical engineering fundamentals.

Introduction

Since the discovery of controlled radical polymerization (CRP) in the early nineties (Georges et al., 1993), an ever increasing activity has been focused on the production of polymers with narrow molecular weight distributions and well-defined architectures (such as block copolymers, stars or brushes). This work describes an experimental research on the nitroxide-mediated radical polymerization (NMRP) of styrene (S) and divinylbenzenes (DVB) in xylene (X) solution at 130 °C, using the stable radical TEMPO (2,2,6,6-tetramethylpiperidinyl-1-oxy) as mediator and AIBN (azobisisobutyronitrile) as initiator. Measurements of absolute molecular weights and *z*-average radius of gyration of the produced copolymers have been performed for different polymerization times using a SEC system with coupled refractive index (RI) and multi-angle laser light scattering (MALLS) detectors.

The main difference between conventional free radical polymerization (FRP) and NMRP is due to the dynamic equilibrium described by Eq. (1), where $-\mathrm{P}^{\bullet}$ represents an active polymer radical, X a stable radical (e. g. TEMPO) and $-\mathrm{P}-\mathrm{X}$ a dormant alkoxyamine:

$$-\mathrm{P}^{\bullet} + \mathrm{X} \underset{k_{act}}{\overset{k_{deact}}{\rightleftharpoons}} -\mathrm{P}-\mathrm{X} \tag{1}$$

This intermittent equilibrium reduces substantially the concentration of active radicals and concomitantly the probability of termination. Consequently, the expected life time (t_l) of a polymer molecule in NMRP attains several hours, in contrast with the few seconds characteristic of FRP, as described by Eq. (2):

$$t_l = \frac{R}{r_t} \simeq \frac{1}{2k_t R} \tag{2}$$

with R representing the concentration of active radicals, r_t the rate of termination and k_t the correspondent rate coefficient. Is therefore possible to reduce the frequency of termination of polymer chains to levels below 5% , the result being a huge increase in the homogeneity of the products. Nowadays, besides NMRP other CRP techniques like Atom Transfer Radical Polymerization (ATRP) or Reversible Addition-Fragmentation Chain Transfer Polymerization (RAFT) are used with the aim of synthesizing

* Corresponding author. Tel. +351-273-303088. E-mail: rdias@ipb.pt.

more homogeneous linear polymers. More recently these concepts have been extended to non-linear polymerizations by trying to obtain also more homogeneous polymer networks with potential applications as advanced materials (Ide and Fukuda, 1997, 1999; Achilleos et al., 2007; Gao et al., 2008). Considering the NMRP of S/DVB, here we also show that a recently developed general kinetic approach can be used to assist in the design of such branched polymers.

Experimental Part

Experiments were carried out at 1 dm^3 scale using a 2.5 dm^3 maximum capacity stainless steel semi-batch reactor which has been described in detail elsewhere (Gonçalves et al., 2007). In this work the reactor was operated only in batch mode. Xylene at 98.5% purity, AIBN at 98% purity, TEMPO at 98% purity, styrene stabilized with 0.005% w/w 4-tert-butylcatechol at 99% purity and commercial grade divinylbenzene stabilized with 0.1% w/w 4-tert-butylcatechol at 80% purity have been purchased from Sigma Aldrich and used as received. That commercial DVB is a mixture of isomers, comprising 56.2% m-divinylbenzene and 24.2% p-divinylbenzene, plus 19.6% of ethylvinylbenzene. Xylene solvent is also a mixture of xylenes plus ethylbenzene ($\leq$ 25% in the latter component). Typically, NMRP and conventional S/DVB copolymerizations were carried out as follows: the empty reactor was purged with an argon stream (40 cm^3/min) and the heating process in order to reach 130 °C was started. After 15 min, the predetermined amounts of styrene, xylene, divinylbenzene and TEMPO (in NMRP experiments) were charged to the reactor. Until completion of the heating process the polymerization system was bubbled with argon at a flow rate of 40 cm^3/min. Owing to energy losses and insufficient heating power, around 100 and 120 min were needed to reach the set-point temperature of 130 °C in the conventional and NMRP experiments, respectively. This difference is caused by the heat generated by the auto-initiation of styrene in the conventional runs during the heating period. When the set-point was reached, samples of polymer were withdrawn from the reactor to be analyzed by SEC/RI/MALLS and immediately afterwards AIBN was added to the system, defining the initial time of the polymerization $t = 0$. The analysis of these samples has confirmed the existence of some thermal initiation of styrene during the heating process in conventional runs (monomer conversion of about 4 % was experimentally measured) and conversely, the absence of this phenomenon in the NMRP experiments has been found. After $t = 0$ samples of polymer were withdrawn from the reactor at prescribed polymerization times and analyzed by SEC/RI/MALLS. During the polymerization process the flow rate of the argon stream spargeing the system was reduced to 20 mL/min in order to prevent appreciable mass losses from the reactor, since it is operated at atmospheric pressure and the polymerization temperature is close to the xylene boiling point (around 140 °C).

Kinetic Modeling

Based upon a work started in the early nineties (Costa and Dias, 1994), it has been recently shown that molecular size distributions (MSD), sequence size distributions (SSD) and *z*-average radius of gyration distributions (RGD) can be predicted for complex irreversible non-linear polymerization systems (Costa and Dias, 2005, 2007; Dias and Costa, 2006, 2007). Besides the detailed molecular architecture which becomes feasible to describe, this general kinetic approach is valid for different kinds of reactors (batch, plug flow, semi-batch or CSTR) and is free of several mathematical simplifications with non-universal applicability. Moreover, this approach allows the development of a computational tool that can be used to simulate different polymerization systems in an automated fashion. Eqs. (3), (4) and (5) are the general master equations allowing the prediction of the MSD, SSD and RGD after specification of the chemical

Table 1: Chemical groups and kinetic scheme considered in the modeling studies of NMRP of S/DVB.

groups and kinetic scheme of the polymerization system.

$$\frac{\partial G}{\partial t} = G_{\mathcal{R}_P} + \frac{G_F(t) - G}{\tau} - \mathcal{R}_v G; \qquad G_{|t=0} = G_0\left[\mathbf{s_0}(t, \mathbf{s})\right] \tag{3}$$

$$\frac{\partial U}{\partial t} = G_{\mathcal{R}_S} + \frac{U_F(t) - U}{\tau} - \mathcal{R}_v U; \qquad U_{|t=0} = U_0\left[\mathbf{s}_0(t, \mathbf{s})\right] \tag{4}$$

$$\frac{\partial G_n^H}{\partial t} = G_{\mathcal{R}_{H_n}} + \frac{G_{n\ F}^H(t) - G_n^H}{\tau} - \mathcal{R}_v G_n^H; \qquad G_{n\ |t=0}^H = G_{n\ 0}^H\left[\mathbf{s_0}^-(t, \mathbf{s}^-), \mathbf{s_0}^+(t, \mathbf{s}^+)\right] \tag{5}$$

In the present polymerization system, modeling studies were performed considering a kinetic scheme comprising a total of 36 chemical groups and 125 different chemical reactions, as briefly summarized in Table 1. Note that due to the existence of two isomers in commercial DVB, this polymerization system becomes more complex than a crosslinking process involving for instance pure diacrylates or dimethacrylates. Indeed, *m*-DVB, *p*-DVB and the correspondent pendant double bonds (*m*-PDB and *p*-PDB, respectively) have different reactivities (Gonçalves et al. (2007) and references therein) and therefore must be distinguished in the kinetic modeling. Moreover, due to the relatively high polymerization temperature (130 °C) which is required, other complex details arising from the thermal initiation of styrene must be taken into account in the present studies.

Results and Discussion

In Figure 1(a) is presented a typical kinetic plot showing the living character of a NMRP run. The modified monomer conversion $ln(M_0/M) = -ln(1-p)$ should roughly (after an initiation period) follow a linear growth with reaction time and this is confirmed with the experimental measurements presented in Figure 1(a). The predicted values were obtained using kinetic parameters available in the literature for linear NMRP polymerization systems (Zhang and Ray (2002), Fu et al. (2007) and references therein). Note that monomer conversion is almost not affected by the reactivities of *m*-PDB and *p*-PDB, since the concentrations of these species in the polymerization system is very low.

Figure 1(b) shows in detail the improved control of the molecular architecture achievable in NMRP synthesized polystyrene (PS) samples as compared to the FRP products. From the chromatograms of PS samples with different polymerization times shown in Figure 1(c) it is possible to observe the growth of molecular weights without concomitant broadening of the distribution. In fact, linear products with an

approximately constant polydispersity index (around 1.1) can be produced at increasing polymerization times (monomer conversions) using the NMRP technique.

Measured and predicted time evolution of $\overline{M}_n$ and $\overline{M}_w$ in a NMRP copolymerization of S/DVB with $y_{DVB} = 0.5\%$ and initial molar ratio TEMPO/AIBN=1.1 are presented in Figure 1(d). A good agreement between experimental observations and predictions is here observed using the reactivity of pendant double bonds as fitting parameters. It was estimated that the apparent reactivity ratio of PDB comparatively to styrene is $r = k_p^*/k_{p11} = 0.35$ (similar to the one found in Gonçalves et al. (2007) with FRP of S/DVB). It is plausible that the value of this reactivity ratio becomes affected by the effect of intramolecular cyclization reactions which were neglected in the present calculations. Indeed, these effects should be more important at 50% dilution as compared with bulk conditions used to estimate the equal reactivity of pendant vinyls in related works (Ide and Fukuda, 1997). An apparent decrease of the reactivity ratios of pendant vinyls with respect to the monomers has been found by these authors (Trigo et al., 2008) and other research groups (Gao et al., 2008) for other polymerization systems at diluted conditions, namely dimethacrylates and diacrylates, respectively.

Figure 1(e) compares the observed and predicted evolution of $\overline{M}_w$ for linear and non-linear polymer formation. The well-known linear growth of $\overline{M}_w$ for linear polystyrene does not occur with S/DVB copolymerization owing to the build-up of branched products. These results show that non-linear copolymerizations can be used to modify the properties of linear polymers with the goal of producing advanced materials (such as hyperbranched polymers). Figure 1(f) shows in detail the impact on the polymer molecular sizes of the presence of a small amount of DVB (about 0.5% mole fraction) in the NMRP polymerization system. A fraction of polymer molecules of molecular architecture close to linear polystyrene is present (showing an ill-separated peak at higher elution times) but most of polymer is branched.

Figure 2 compares experimental measurements (by SEC/MALLS) and theoretical predictions of the *z*-average radius of gyration of these non-linear polymers. This confirms the usefulness of the proposed kinetic approach namely to design with improved detail the molecular architecture of such materials. Note that results presented in Figure 2(b) show a more compact structure of NMRP S/DVB copolymers as compared with the FRP analogues. This means that the properties of these polymers can be manipulated in a known way through the use of CRP techniques.

Conclusions

Molecular architecture of NMRP S/DVB copolymers measured by SEC/MALLS shows important differences not only when compared with the linear case but also with respect to the FRP of the same monomers. It has now been shown that a recently developed general kinetic approach can deal with the complexities of this polymerization system, namely those caused by the huge number of different chemical species and involved reactions. The final goal of this research is to design hyperbranched polymers and networks with a well defined structure (which should be predicted by appropriate theoretical means) to be used for biomedical purposes or exploited as advanced materials. Earlier works on similar chemical systems (Ide and Fukuda, 1997) have now been extended with predictions and measurements of average molecular weights and radius of gyration of sol fraction. Likely influence of intramolecular reactions has been detected at 50 % dilution, showing that at best only in bulk conditions more or less ideal networks can be produced. Ongoing researches are expected to provide more assertive results.

Styrene polymerization under high shear

S. Mohammadi, M.R. Moghbeli, M. Alavi [1]
Chemical engineering Department, Iran University of Science and Technology(IUST), Farjam Str., Tehran, Iran

Abstract: free radical bulk polymerization of styrene with 2,2-azobisisobutironitrile (AIBN) as an initiator has been studied in a spinning disc reactor (SDR).multi pass technology has been used in this study. It is believed that multi passed product has better quality than one passed. The excellent heat and mass transfer that can be achieved in the highly sheared thin films that produced on the surface of disc due to centrifugal acceleration are the most important reasons of improving the product quality.

Keywords: polymerization, polystyrene, shear, AIBN

1-Introduction

Spinning disc technology has been demonstrated to achieve significant enhancements in free radical polymerization rate. [1, 2] it is believed that these enhancements are related to the centrifugal and shear conditions that exist on the disc. [2].

Bulk polymerization of styrene is a mass and heat transfer limited process. we have designed a thin film spinning disc reactor. This reactor provides good heat and mass transfer as well as micro mixing characteristics.
In bulk processes where the viscosity of the mixture increases by about seven orders of magnitude during the course of polymerization SDR can solve the problem. The occurrence of hot spots and temperature peaking results in broadening of the molecular weight distribution , he effects of which are translated into a poor polymer product quality.[3]
Benefits that can be obtained by using SDR are high quality of product, time saving, temperature controlling and high rate polymerization. In this study has been used multi pass disc and the data has been compared to those has been passed single time from the disc and also the data has been obtained from batch reactor.

2. Experimental

2.1.Materials

Styrene monomer and AIBN as initiator from Merck Co are being used for experiments.

2.2.Apparatus

The apparatus used for this study, consisted of a batch reactor and a spinning disc reactor (SDR). The batch reactor system shown schematically in figure 1 consisted of 250 ml capacity volume Pyrex flat glass .the reactor stood in water bath in the center of a magnetic plate which together with a magnetic stirrer in the reaction mixture was used to

[1] Corresponding author. Tel +982173912716. E-mail:alavi.m@iust.ac.ir

provide uniform temperature and polymer melt. A thermometer was inserted in the water bath.

A schematic of SDR reactor is shown in figure 1. It consists of a chamber enclosed in water cooled housing; the chamber is located on a double pipe rotating shaft driven by an electric motor. The rotating disc system is made of stainless steel 316 and was 20 mm in diameter. The surface of disc is smooth. The disc is rotated by an electromotor positioned

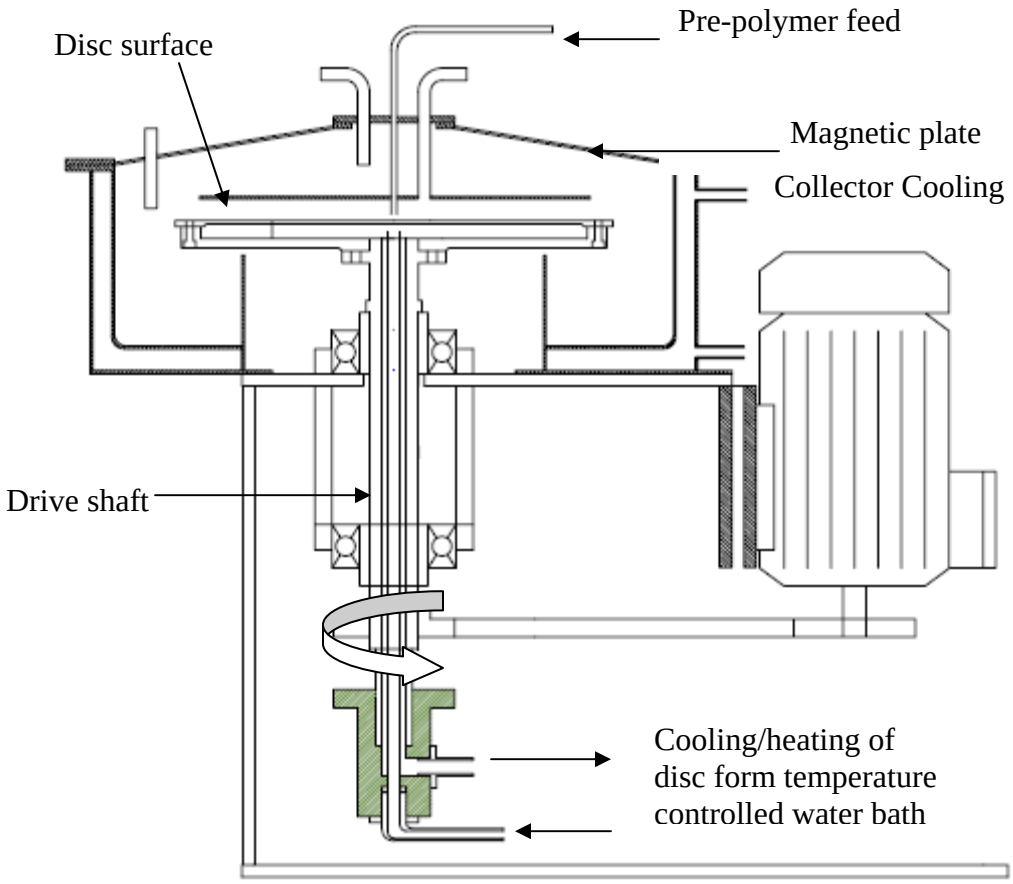

Figure 1. Schematic of spinning disc reactor

on the central shaft, which supported double disc arrangement The speed of disc is variable by inverter system that is connected to the rotating shaft. The system can used to vary the disc speed in the range 0-3000 rpm. Several copper coils are around the out side of reactor for preventing further polymerization and cooling the product. The temperature of disc is controlled by continues flow of water through a narrow channel underneath it. The water is pumped from a temperature – controlled water bath up the central shaft pipe and is returned to the bath through the outlet shaft pipe. The reactor set-up is shown in figure 2.

Figure2.Spinning disc reactor

3.3. Procedure

3.3.1.Polymerization in batch reactor

Tests were Carried out to investigate the effectiveness of the spinning disc on bulk polYmerization of styrene. 200 ml styrene polymerized with 1 % w/w AIBN as initiator at 70 °C. samples were taken everx 20 minutes for detarmining the conversikn. for experiments runs were perfmrmed each having different prepolymer stage eNding to conversion of 30% and 50% t(at has been chosen for this study.

3.3.2.Polymerization in SDR reactor

The SDR reactor(temperature of heating disc system) is set to 70°C and hot Pre-polymer from batch stage is fed into the center of disc through a feeder. centrifugal forces of rotating disc force the liquid to flow over the disc from the center to edge of surface in form of very thin film , the sheared film gets thrown off the surface, hits the cold walls and polymerization is being stopped. The product collected and conversion were determined. Polymer that collected from collector is being preheated and then fed in to the disc again and the product collected and conversion were determined and for 3 times the polymer is passed on the surface of disc.

4.Samples analysis

The quality of the polymer and conversion in the samples collected from the batch and spinning disc surface were assessed using gel permeation chromatography (GPC).

5.Results and discussion

5.1. batch reactor

The data that obtained from batch reactor is shown in figure 3.these test carried out for comparison of performance of SDR and obtained profile has been used as a standard.

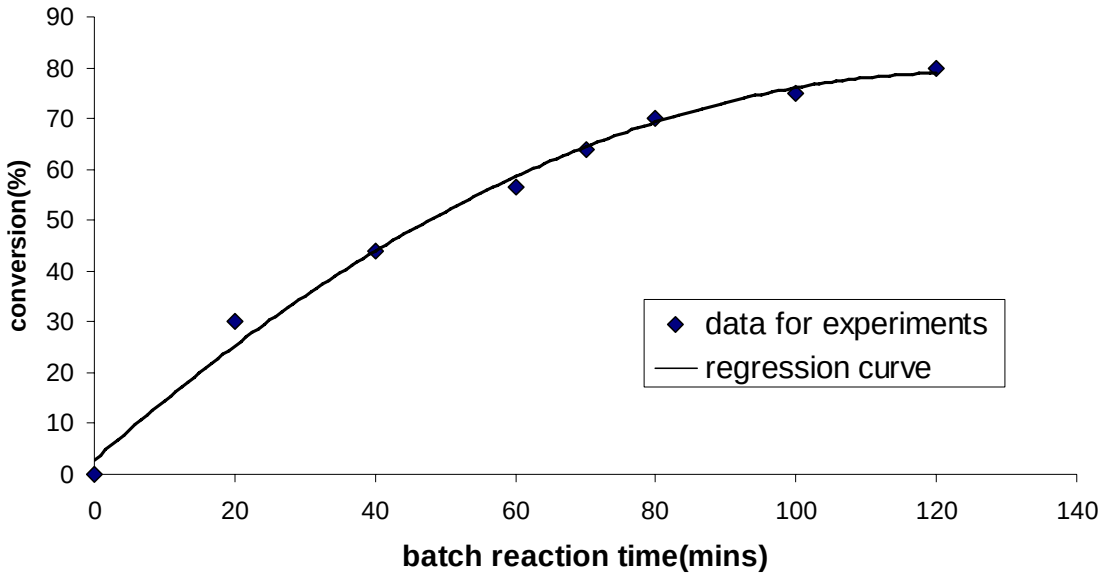

Figure3 .batch styrene polymerization profile

5.2 SDR reaCtor

Several test has been carried out tg study performance of SDR with fixed disc speed of 1500 rpm and different feed conversion. The general procedure of performing SDR runs include 4 steps: 1. preparation of feed (pre-polymer) in batah reactor that explained above 2. Transferring fee$ to disc.3 and 4 are transferring SDR product as feed to disc again. It means thap each beed step is the product of previous step.

5.2&1.Effect of pre-polymer conversion

The conversion result of runs are given in fig 4-5.
From fig 5,6 it can be seen that a rise in the conversion of feed in to the SDR is accompanied by steady increase in product conversion in one pass on the disc rotating at 1500 rpm. It is known that a direct proportionality relationship exists between the residence time on the disc and liquid viscosity, it is expected that the corresponding rise in exposure time on the spinning disc allows polymerization proceed to higher conversion.[4] In fig 5 the changes of conversion after each pass on the disc for prepolymer of 30% and in fig6 for pre-polymer of 50% can be seen.

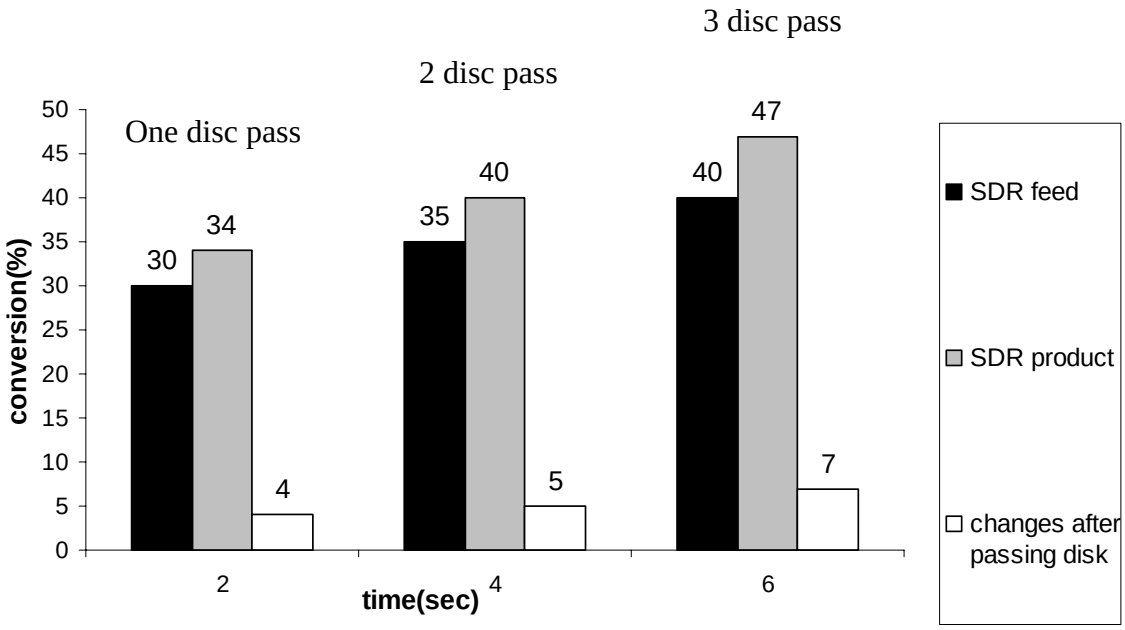

Fig4.Styrene polymerization changes after 3 disc pass for pre-polymer 30%

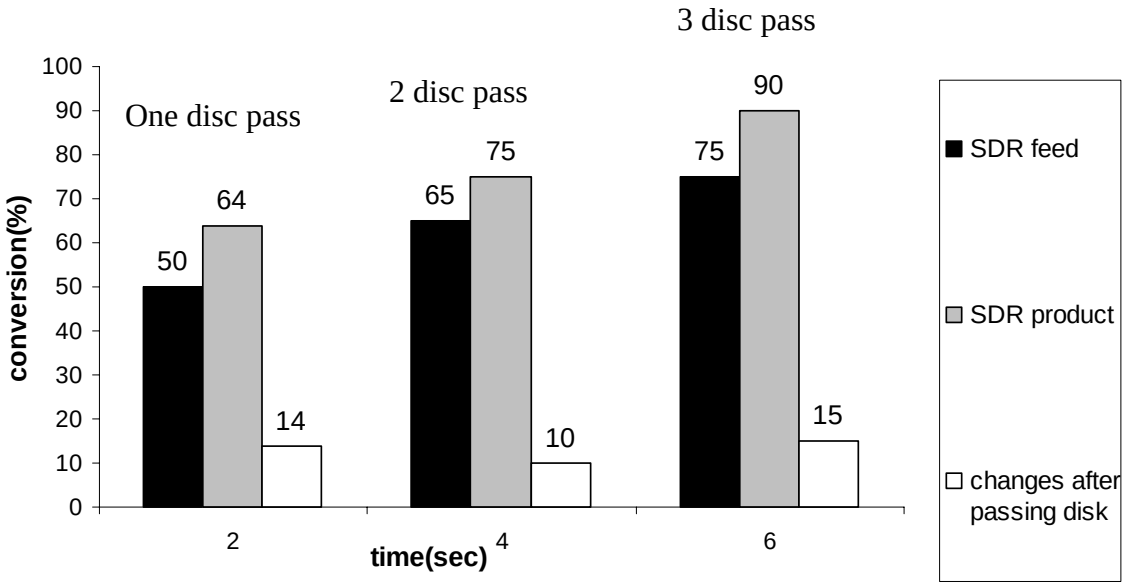

Fig5.Styrene polymerization changes after 3 disc pass for pre-polymer 30%

As it has shown in fig 5 and fig 6 total times for each step is 2 seconds and by comparing the results in fig 4 , 5 and fig 3 we can see the time saving by using SDR reactor.

Table1.Molecular weight properties of final polymer product from batch and SDR reactor

Reactor type	Conversion(%)	M_n(gr/mol*10^4)	M_w(gr/mol*10^4)	PDI
batch	30	2.3929	4.1132	1.71
SDR	34	2.3720	4.0479	1.70
SDR	45	2.4302	4.4441	1.82
Batch	50	3.0175	4.5394	1.5
SDR	75	2.3272	4.6965	2.018
SDR	90	2.7164	4.5299	1.667

results of GPC test has shown in table 1. a slight decrease in the number average and weight average molecular weight of the SDR product was observed compared with the pre-polymerized SDR feed as well as significant decrease in monomer concentration(increase in conversion) combined with a slight increase in polydispersity. As we can see multi passing has good effect on polydispersity of product.

Novel Stimulus Responsive Coating for Polystyrene Particles

Bruno Reis[1*], Simon Biggs[1]

[1] IPSE-SPEME – Institute of Particle Science and Engineering, School of Process, Environmental and Materials Engineering, University of Leeds, Leeds LS29JT, UK

Keywords: Stymulus-Responsive Polymers, Poly(N,N-Dimethylaminoethylmethacrylamide), Poly(N-Methylmethacrylate), Rheology Behaviour
Topic: Advancing the chemical and biological engineering fundamentals

Abstract

Smart or intelligent (co)polymers are materials which exhibit reversible changes in properties, in response to small physical or chemical changes in their environment. Our main purpose is to characterize novel stimulus responsive coatings on polystyrene latex particles which, in this case, are based upon in the coating with poly(N, N-dimethylaminoethylmethacrylate) (pDMAEMA)-poly(N-methylmethacrylate) (pMMA). For this stimulus responsive polymeric system, it was observed three pH regions of interest as function of temperature: (i) for pH below 5, the particles diameters underwent a monotonic rise with increasing pH and then reached a peak value of $\approx$380 nm, and the fluid presented Shear Thinning behaviour; (ii) from pH = 5 to 6, the hydrodynamic diameter remained constant and the fluid had Newtonian behaviour; (iii) from pH = 6 to 8.40, the diameter began to decrease and dropped to $\approx$230 nm and the fluid presented once again Shear Thinning behaviour. It was showed that the same transition occurs with different properties, by DLS and Rheology.

1 Introduction

Stimulus responsive polymers, also referred to as “intelligent”, “smart”, or “environmentally sensitive” polymers, are systems that exhibit large and sharp, physical or chemical reversible changes in response to small external changes in environmental conditions (Aguilar *et al*, 2007). The stimulus can be the exposure to the light (UV irradiation), a mechanic constraint, an application of an electric or magnetic field, changes in environmental conditions (like pH, ionic strength, temperature) or the polymer molecular weight and its polydispersity and tacticity. The applications of these kind of materials have wide ranging uses in areas such as: environmental (depollution of water), biomedical (Aguilar *et al*, 2007), biological molecules recognition (Gil and Hudson, 2004), pharmaceutics (drug-delivery systems), personal care products (shampoos, cosmetics) and agrochemical formulations (B. Jeong and A. Gutowska, 2002).

Particle surfaces can be modified to enhance properties by changing the chemical composition or the physical particle structure using polymeric materials. One approach is to synthesize intelligent latex particles by coating them with a stimulus-responsive polymer sheath (Yang *et al*, 2007). The polymer coating will expand or collapse depending of the applied stimulus. In the collapsed state, the particles are attracted to each other and can form an aggregate network where the solids are easily separated from the liquid phase. Switching the trigger (under appropriate conditions) will allow the particle system to re-disperse and form a stable dispersion (Binks (2004)). In this way, we may accurately control the dispersion properties.

1.1 Temperature Responsive Polymers

Some polymer solutions become cloudy upon either cooling or heating, due to the fluctuations in the refraction index caused by the partitioning into a polymer rich phase and a solvent rich phase. When a polymer solution exhibits a cloud point upon cooling, it is said to have an upper temperature critical solution (UCST), and upon heating a lower critical solution temperature (LCST) (Gil and Hudson, 2007). The phase separation and precipitation are reversible with no inherent limit in lifetime. Polymers such as poly (N,N'-diethyl acrylamide) (PDEAAm) exhibit a sharp phase transition in water (LCST) in the range of 25-35ºC (Gil and Hudson, 2004), poly(dimethylaminoethyl methacrylate) (PDMAEAMA) close to 50ºC (Aguilar *et al*, 2007) and poly (N-(L)-(1-hydroxymethyl) propylmethacrylsmide) close to 30ºC (Aguilar *et al*, 2007).

Although less popular and studied than pNIPAM, in terms of transition mechanism and also in specific applications, the scientific and practical interests for pDMAEMA are continuously increasing (Pagonis and Bokias, 2004). These poly (N-substituted acrylamides) are soluble in water and in polar organic solvents, with pDMAEMA being more hydrophilic than pNIPAM. Some applications of pDMAEMA based products have been proposed, ranging from two-phase catalysts to hydrogels for drug-delivery purposes or polymer supports for protein synthesis.

At very low temperatures, under its lower critical solution temperature, the solution is stabilized by the presence of hydrogen bonds between the amine groups, water and by ice-like structures which water molecules form around the hydrophobic groups. As the temperature increases, the hydrogen bonding weakens and the attraction between hydrophobic groups increases leading to an eventual demixing of the pDMAEMA chains, above the LCST (J. Koetz, 2001). The loss of entropy, by demixing, is more than compensated by the gain of entropy from the water molecules that lose their ice-like structure in the presence of dimethyl.

1.2 pH Responsible Polymers

pH-sensitive polymers are polyelectolytes that have, in their structure, weakly ionisable pendant groups, which can accept or release protons in response to changes in environmental pH, The pH-responsive polyelectrolytes can be divided in two main classes: weak poly(acid)s, that are dissociated at high pH, and weak poly(base)s that are protonated at low pH (Amalvy *et al*, 2003). When these polymers are near the critical pH, they gradually suffer a reversible transition in their conformation, from an expanded to collapsed state and most of them become water insoluble. The rapid change in hydrodynamic volume is caused by the variation in the charges that surround the ionic groups.

pDMAEMA is a pH responsive polybase where the amine groups, in its side chains, gain protons under acidic condition and release them under basic condition (Pagonis and Bokias, 2004). This polymer also has hydrophobic groups on the amine group. The nitrogen from pDMAEMA, under acidic conditions, is protonated giving rise to internal charge repulsion between neighbouring dymethyl groups. This leads to the expansion of the polymer overall dimensions. As the pH of the solution increases, the nitrogen becomes less ionised and the charge repulsion is gradually reduced giving rise to an increase of polymer-polymer interaction. When certain critical charge density is attained, conformational transition occurs (Amalvy *et al*, 2003).

The aim of this research is to characterize the stimuli responsiveness, colloidal stability and also the rheological properties of a novel stimulus responsive particle coating, polystyrene based upon poly (N, N-dimethylaminoethylmethacrylate) (pDMAEMA) - poly (N-methylmethacrylate) (pMMA). The styrene block is an excellent anchor point for linkers, however it has the disadvantage of being quite hydrophobic. Coupling pDMAEMA-pMMA to the styrene polymer should provide a greater range solvent compatibility over pure grafted DMAEMA or MMA.

2 Experimental

2.1 Material

Poly (N-methylmethacrylate) (pMMA)-Poly(N,N-(dimethylamino)ethyl methacrylate) stabilized polystyrene latex particles suspension, also known as pS/(pDMAEMA-pMMA), with a solid content of 11.9%, an average hydrodinamic diameter of 350 nm, a surface tension of supernatant of 70nm and a polydispersity index about 0.021 (DLS) were kindly provided by Dr. Syuji Fujii of Sheffield University.

2.2 Procedure

The hydrodynamic diameter and the size distribution of the pS/(pDMAEMA-pMMA) suspension, as a function of temperature, pH and salt concentration were measured using a BI-200SM Laser Light Scattering Goniometer (Brookhaven Insturments, Ltd.). A Zetasizer Nano ZS (Malvern Insturments, Ltd.) was used to measure the zeta potential as a function of the pH and KNO_3 concentration. A Bohlin C-VOR Rheometer was used to study the rheology at different pH values and solids concentrations.

3 Results and Discussion

3.1 Zeta Potential

Polystyrene and pMMA are hydrophobic and have a negative surface charge (zeta potential negative) at all pHs. pDMAEMA is more hydrophilic due to the protonation of the amine groups in water and has a positive zeta potential at low pH. Positive zeta potentials were detected at low pH values due to the cationic nature of the pDMAEMA brushes. Three experiments were undertaken to investigate how the zeta potential varies with pH and salt concentration in the system. The first measurement was carried out without any electrolyte and the other two with different KNO_3 concentrations, i.e 0.01 M and 0.1 M. The isoelectric point (IEP) of the particle suspension, without salt, was found to be close to pH 8. Below this pH the outer polymeric shell of the particles swells and pDMAEMA is found to dominate the zeta potential and the overall behaviour of the particles. For a pH above 8, the pDMAEMA shrinks and eventually collapses on the particle surface and the underlying polystyrene dominates the recorded zeta potential.

Addition of KNO_3, was seen to shift the IEP from pH 8.05 to 7.81, with 0.01M of KNO_3, and to 7.50 when with 0.1M of KNO_3. In this case, the variation of the IEP is significant and as the salt concentration increases the IEP of the pS/(pDMAEMA-pMMA) decreases. The concentration of salts is known to influence the phase transition of responsive polymers (Ballauff and Borisov, 2006, and Read *et al*, 2005). In relation to the behaviour of zeta potential with pH, we observe that it is broadly the same for the 3 salt conditions. When the pH increases from an acidic to a basic environment, the zeta potential switches from a cationic to anionic state as the pDMAEMA discharges.

3.2 Dynamic Light Scattering

Dynamic light scattering (DLS) was used to characterize the solution properties of the pS/(pDMAEMA-pMMA) copolymer under alkaline and acidic conditions. The size of a particle is calculated from the translational diffusion coefficient which is directly related to the hydrodynamic diameter for DLS measurements. The measurements were performed at 25, 30 and 35 ºC, below the LCST of pDMAEMA, for two different salt concentrations (0.1M and 0.01M KNO_3) and different pHs (Figure 1). For each experimental condition, the reported values are averages of 2 measurements. It was observed that the diameter of pS/(pDMAEMA-pMMA) particles (i) for a low pH shows a monotonic rise with increasing

pH, and then reaches a peak value of ≈380 nm, (ii) from pH = 5 to 6, the hydrodynamic diameter stays approximately constant and (iii) from pH = 6 to 8.40 it decreases gradually to ≈230 nm. For pH values above 8.40, the hydrodynamic diameter increases due to flocculation. Flocculation leads to a broader size distribution.

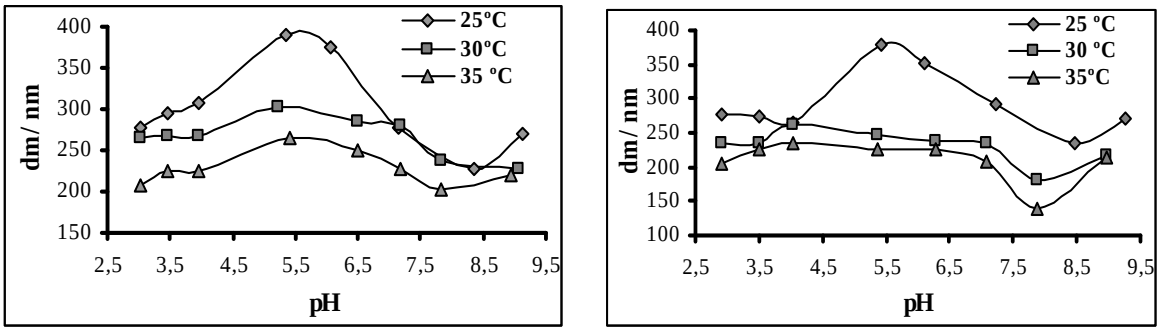

Figure 1. Hydrodynamic diameter average *versus* pH for pS/(pDMAEMA and pMMA) particle concentration of 0.01% (*w/w*) in 0.01M KNO_3 (right) and in 0.1M KNO_3 (left).

Under pH 6, the PDMAEMA are protonated and the repulsion between NH^+ tends to swell the polymeric chains grafted to the polystyrene surface. A decrease in pH (pH< 5) leads to a higher protonation degree of PDMAEMA chains and thereby a stronger repulsion, increasing the hydrodynamic diameter. However, the decrease of the pH also results in adverse effects of swelling. Indeed, for a lower pH range, the concentration of NO_3 ions increase (from HNO_3 solution) and this tends to disrupt the hydrophobic hydration, therefore the chains collapses due to the polymer-polymer interactions. In collapse state polystyrene rule the suspension and the zeta potential decrease. A higher concentration of HNO_3 induces a higher ionic strength; hence a higher concentration of counterions induces a smaller repulsion between the polymeric chains on the particles surface as the protonated nitrogen ions are screened from each other. The $[NO_3^-]$ is enough to penetrate into the brushes of the polymers chains, to push over the water molecules and to relocate, between NH^+ and the adjacent polymer chains. In this case, we suggest that this mechanism is the same as the one acting in the presence of high salt concentrations. As salt concentration rises, the isoelectric point (IEP) and hydrodynamic diameter average of PS/(PDMAEMA-PMMA) suspension decreases.

Another process that can also occur is the cationic flocculation. We realize that the H^+ from the acid solution may establish bonds between nitrogens. When the samples are dipped in an acidic concentrate solution for equilibrium, the band N-H becomes more intense than when dipped to equilibrium in pure water or alkali solutions. Hence, the hydrogen bonding can be a non-negligible force in this system and can act to facilitate aggregation of the PDMAEMA chains. At pH = 8.40 the flocculation occurred, as we mentioned, in DLS measurements. A KOH solution was used to increase the pH, which resulted in the deprotonation of nitrogen atoms. The attraction force between hydrophobic groups increases and the PDMAEMA chains start to collapse and the aggregation between the chains of different particles occurs (pH> 8.50).

3.3. Rheology

To concentrate the pS/ (pDMAEMA and pMMA) particles at 23% (*w/w*), it was used a centrifuge (20 000 rpm/ 5 minutes) and, above it, filtration technique (0.2 μm filter). We observed, for all concentrations studied, that for 5< pH< 7, the pS/(PDAEMA-pMMA) fluid has a Newtonian behaviour and for pH values under 5 and above 7, the pS/(pDMAEMA and pMMA) presents a Shear Thinning fluid (Model Cross). The aggregation phenomenon occurs in this pH range. For pH's 7.31 and 7.84, the viscosity is larger than for basic pH, because it is near to the IEP. The Van der Walls forces are higher than the repulsion forces between the

electrical double layers under these conditions and flocculation occurs. Shear promotes the rupture of the weak flocs and the viscosity decreases as shear rate increases. At around pH 7 the flocs are more resistant, but less dense than basic pH values. If we observe the DLS measurements it will be possible to establish a relation between the swelling and shrinking polymer chains with the flocculation phenomenon and thus with the rheology. For pH's above 7 (Figures 2) the pDMAEMA collapses and as flocculation occurs it will form hard flocs - Charge Patch Flocculation. For 5< pH< 7, the polymer swells and therefore the chains aggregate - Bridging Flocculation. In this last flocculation mode, the flocs have no resistence and are destroyed when exposed to the bob movement. It was to be expected for pH 4.28 the same rheological behaviour (Newtonian behaviour) that it was observed at pH 6.04. As previoulsy mentioned, it was suggested that H^+ and NO_3^- played bonds between the amine group nitrogens and that is why the polymeric chains shrunk. As the particles become once again hydrophobic, they repel the water molecules and tend to aggregate.

At hight concentrations and low shear rate, the Newtonian plateau seems to disappear and to develop into a yield stress (Figures 2). At shear rates exceeding 10^3 s^{-1}, the high concentration samples display a shear thickenning behaviour. For higher shear rate values, the network does not have time to re-arrange and the particles do not acquire flow properties. In this case, the elastic force is greater than the viscous force.

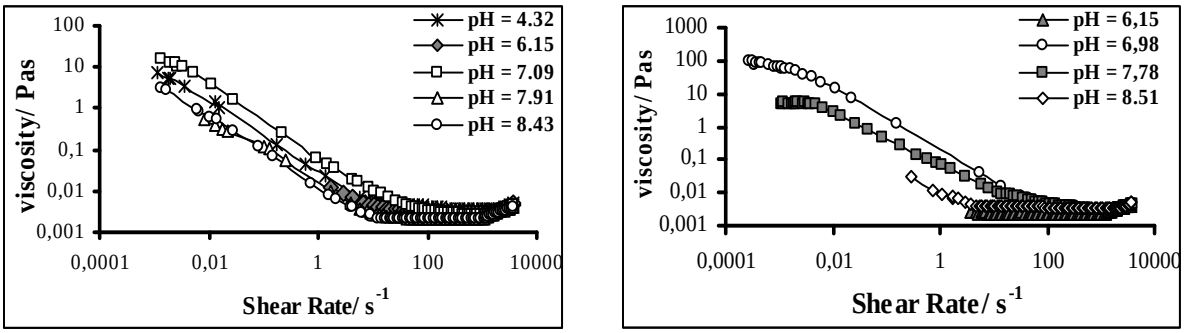

Figure 2. Viscosity *versus* shear rate for different pH's. Filtration Technique, 29% (*w/w*) (right). Filtration Technique, 38% (*w/w*) (left).

Figure 2 (graphic on left) shows for pH 8.51 Newtonian behaviour. In this situation, with the increase of particle concentration, the flocs sedimentation occurred, as it was observed in the end of the measurement.

If we plot a high shear viscosity (or low shear rate) and hydrodynamic diameter average versus pH, we observed that the range, where the diameter and viscosity decrease, are the same (Figure 3). Once again it was showed the relation between DLS and Rheology. The same transition occurs with different properties.

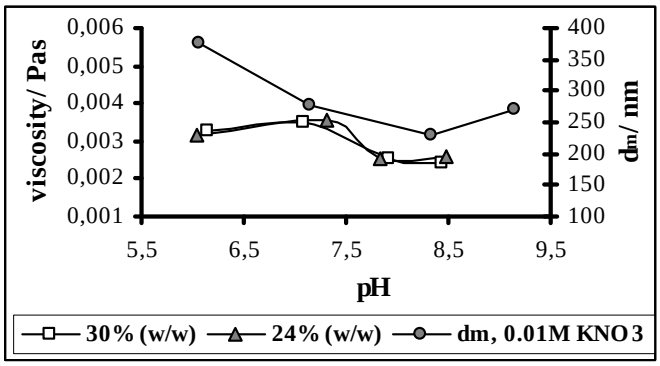

Figure 3. High shear viscosity, η_∞ , hydrodynamic diameter average of the core-shell latex versus pH.

4 Conclusions

Smart polymers have attracted our attention as versatile system stimuli responsive. In the course of our work, it was observed three pH regions of interest: (i) for pH below 5 the particles diameters underwent a monotonic rise with increasing pH and then reached a peak value of $\approx$380 nm; (ii) from pH = 5 to 6 the hydrodynamic diameter remained constant; (iii) from pH = 6 to 8.40 the diameter began to decrease and dropped to $\approx$230 nm. For pH values below 6, the hydrodynamic diameter decreased, because the NO_3 anions coming from the acid solution within the pS/(pDMAEMA-pMMA) suspension were placed between the protonated nitrogens, decreasing the repulsion between them. The results also show that with the increased of KNO_3 concentration, the particles become more compact, since the NO_3 anions are enough to penetrate the brushes of the polymers chains, to force out the water molecules and to be placed between the amine's nitrogens. At pH 8.40 the flocculation occurred due to the deprotonation of nitrogen atoms. Rheological measurements show us the same transitions that we observed by DLS technique. The pS/(pDMAEMA and pMMA) suspension presents as Shear Thinning fluid (Model Cross) for pH values below 5 and above 7. The aggregation phenomenon occurs in these pH values. The fluid has a Newtonian behaviour for pH around 6. It was also observed that with the increasing of pH, the flocs are more compact and dense and rapidly settled on the Money Cell's cup. It was demonstrated that the same transition occurs with different properties, by DLS and Rheology.

Keywords: ETS-4, ETS-10, Ion Exchange, Batch experiments
Topic: Advancing the chemical and biological engineering fundamentals.

Abstract

Cadmium is one of the most toxic non-essential heavy metals present in the environment, even at low concentrations. In this work the ability of microporous titanosilicates ETS-4 and ETS-10 for the uptake of Cd^{2+} ion from aqueous solutions has been investigated, assessing the potential of these materials in water remediation. With this purpose, batch stirred tank experiments have been carried out by contacting a fixed volume of solution with known masses of titanosilicate. The evolution of the cadmium concentration with time has been monitored by Inductively Coupled Plasma Mass Spectrometry. pH is an important variable in ion-exchange processes, hence its effect has been studied. Results have shown expected trends, and revealed that Cd^{2+} uptake is clearly more effective at pH values around 6.

1. Introduction

The removal of toxic heavy metal ions from sewage, industrial and miningwaste effluents has been widely studied, especially in recent years. Their presence in streams and lakes has been responsible for several types of health problems in animals, plants and human beings (Hui et al., 2005). Cadmium is a non-essential element and one of the most hazardous trace elements, being considered a “priority metal” from the standpoint of potential hazard to human health. Aquatic ecosystem pollution by Cd^{2+} usually arises from several industrial processes, such as electroplating, battery and accumulator manufacturing, production of ceramics and pigments, plastic manufacturing, metallurgical alloying, smelting and acid mine drainage. Different technologies are described in literature for removal of heavy metals, such as chemical precipitation, electro-flotation, reverse osmosis, adsorption and ion exchange. Although ion exchange may be considered attractive because of the relative simplicity of application, the cost and the regeneration of adsorbents are limiting factors (Petrus and Warchol, 2003), hence it is of interest to research new materials to replace expensive activated carbons and resins. Natural and synthetic zeolites are gaining considerable interest because of their high selective and ion exchange capacity (Trgo et al. 2006; Lopes et al., 2007).

Titanosilicates are three-dimensional crystalline solids with remarkable physical and chemical properties, such as selective sorption, ion exchange and catalytic activity (Rocha and Anderson, 2000; Lv et al., 2005). The structure of these materials is built from SiO_4 tetrahedral and TiO_6 octahedral units linked to each other by shared oxygen atoms, forming regular cavities and channels of molecular dimensions. Each TiO_6 octahedron in the titanosilicate global structure carries a -2 charge, which can be neutralized by extra-framework cations (usually Na^+ and K^+). These compensation species, as well as water molecules or other adsorbed molecules, are located in the channels of the structure and may be exchanged by others (e.g., Cd^{2+}).

Titanosilicate ETS-4 is a small pore member of the Engelhard Titano Silicate (ETS) family. It has a distinct interconnected octahedral–tetrahedral framework structure, which can be systematically fined through dehydration at elevated temperatures. ETS-10 is a wide pore titanosilicate with a remarkable high thermal stability. The most interesting point of its structure is that ETS-10 contains infinite – Ti – O – Ti – O chains, which are surrounded by silicate ring structures. This material shows a disordered structure and has excellent diffusion characteristics. Both ETS-4 and ETS-10 have been suggested as good ion exchangers (Rocha and Anderson, 2000).

2. Experimental

2.1 Materials and solutions

All chemicals used were of analytical reagent grade and obtained from commercial suppliers without further purification. The certified standard stock solution of cadmium (1001 ± 2 mg/L) was purchased from Merck. ETS-4 and ETS-10 used consisted of an off-white microcrystalline powder, whose features may be found in Table **1.** Their synthesis is described elsewhere (Ferreira, et al., 2007; Lv et al.,2007). All glass ware used in the experiments were acid-washed prior to use (nitric acid 25%, 12 hours followed by hydrochloric acid 25% another 12 hours).

Table 1– Features of the ETS-4 and ETS-10 particles used.

Material	ETS-4	ETS-10
Formula	$[Na_9Ti_5Si_{12}O_{38}(OH).12H_20]$	$[(Na,K)_2TiSi_5O_{13}.4H_2O]$
Density, kg/m^3	2200	1800
Ion exchanger capacity, eq/kg	6.39	4.52
Particle diameter, 10^{-6} m	0.5-0.9	5
Pore diameter, 10^{-10} m	3-4	4,9×0,76

2.2 Batch Experiments

Experiments with both ETS-4 and ETS-10 have been carried out following the same procedure. Therefore, they are both indistinctly referred has titanosilicate.

All experiments were carried out in batch conditions, at 295 K ± 1 in a 2 L volumetric flask. Cadmium solutions were prepared daily by diluting the stock solution to the desired concentrations in high purity water (18 MΩcm). Known masses of titanosilicate were added to the cadmium solutions and this time was considered the starting point of the experiment. Table 2 depicts the experimental conditions including the initial solution concentrations and titanosilicate masses. The pH initially registered is 4, and remained approximately constant during the experiment 1. NaOH was added to cadmium solution in order to fix the initial pH of experiments 2 to 4 (see Table 2).

Titanosilicate powder and aqueous solutions were maintained in contact under constant stirring. The time required for solution-solid equilibration was evaluated by carrying out each experiment until the Cd^{2+} concentration remained constant. During this period, several aliquots (10 mL) were taken at different times and each aliquot was filtered through a 0.45 µm Acetate Plus Osmonics filter. The filtrate was adjusted to pH<2 with HCl, stored at 277.15 K, and then analysed. Besides, new experiments were carried out in order to obtain some

additional equilibrium points. With this purpose, solutions with known Cd^{2+} concentrations were contacted with the titanosilicate until the equilibrium was attained. A blank experiment (without titanosilicate) was always run as control, to check that the removal of cadmium occurred by ion-exchange onto the solid and not by, e.g., adsorption on the vessel walls. Cadmium analysis was performed by Inductively Coupled Plasma Mass Spectrometry.

Table 2 – Experimental conditions for isothermal batch operation.

Experimental Conditions	**Exp. 1**	**Exp. 2**	**Exp. 3**	**Exp. 4**
pH (~constant during experiment)	4	6.5	6	6
Temperature, K	295 ± 1			
Solution volume, 10^{-3} m^3	2			
Initial Cd^{2+}concentration, 10^{-3} kg/m^3	0.85			
Mass of titanosilicate, 10^{-6} kg	ETS-4		ETS-10	
	25	25	5	20.1

3. Results and Discussion

Figures 1 and 2 show the normalized Cd^{2+} concentration in the fluid as a function of time, measured for the same initial solution concentrations (C_{A0}), for different ETS-4 and ETS-10 masses, respectively.

Results follow expected trends: cadmium removal increases with increasing pH (see Figure 1), and with increasing titanosilicate mass (Figure 2) since the extensive ion-exchange capacity is proportional to solid mass.

Fast metal uptake occurs in the first few hours of the process, followed by the characteristic slower removal towards the equilibrium (Figures 1 and 2). Such fact dues to the large mass transport driving forces observed at the beginning, since ETS-4 and ETS-10 particles are initially free of cadmium.

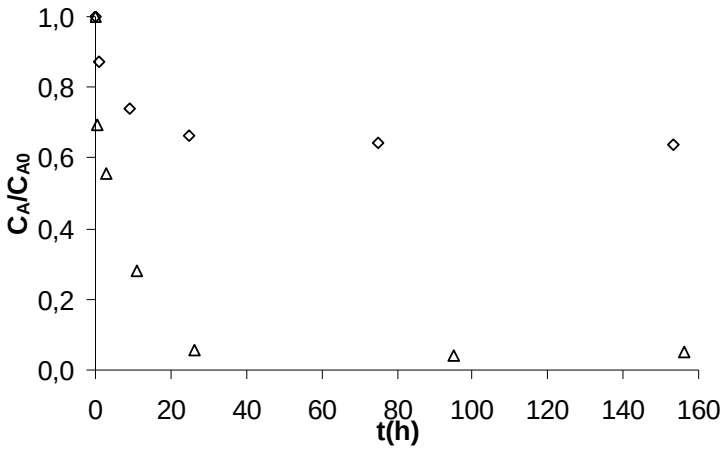

Figure 1: Normalised concentration of bulk solution *versus* time for experiments with ETS-4. Experimental conditions (see Table 2): ◊ Exp.1 and Δ Exp.2.

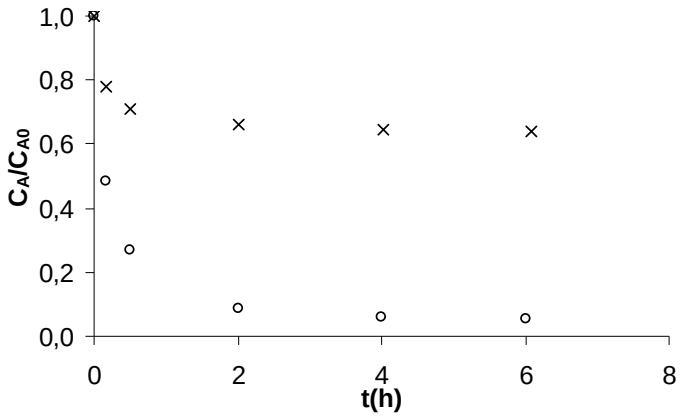

Figure 2: Normalised concentration of bulk solution *versus* time for experiments with ETS-10. Experimental conditions (see Table 2): × Exp.3 and ○ Exp.4.

Figure 3 shows equilibrium data for ETS-4 at pH=4 and pH=6.5. As has been mentioned above, the amount of adsorbed metal by ETS-4 increases with higher pHs. This is a very important result since the pH of industrial effluents and other waste water are around 6.

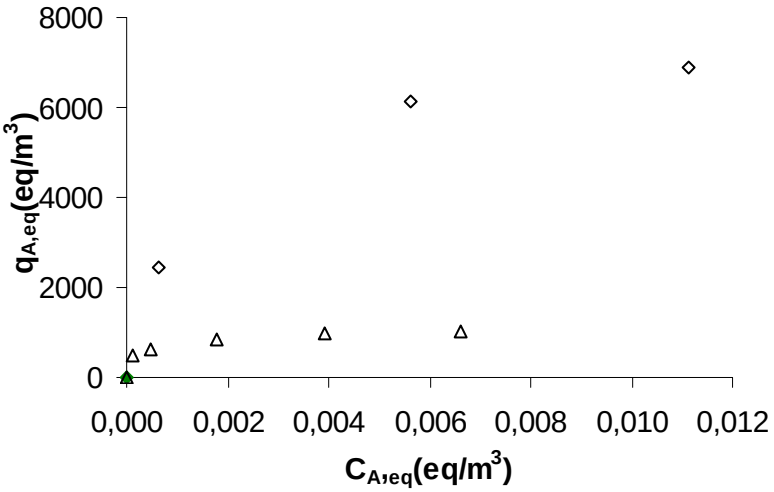

Figure 3: Comparison between equilibrium data measured for ETS-4 (◊, pH=6,5 and Δ, pH=4).

4. Conclusions

In this work the removal of Cd^{2+} from aqueous solution using titanosilicates ETS-4 and ETS-10 has been investigated with batch stirred tank experiments. The effect of pH and titanosilicate mass has been studied. The obtained results follow expected trends and evidence that metal uptake is more effective for pH values around 6.

Keywords: α-pinene, alkoxylation, PVA, sulfonic acid groups
Topic: Advancing the chemical and biological engineering fundamentals

Abstract

The alkoxylation of α-pinene was carried out over poly(vinyl alcohol) containing sulfonic acid groups, as catalyst. The main product of α-pinene alkoxylation was α-terpinyl methyl ether being also formed bornyl methyl ether, fenchyl methyl ether, limonene and terpinolene as by-products.

The absorption band at 1037 cm^{-1} in the FTIR spectrum of PVA_SSA40 (PVA membrane containing 40% of –OH groups esterified with SSA) which does not appear in the spectrum of PVA, indicates the presence of the sulfonic acid groups.

The catalytic activity of PVA with sulfonic acid groups increases when the amount of sulfosuccinic acid used in the polymer crosslinking is increased from 5% to 40%. However, when the crosslinking degree increases from 20% to 40%, the conversion of α-pinene increases only slightly.

Good values of selectivity to α-terpinyl methyl ether were obtained over poly(vinyl alcohol) with sulfonic acid groups.

A simple kinetic model, which fits experimental concentration data quite well, was developed.

1 Introduction

Alpha-Pinene is a renewable raw material usually obtained from pine gum or as a waste from the Kraft process. Its acid catalysed methoxylation yields a complex mixture of monoterpenic ethers, being alpha-terpinyl methyl ether the main product. The alpha-terpinyl methyl ether smells grapefruit-like and might be used as flavour and fragrance for perfume and cosmetic products, as additive for pharmaceuticals as well as in food industry. Strong homogeneous acid catalysts, e.g sulphuric acid, have been used, but the effluent disposal leads to environmental problems and economical inconveniences. These problems can be overcome by the use of solid acid catalysts. Beta zeolite (Hensen et al., 1997) and acidic cation exchange resins have been used for the α-pinene alkoxylation.

Homogenous and heterogeneous catalysts could be immobilized in polymeric membranes in order to improve their selectivity or activity, thanks to environment created by the polymeric matrix around the catalyst (Ozdemir et al., 2006, Vankelecom, 2002). In a previous work, it was observed that PVA membranes with $–SO_3H$ groups have catalytic activity in esterification of acetic acid by isoamylic alcohol (Castanheiro et al., 2006).

In the present work, we report the α-pinene alkoxylation over poly(vinyl alcohol) containing sulfonic acid groups. These groups were introduced by the direct reaction between -OH of PVA and sulfosuccinic acid.

* Corresponding author. Tel + .: +351-266-745311. E-mail:jefc@uevora.pt

2 Experimental

PVA catalysts were prepared by dissolving PVA (MERCK, average molecular weight: 72000) in water at 90ºC, during 6 h. Aqueous 10 wt.% PVA solutions were mixed with the appropriate amounts of sulfosuccinic acid (SSA) and then the mixtures were vigorously stirred at room temperature for 24 h. After that, the homogeneous solutions were poured and cast on a Teflon plate. The cast membranes were allowed to dry at 60ºC during 24 h. The dried membranes were heated at 120ºC, during 2 h (Rhim et al. 2004). The code PVA_SSAx means a membrane containing 2x% of its –OH groups esterified.

The amount of sulfonic acid groups in PVA_SSA was measured by a classic titration. The samples were equilibrated with 10 ml of 0.1 mol/L NaOH solution for 24 h. Then, the amount of H^+ was calculated from the reduction in alkalinity determined by titration.

The FTIR spectra were recorded in a Bio-Rad FTS 155 instrument.

Catalytic experiments were carried out in a batch reactor equipped with a stirrer, at 60ºC. In a typical experiment, the reactor was loaded with 1 mL of α-pinene, 50 mL of methanol and 0.5 g of catalyst. Samples were taken periodically and analysed by GC, using a Konic HRGC-3000C instrument.

3 Results and Discussion

Table 1 shows the results of membrane characterisation. The swelling measurements for each pure component decreased, when the SSA contents increased. This is due to the decrease of the free volume, even though the membrane contains more hydrophilic functional groups (Rhim et al., 2004). The amount of sulfonic groups in PVA_SSA membranes expressed in milli-equivalent (meq) by weight of dry membrane (g), increase with SSA contents.

Table 1. Membrane characteristics[a]. $Q_{methanol}$, $Q_{\alpha\text{-pinene}}$ – swelling degree for methanol and α-pinene, respectively.

Membrane	Thickness (mm)	meq./g_{memb}	$Q_{methanol}$	$Q_{\alpha\text{-pinene}}$
PVA_SSA5	0.112	0.50	0.329	0.054
PVA_SSA20	0.104	2.02	0.223	0.044
PVA_SSA40	0.108	4.00	0.114	0.029

[a]The code PVA_SSAx means a membrane containing 2*x%* of its –OH groups esterified.

Fig. 1 shows the FTIR spectra of PVA and the PVA crosslinked with sulfosuccinic acid, PVA_SSA40. The absorption band at 1730-1735 cm^{-1}, in the spectrum of PVA_SSA40, usually assigned to the ester group (-CO-O-), suggests that the crosslinking with SSA was succeeded. The absorption band at 1037 cm^{-1} in the spectrum of PVA_SSA40, which does not appear in the spectrum of PVA, indicates the presence of the sulfonic acid groups by the introduction of SSA (Rhim et al., 2004).

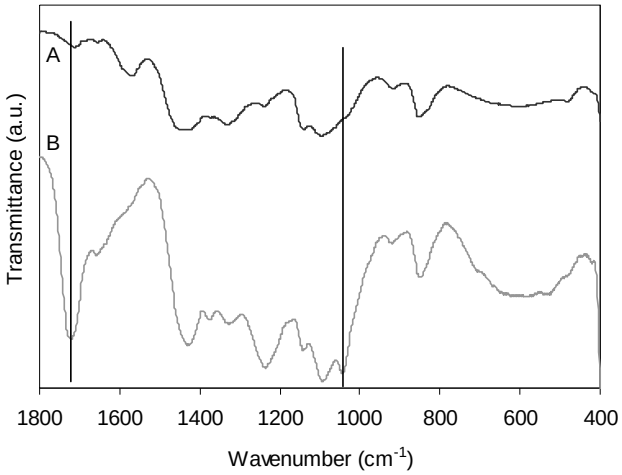

Fig. 1. FTIR spectra of PVA matrixes. (A) pure PVA; (B) PVA_SSA40.

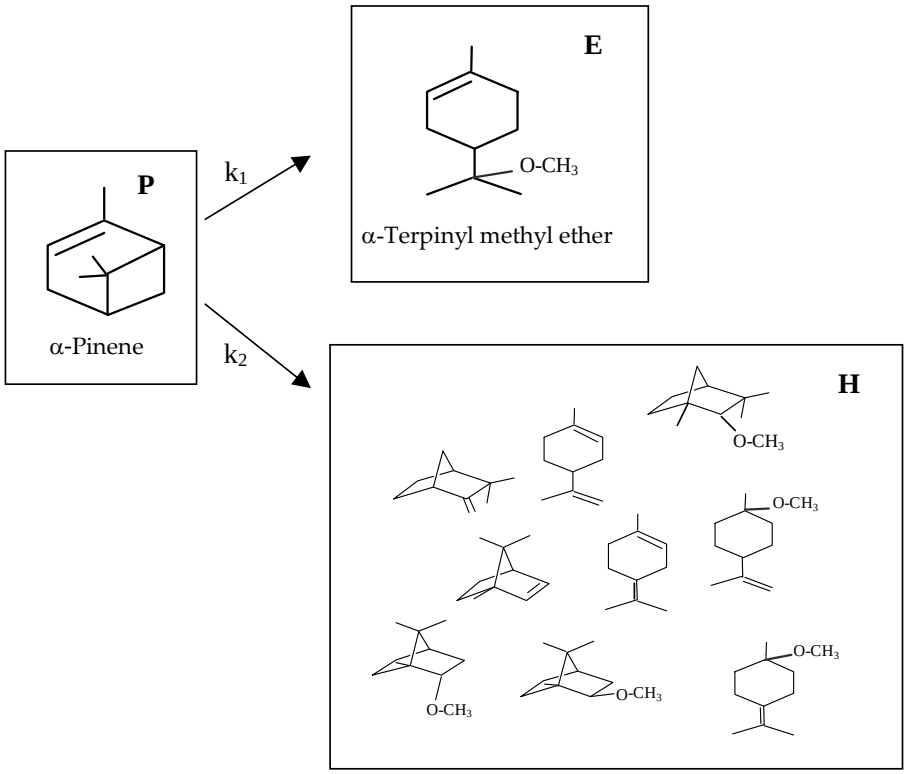
The main product of α-pinene methoxylation was α-terpinyl methyl ether being also formed bornyl methyl ether, fenchyl methyl ether, limonene and terpinolene as by-products (scheme 1).



Scheme 1

Fig. 2 shows the concentration profiles obtained for the catalyst PVA_SSA20. In the Fig. 2, “others” lumps all the minor products.

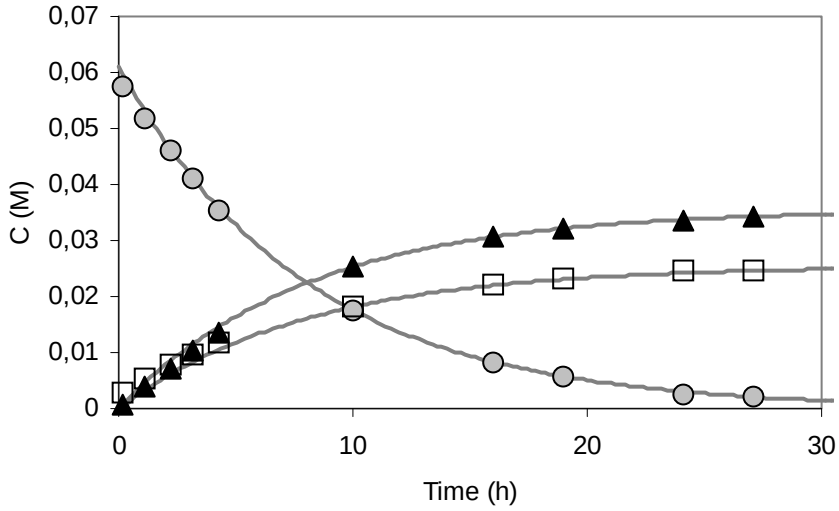


Fig. 2. Alkoxylation of α-pinene over PVA_SSA40. Concentration vs. time. (⊙) α-pinene; (▲) α-Terpinyl methyl ether; (□) H-lumps all the minor components. The solid lines represent the model fitted to the data points.

The α-pinene concentration profile over PVA_SSA5, PVA_SSA20 and PVA_SSA40 catalysts were shown in Fig. 3. It was observed that the conversion increases when the amount of sulfosuccinic acid used in the polymer cross-linking is increased from 5% to 20%. This behaviour can be explained by the increase of the amount of sulfonic acid groups in the PVA matrix. However, when crosslinking degree increases from 20% to 40%, the conversion of α-pinene increases only slightly. This is, probably, due to the increase of restrictions on the mobility of molecules, in the polymer matrix.

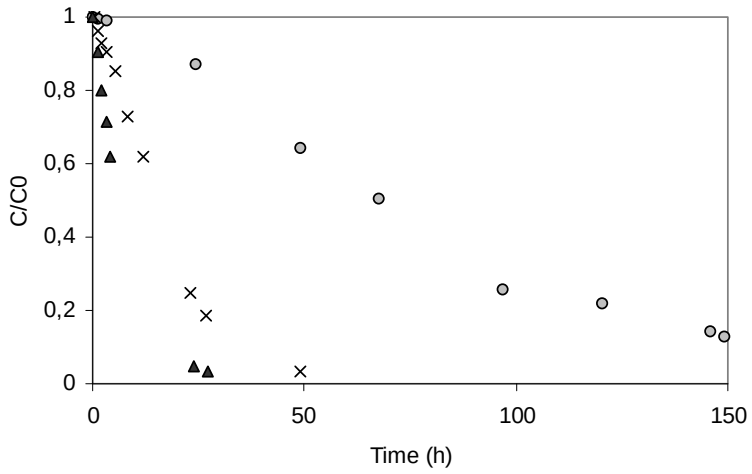

Fig. 3. Alkoxylation of α-pinene over poly(vinyl alcohol) with sulfonic acid groups. Effect of crosslinking degree on the concentration profiles of α-pinene. (⊙) PVA_SSA5; (x) PVA_SSA20; (▲) PVA_SSA40.

Fig. 4 shows the selectivity to the α-terpinyl methyl ether at 95% of α-pinene conversion, for PVA_SSA5, PVA_SSA20 and PVA_SSA40. It was observed that all of the catalysts tested on α-pinene alkoxylation exhibited good selectivity to α-terpinyl methyl ether (about 60% near complete conversion).

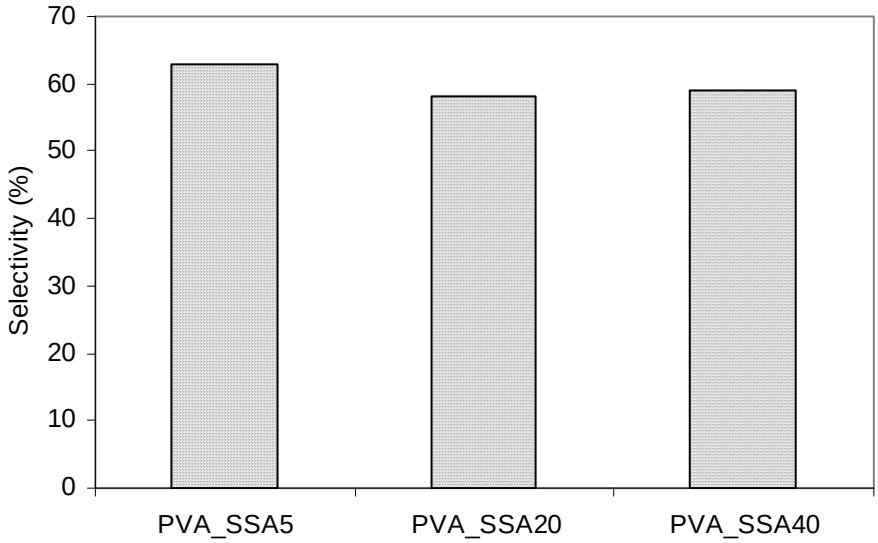

Fig. 4. Alkoxylation of α-pinene over poly(vinyl alcohol) with sulfonic acid groups. Selectivity to α-terpinyl methyl ether at 95% of α-pinene conversion.

A simple kinetic model is proposed. It is assumed first order kinetics. The reaction rate of these two pseudo elementary reaction are expressed as:

$$r_1=k_1C_p \quad (1)$$

$$r_2=k_2C_p \quad (2)$$

For batch reactor the mole balance equations may be written as:

$$\frac{dCp}{dt}=-\frac{W}{V}\left(r_1+r_2\right) \quad (3)$$

$$\frac{dC_E}{dt}=\frac{W}{V}r_1 \quad (4)$$

$$\frac{dC_H}{dt}=\frac{W}{V}r_2 \quad (5)$$

The fitting of the model to data points is shown in Fig. 2.

4. Conclusions

Poly(vinyl alcohol) crosslinked with succinic acid containing sulfonic acid groups, was used as catalysts in the alkoxylation of α-pinene.

The main product of α-pinene alkoxylation was α-terpinyl methyl ether being also formed bornyl methyl ether, fenchyl methyl ether, limonene and terpinolene as by-products.

The conversion increases when the amount of sulfosuccinic acid used in the polymer crosslinking is increased from 5% to 20%. However, when crosslinking degree increases from 20% to 40%, the conversion of α-pinene increases only slightly.

All of the catalysts tested on α-pinene alkoxylation exhibited good selectivity to α-terpinyl methyl ether.

A simple kinetic model, which fits experimental concentration data quite well, was developed.

Topic: Advancing the chemical and biological engineering fundamentals: (Bio) Catalysis & reaction engineering

Abstract

This paper describes the preparation and characterization of 1% wt. Pt catalysts supported in carbon aerogels for the application in the liquid-phase selective hydrogenation of cinnamaldehyde. Carbon aerogel supports with different textures were activated with hydrogen peroxide and ammonium peroxydisulfate leading to large amounts of surface groups but keeping unchanged their textural properties. After introducing Pt, the surface chemistry and morphology of the catalysts was characterized by analytical techniques like SEM, TPD, N_2 adsorption isotherms, mercury porosimetry and H_2 chemisorption. Catalysts prepared with activated aerogels exhibited good selectivity towards the desired product, cinnamyl alcohol. A high temperature post-treatment of the catalysts failed to enhance their selectivity, mainly leading to hydrocinnamaldehyde production.

1. Introduction

The synthesis of carbon aerogels was first reported by Pekala (1990). Depending on the solvent removal step, these materials are referred to as: (i) aerogels if supercritical CO_2 is used; (ii) xerogels when the removal takes place under ambient temperature and pressure conditions; and (iii) cryogels: if a freeze-drying method is used. Carbon aerogels are one of the most promising new carbon forms for many applications such as adsorbents, catalysts or capacitors (Moreno-Castilla, 2005; Maldonado-Hodar, 2007). Their potential is based on their unique properties: purity, homogeneity and above all, controllable porosity. Between the different precursors and methods developed during the last years, the sol-gel polymerization of resorcinol (R) and formaldehyde (F) is the most common. The porous texture of carbon aerogels, and consequently their applications, strongly depends on several experimental conditions. The most important is the polymerization step, since it defines the structure and consequently the porous texture of the organic aerogels.

Polymer-based (Moreno-Castilla, 2005; Samant, 2004) and other carbon materials like nanofibers, nanotubes or fullerenes (Serp, 2003) are an important class of materials to produce noble metal supported catalysts. This type of catalysts is extremely useful in the liquid phase heterogeneous selective hydrogenation of unsaturated aldehydes to the corresponding unsaturated alcohols. This is a key process for the production of important intermediates in the preparation of fine chemicals for fragrance, pharmaceutical and

*Corresponding author. Tel + 351-225 081 645. E-mail: jlfaria@fe.up.pt

agrochemical industries. Unfortunately, there are some constrictions, both thermodynamic and kinetic, that limit the selectivity towards the unsaturated alcohol formation. In spite of these drawbacks, the selectivity to unsaturated aldehydes using heterogeneous catalysts can be improved by careful design of the catalysts, controlling the type and surface chemistry of the support, the nature of the active metal, and the addition of a promoter, among others.

In this work, we prepared several carbon aerogel supported Pt catalysts, using materials with different textures and surface chemistries, seeking to establish appropriate structure/activity relationships, which are useful for smart catalyst design.

2. Experimental

2.1 Catalyst preparation

Organic aerogels were synthesized by polymerization of resorcinol with formaldehyde in aqueous solution, according to the methodology developed originally by Pekala *et al.* (1990) using alkali carbonates (M_2CO_3; M = Li or Cs) as polymerization catalysts. This process yields organic RF-aerogels which were carbonized in N_2 flow at 900ºC. Carbon aerogels will be here referred as Li900 and Cs900 indicating the metal alkali and the carbonization temperature used in their synthesis.

Samples of Li900 carbon aerogel were further oxidized (1 g carbon/10 mL of solution) with concentrated hydrogen peroxide (HP, H_2O_2, 9.8 M) and with a saturated solution of ammonium peroxydisulfate (AP, $(NH)_4S_2O_8$) in sulfuric acid (H_2SO_4, 1M) during 48 h at ambient temperature (Moreno-Castilla, 1995). After oxidation, the samples were washed with distilled water and dried at 120ºC in an oven during 24 h. The samples oxidized with H_2O_2 and with $(NH)_4S_2O_8$ will be here referred as Li900H and Li900S, respectively.

Supported Pt (1 wt. %, $Pt(NH_3)_4(NO_3)_2$) catalysts were prepared by incipient wetness impregnation on the above described materials. Prior to reaction, the resulting catalysts (Li900Pt, Li900HPt, Li900SPt and Cs900Pt) were treated in N_2 for 4 hr and reduced in H_2 for 2 hr. A post-reduction treatment (2 hr, N_2) was performed at 700ºC to remove part of the surface groups (Li900Pt700, Li900HPt700, Li900SPt700 and Cs900Pt700).

2.2 Catalyst characterization

The surface morphology of the aerogels was studied by SEM (LEO, model Gemini-1530, equipped with EDX microanalysis). Textural characterization was carried out using mercury porosimetry (Quantachrome Autoscan 60) and N_2 adsorption at -196ºC (Quantachrome autosorb-1). Mercury porosimetry allowed the determination of pore volume (V_{MES}: 3.5 nm < dpore < 50 nm and V_{MAC}: dpore > 50 nm) and the external surface area (S_{EXT}: dpore > 3.7 nm). The BET equation (Brunauer, 1938) and Dubinin-Raduskevich and Stoeckli *et al.* (2002) relations were used for analysis of N_2 adsorption isotherms.

The surface chemistry of the carbon aerogels was characterized by temperature-programmed desorption (TPD). TPD experiments were carried out by heating the samples to 1000ºC in He flow (60 cm^3 min^{-1}) at a heating rate of 50ºC min^{-1}. The amount of evolved gases was recorded as a function of temperature using a quadrupole mass spectrometer (Balzers, model Thermocube), as described elsewhere (Alvarez-Merino, 2000). The oxygen content was calculated from the amounts of CO and CO_2 released during the TPD experiments.

Pt dispersion (D_{Pt}) and average particle size (d_{Pt}) were obtained by H_2 chemisorption measurements performed at 40 ºC. Assuming the formation of spherical particles and a H:Pt = 1:1 stoichiometry it was possible to determine the Pt particle size (d_{Pt} = 1.08/D_{Pt} (nm)). H_2 chemisorption isotherms were measured in conventional volumetric equipment made of Pyrex glass, free of mercury and grease, which reached a dynamic vacuum better than 10^{-6}

mbar at the sample location. Equilibrium pressure was measured with a Baratron transducer from MKS.

2.3 Catalytic hydrogenation

Hydrogenation of cinnamaldehyde was carried out in a 100 mL well-stirred stainless steel high pressure reactor at 90ºC and 10 bar (total pressure). The reaction mixture contained heptane (solvent), cinnamaldehyde, decane (internal standard for gas chromatography) and the catalyst. As the reaction proceeded samples were withdrawn to monitor product distribution. The analysis was performed in a DANI GC-1000 Gas Chromatograph, equipped with a WCOT Fused Silica column (length 30 m, 0.32 mm i.d., film thickness 1 µm). The results of the reaction runs were analyzed in terms of cinnamaldehyde conversion, turn-over frequency and product selectivity.

3. Results and discussion

3.1 Support characterization

The selection of the polymerization catalyst had a great influence over the porous texture of the aerogel: smaller cations like Li were found to produce materials with significant mesoporous volume, whereas larger Cs cations led to macroporous materials (Figure 1). The higher BET surface area (increase of about 150 $m^2\ g^{-1}$) of the Li900 materials relatively to the macroporous material (Table 1) is explained in terms of smaller particle size.

The aerogel surface oxidation treatments resulted in the formation of different oxygen-containing groups like carboxylic acids, lactones and phenols. The introduction of these groups was achieved without any significant changes of the initial textural properties of the aerogels (a decrease of only *ca.* 4% was observed in the S_{BET} values). On the other hand, the surface acidity of the material was seriously affected by the oxidation procedure. The acidic character of the samples, determined by pH_{PZC} measurements, was found to increase in the following order: Li900S (3) > Li900H (5) > Li900 ≈ Cs900 (10). In addition, the amount of O_2 present at the surface was found to increase with decreasing pH_{PZC}, i.e.: Li900S (10 wt.%) > Li900H (3% wt.%) > Li900 ≈ Cs900 (1 wt.%).

Table 1. Textural properties of the carbon aerogels.

Support	S_{BET} ($m^2\ g^{-1}$)	V_{MIC} † ($cm^3 \cdot g^{-1}$)	L_0 † (nm)	S_{ext}* ($m^2 \cdot g^{-1}$)	V_{MES}* ($cm^3 \cdot g^{-1}$)	V_{MAC}* ($cm^3 \cdot g^{-1}$)
Li900	902	0.37	1.0	191	1.06	0.00

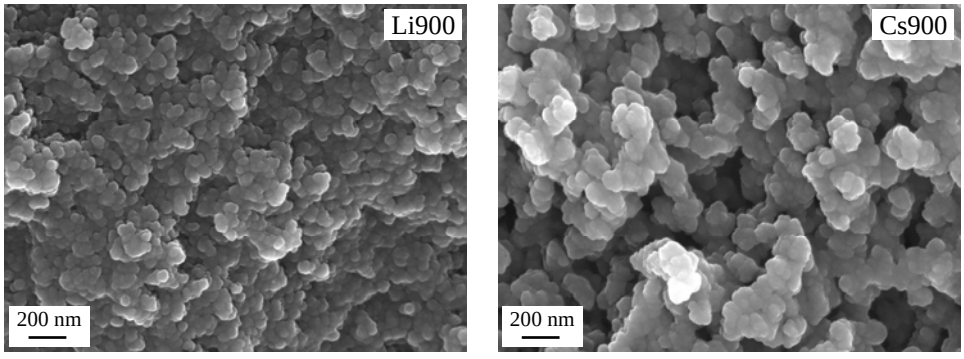

Figure 1. SEM images of Li900 and Cs900 aerogels.

3.2 Metal-phase characterization

Platinum dispersions and particle sizes of the carbon aerogel supported catalysts are given in Table 2. Excellent Pt dispersions over the untreated aerogels (Li900Pt and Cs900Pt) were observed, but somewhat lower values were detected when using the oxidized supports (Li900HPt and Li900SPt). There are two main factors that can affect the metal dispersion over a support: (i) the available surface area and (ii) the interaction between the surface and the precursor solution. The textural properties of the supports were not significantly changed by the oxidation treatments, as already showed, but the presence of oxygenated surface groups increased the hydrophilic character of the surface. Taking into consideration that the surface is negatively charged (pH_{PZC} < pH precursor solution) and the cationic nature of the precursor ($[Pt(NH_3)_4]^{+2}$) an improved metal dispersion was expected when using the oxidized supports, in comparison to the catalysts prepared using the untreated ones. However this is not the case, because the oxygen surface groups act as anchoring sites, which can retain the Pt-precursor molecules at the entrance of the pores preventing the Pt diffusion through the porous structure. On the other hand, during the reduction treatment, the less stable oxygen surface complexes will be removed, which can promote the mobility of the platinum particles favoring their agglomeration (Román-Martínez, 1994).

When a post-reduction treatment is carried out in N_2 at 700 ºC, the experimental conditions are severe enough to induce some sintering of the Pt particles. This seems to be related to the surface chemistry of the materials as the Pt particle size supported in untreated aerogels increases *ca.* 2.3 times while for the activated supports an increase of only 1.5-1.6 times is observed. Besides a sintering effect, the treatment at 700ºC is also able to purge the surface of many of the oxygenated surface groups.

Table 2. Pt dispersion and particle size for the aerogel supported catalysts.

Catalyst	**D_{Pt} (%)**	**d_{Pt} (nm)**
Li900Pt	74.1	1.5
Li900Pt700	31.3	3.4
Li900HPt	46.1	2.3
Li900HPt700	30.5	3.5
Li900SPt	44.4	2.4
Li900SPt700	28.7	3.8
Cs900Pt	87.3	1.2
Cs900Pt700	40.3	2.7

3.3 Hydrogenation of cinnamaldehyde

Some of the possible pathways for the selective hydrogenation of cinnamaldehyde (CAL) in a non alcohol solvent are shown in Figure 2. The thermodynamically preferred path goes through the hydrogenation of the C=C bond yielding the saturated aldehyde (hydrocinnamaldehyde, HCAL). Selective hydrogenation of the C=O bond gives the unsaturated alcohol (cinnamyl alcohol, COL). Both COL and HCAL can be further hydrogenated to produce the fully saturated alcohol (hydrocinnamyl alcohol, HCOL). In some experiments, a number of side-products involving the loss of the hydroxyl group (*β*-methylstyrene (MS) and 1-propylbenzene (PB)) were also detected in different amounts, indicating a strong adsorption over the metal sites and a possible poisoning effect.

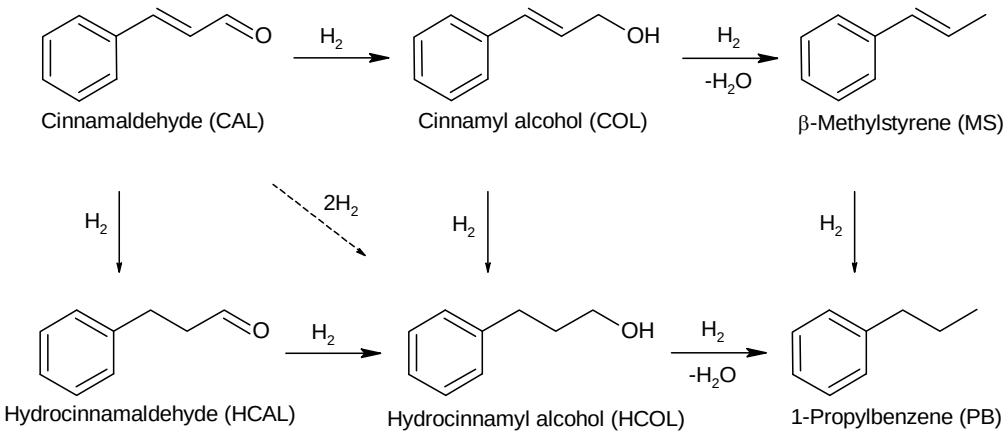

Figure 2. Reaction scheme for the selective hydrogenation of cinnamaldehyde.

The reaction results obtained at 90ºC and 10 bar (total pressure) are gathered in Table 3. Taking into account the average pore size diameter in both aerogels (12 and 48 nm) and the cinnamaldehyde molecule size (< 1 nm) we could expect the absence of internal mass transfer limitations during the reaction. This assumption was confirmed by the higher activity (TOF) exhibited by Li900Pt regarding the macroporous Cs900Pt catalyst.

Table 3. Initial turn over frequency and selectivities towards COL, HCAL and HCOL, measured at 50% conversion of CAL.

Catalyst	TOF (s^{-1})	S_{COL} (%)	S_{HCAL} (%)	S_{HCOL} (%)
Li900Pt	1.6	11	54	20
Li900Pt700	3.4	12	54	25
Li900HPt	1.6	53	18	20
Li900HPt700	3.5	21	41	28
Li900SPt	2.3	36	23	25
Li900SPt700	4.4	21	44	27
Cs900Pt	0.9	24	34	35
Cs900Pt700	2.8	12	54	19

Oxidation of the carbon materials had a marked effect over the selectivity towards cinnamyl alcohol. Selectivity increased by a factor of 4.8 for Li900HPt (53% at 50% conversion of cinnamaldehyde) and 3.3 for Li900SPt (36%) compared with the catalyst prepared using the non-treated support (11%).

In previous studies we used a high temperature treatment to enhance selectivity of the catalysts (Solhy, 2008). In the present study a thermal treatment at 700ºC in N_2 increased the TOF up to a factor of 3 and shifted selectivity to the C=C bond. The selectivity towards the carbonyl group appears to be related to the surface chemistry of the material, as a more acidic surface favors the interaction with the carbonyl group and a more basic surface favors the reduction of the olefinic bond.

4. Conclusions

Macro or mesoporous carbon aerogels were obtained depending on the type of polymerization catalyst used. Oxidation treatment with H_2O_2 and $(NH_4)_2S_2O_8$ allowed the porous structure to remain relatively unchanged while introducing significant amounts of oxygenated groups. The acidic character of most groups led to a strong decrease of the pH_{PZC} of the support surface. The Pt dispersion over the aerogels was strongly influenced by these chemical modifications, decreasing in all cases after oxidation treatments. The

increased acidity of the Li900HPt and Li900SPt supports leads to a higher selectivity towards cinnamyl alcohol when compared with that obtained with Li900Pt. A thermal treatment at 700ºC removed most of the support surface groups and shifted the selectivity back to the hydrogenation of the C=C bond.

Extraction of nickel from spent nickel catalyst with inorganic acid

S. Meysam Hashemnejad[1], Matin Parvari[1]*
[1] Chemical Engineering Department, Iran University of Science and Technology, Farjam Str., Tehran, Iran.

Keywords: Nickel recovery, Leaching, Hydrometallurgical, Spend catalyst
Topic: Recovery of Nickel Catalyst.

Abstract

This study examined the recovery of nickel from spent nickel catalyst ($NiO/CaAl_4O_7$) by hydrometallurgical technique with sulfuric acid. The influences of temperature, acid concentration, solid: liquid ratio and contact time has been studied. Under optimum conditions (temperature: 120℃, acid concentration: 70% (v/v), solid: liquid 1/20, time of reaction: 220min) 99% Ni were extracted as sulfate phase. In addition to the economical advantages the proposed procedure will be helpful in saving the wastage of metal and protecting the environment from metal pollution.

1 Introduction

A considerable attention is given to the problem of utilization and processing of solid wastes containing nonferrous metals. Wastes of this kind are toxic substances hazardous to the environment, on the one hand, and a valuable chemical raw material, on the other [1]. For many years, nickel has been considered as the most suitable metal in steam reforming of hydrocarbons. Nickel is cheap, sufficiently active, and allows suitable catalysts to be economically produced [2]. In the course of operation, the catalysts lose activity as a result of changes in their composition and structure. At high temperatures, the catalyst undergoes sintering and its active surface area decreases. In the course of time, a considerable fraction of nickel cations diffuses from the catalyst surface deep inside alumina, active nickel oxide is converted on alumina into inactive nickel aluminate, and spinel-like compounds, inactive in catalysis, are formed [1].The increasing demand for metals in the world has required intensive studies for the extraction of metals from low-grade ores and/or secondary resources. Extraction of nickel can be performed from secondary resources like spent catalysts [3]. Regeneration of spent catalysts after many cycles of use is not possible by ordinary techniques and it poses a significant waste disposal problem for most of the hydrogenation and fertilizer plants [4].

Commonly, two methods are suggested for recovery of nickel from ores and raw materials of technological origin: pyrometallurgical technique, whose main product is ferronickel obtained at high temperatures, and hydrometallurgical, based on leaching-out of nickel from raw materials with various acids and solutions of ammonia and ammonium salts. The hydrometallurgical method for nickel recovery, compared with the pyrometallurgical technique, is the most promising because it conforms to the principle of combination of environmental and economical interests (markedly diminishes the number of technological procedures, does not require fuel expenditure for high-temperature processes, minimizes the amount of solid wastes and toxic discharges into the atmosphere). One more advantage of the given technique is that it can recover from leaching solutions, at an appropriate choice of methods used, both metallic nickel (electrolytically) and its salts [1].

* Corresponding author. Tel +98(21)73912755, Email: Parvari@iust.ac.ir

Increasing environmental concerns and legislation regarding the disposal of hazardous residues are forcing companies and countries to process their own waste products and residues, Spent hydroprocessing catalysts have been classified as hazardous wastes by the Environmental Protection Agency in the USA (Rapport, 2000) [5]. So the treatment of this waste is compulsory due to its toxicity and polluting character. This situation has resulted in increasing emphasis on the production of nickel from secondary sources like spent catalysts.

2 Experimental section

2.1. Apparatus and Materials

A Perkin-Elmer ® Model 2380 atomic absorption spectrometry (AAS) with air-acetylene flame and hallow cathode lamps were used for the analysis of nickel. All instrumental settings were those recommended in the manufacturer's manual book and the instrumental conditions were shown in Table 1.

Structural characterization of the nickel catalyst was performed by powder X-ray diffraction (XRD) data were collected at room temperature using a PW-1800 Philips diffractometer with Cu Kα1 radiation (λ = 1.5406 Å) at 40 kV, 30 mA for determining crystalline phases.

The chemical composition of catalysts was analyzed semiquantitatively by standardless X-ray fluorescence (XRF) spectroscopy (EAGLE II μ-Probe, EDAX) with RhKα radiation using the fundamental parameter model. The X-ray beam was focused to a spot size of 300 μm on the sample surface.

Spent nickel oxide catalyst used in this study was kindly provided (supplied) by Arak petrochemical complex (Iran). We can find out, structure of nickel catalysts by X-ray diffraction (XRD). Figure1 shows presence of NiO and CaAl4O7 as the major phases and CaAl2O4 as the minor phase. The content of nickel in the catalyst sample was 14.06% as indicated by X-ray fluorescence analysis.

2.2. Procedure

The spent catalyst was ground and sieved to achieve appropriate particle size. Leaching experiments were carried out in a 250mL thermostatically controlled stirrer tank. In each experiment we used particle size<100μm and also stirring velocity adjusted at the maximum rate (1000 rpm) to eliminate these factor in leaching [4, 2]. At first, 5 g of spent catalyst was added to certain amount of sulfuric acid having a specified concentration (30, 50, 70 and 90%) and different temperature (80,100,120 andĊ140 or higher) to determine best temperature and acid concentration and then other factors, solid: liquid ratios (S/L) and time of reaction were analyzed. Nickel was leached-out from the catalyst in accordance with following reaction [3].

$NiO + H_2SO_4 \rightarrow NiSO_4 + H_2$

The reaction of support phase with acid is very week that we can obviously say it is totally inactive toward H_2SO_4 .After separation of nickel sulfate solution and washing the solid which settles at the bottom of a liquid, the specimens were chemically examined for determination of nickel content using atomic absorption spectroscopy (AAS), and then the percentage extraction of nickel was calculated by following equation.

Ni recovery (%) = (mass of nickel out by acid / total mass of nickel determined by XRF analyses) *100

3 Results and discussion

3.1. Effect of temperature and acid concentration

Leaching of spent nickel catalyst was carried out at different temperatures and acid concentration ranging from 80 to 140 Ċ and 30 to 90% respectively. Solid: liquid ratio was maintained in S/L: 1/10 (gr/ml) in each experiment and the treatment of solid with acid was kept in one hour. Fig. 2 demonstrates the effect of varying acid concentration by volume and temperature. The obtained result shows that the maximum nickel recovery was found 82% at 120Ċ and 70% acid concentration.

O

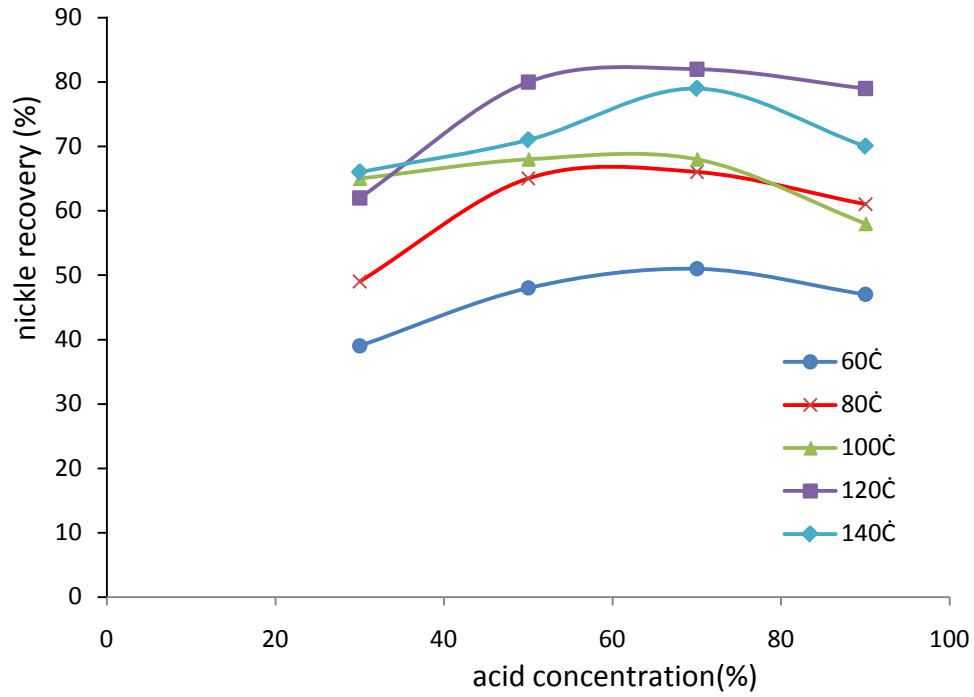

Fig. 2. Effect of temperature and acid concentration on recovery of nickel from spent nickel catalyst. S/L: 1/10, time of reaction: 1 hr.

3.2. Effect of solid/liquid ratio

The other important factor that affects on extraction yield is the ratio of solid to acid solution. It was found that the minimum ratio of S/L is approximately 1/20 (gr/ml) to reach the highest value of nickel recovery (figure3).

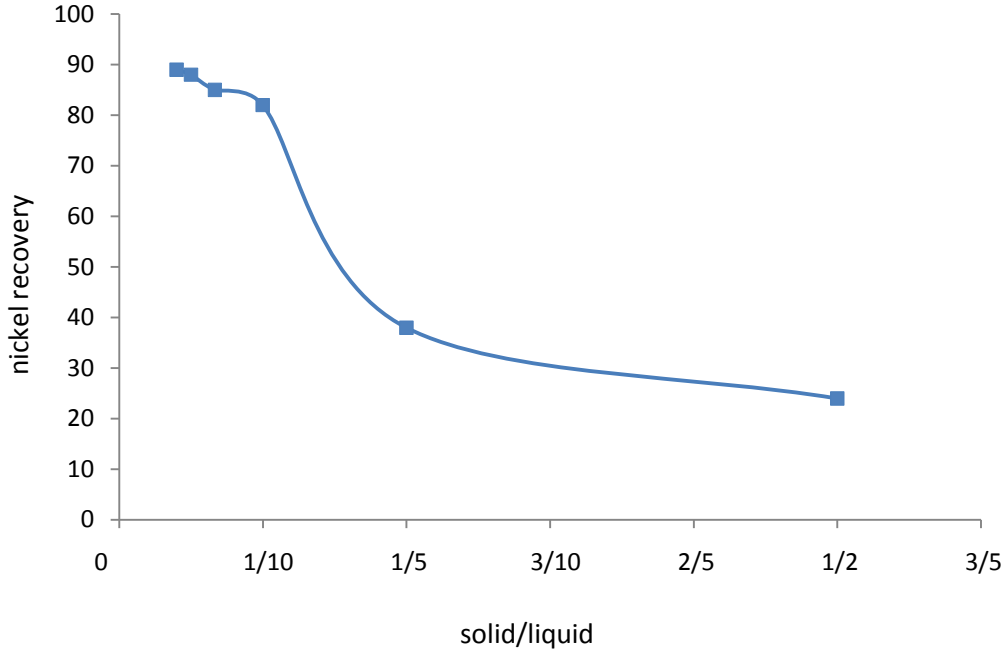

Fig. 3. Effect of solid/liquid ratio on recovery of nickel catalyst. H_2SO_4 concentration 70%(v/v) and temperature:120Ċ.

3.2. Effect of reaction time

Extraction of nickel from spent Ni catalyst was carried out at different time of reaction from 20 to 220 minute. In all these experiment other factors were adjusted at their best condition (temperature: 120Ċ, acid concentration: 70% (v/v) and S/L: 1/20). We can obviously find out from figure 4 that time of contact is the other mains factors. Metal removal can be continued till 220 minute. At this time all nickel can be removal as sulfate.

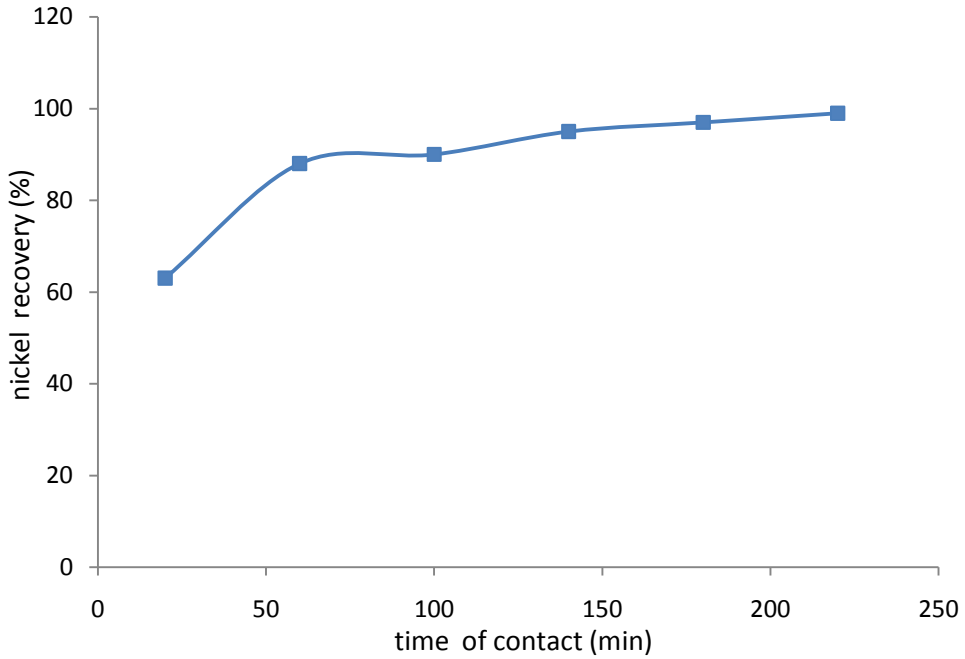

Fig. 4. Effect of contact time on nickel recovery. H_2SO_4 concentration 70 %(v/v) and temperature: 120Ċ, S/L: 1/20.

4 Conclusions

Extraction of nickel was carried out from spent nickel catalysts using in steam methane reforming by sulfuric acid as inorganic component, also there is chance to regenerate these catalysts and reuse in the processes. The recovery of nickel was more than 99 percentages during the leaching process. The optimum experimental parameters achieved under the following conditions: temperature 120Ċ, acid concentration 70% (v/v), solid: liquid 1: 20 and contact time 220 minute. Although in all these experiments eliminate the stirring rate and particle size diameter factors.

Acknowledgment

The authors would like to thank Arak petrochemical complex for providing Ni catalyst.

Abstract

Ferric ion is one of the most important oxidants used in leaching processes. In this study a comparison between the oxidation of iron at atmospheric pressure and under an oxygen pressure of 2 and 6 bar was carried out. The results showed that H_2O_2 was the most effective oxidant agent. However, it is a very expensive reagent to be used in a leaching process at industrial scale. As an alternative, ferrous ion oxidation may be carried out in an autoclave, where it is possible to have more than 20% of the total iron in its ferric form at 95 ºC and $P(O_2)$=6 bar in 1 h, with the expected beneficial effects on the leaching rates of sulphide minerals.

1 Introduction

Ferric ion is commonly used as oxidant agent in the leaching of sulphide minerals. Thus, for example, the leaching reaction of zinc sulphide follows the reaction below (Aydogan et al., 2005; Dutrizac et al., 2003):

$$ZnS + Fe_2(SO_4)_3 \rightarrow ZnSO_4 + 2FeSO_4 + S^0 \quad (1)$$

When the leaching is carried out in acid media under oxygen pressure, the ferric ions spent in reactions 1 or 2 are regenerated through reaction 3 (Filippou, 2004):

$$2ZnS + 2Fe_2(SO_4)_3 \rightarrow 2ZnSO_4 + 4FeSO_4 + 2S^0 \quad (2)$$

$$4FeSO_4 + 2H_2SO_4 + O_2 \rightarrow 2Fe_2(SO_4)_3 + 2H_2O \quad (3)$$

Therefore, according to reaction 3, oxygen is transferred from the gaseous phase to the liquid phase and reacts with ferrous ions, in the presence of sulphuric acid, to produce ferric ions. The ferric ions will then dissolve zinc sulphide (equation 2).

The consumption of ferric ions in the leaching reaction (Eq. 1 and 2) leads to the decrease of the redox potential and to the observed reduction of the leaching rate. Therefore, it is advantageous to carry out the oxidation of Fe(II) to Fe(III) during the leaching by the addition of external oxidants. In fact, this procedure would allow maintaining the concentration of the oxidant and the redox potential but minimizing the consumption of fresh reagent. Oxidizing agents such as air, oxygen (O_2) and hydrogen peroxide (H_2O_2) may be used to promote the oxidation of ferrous ions in aqueous solution. In acidic solutions, the oxidation of ferrous ion with O_2 follows reaction 4 (Rönnholm, 1999):

$$Fe^{2+} + \frac{1}{4}O_2 + H_3O^+ \rightarrow Fe^{3+} + \frac{3}{2}H_2O \quad (4)$$

* Corresponding author. Tel + 351-21-8417311. E-mail: jcarv@ist.utl.pt

The kinetics of the oxidation of Fe(II) ions by gaseous oxygen (reaction 4) is a second order reaction with respect to Fe(II) concentration (Chmielewski, 1984, Vracar, 1997). Thus, the equation of the process rate is:

$$\frac{d[Fe(III)]}{dt} = -\frac{d[Fe(II)]}{dt} = k[Fe(II)]^2 \quad (5)$$

or:

$$\frac{1}{[Fe(II)]_t} = kt + \frac{1}{[Fe(II)]_0} \quad (6)$$

Where $[Fe(II)]_t$ is the concentration of the ferrous ions within a determined period of time (mol/L), $[Fe(II)]_0$ is the concentration of ferrous ions at time=0 (mol/L); k is the rate constant (L/(mol.min) and t is the time (min). Therefore the kinetic constants may be calculated from the slope of the lines that represent $[Fe(II)]^{-1}$ vs time, for t=0.

Hydrogen peroxide is also used as an oxidizing agent for iron. In fact, the reduction potential of the pair H_2O_2/H_2O (E_0 (H_2O_2/H_2O) = 1.77 V) is very high and will oxidize the ferrous ions in accordance with the following reaction (Aydogan, 2006):

$$H_2O_2 + 2Fe^{2+} + 2H^+ \leftrightarrow 2H_2O + 2Fe^{3+} \quad (7)$$

The use of H_2O_2 in hydrometallurgical processes, despite its relatively high price, has a great potential, as mentioned in several recent studies concerning the sphalerite leaching (Aydogan, 2006, Pecina et al., 2008).

In this study, oxidation tests using synthetic solutions containing only ferrous sulphate and sulphuric acid were performed at atmospheric pressure and at pressures of 2 and 6 bar using a Parr autoclave.

2 Materials and methods

All the chemicals were Analytical Grade and all solutions were prepared with deionised water. Measurements of the pH and of the redox potential were carried out with a pH/E meter from Metrohm. The solutions were analysed for iron concentration by atomic absorption spectroscopy (Perkin Elmer, AAnalyst 200) and ferrous ion was determined by volumetric analysis with potassium dichromate (Vogel, 1972).

3 Experimental procedure

Oxidation tests at atmospheric pressure were performed in a five-necked round bottom reactor (1 L, 13 cm diameter) heated by a thermostatic oil bath. For stirring, a single round paddle (6.5 cm diameter) was used. The 800 mL of leaching solution ($FeSO_4$ + H_2SO_4) was added to the reactor and when the temperature was reached, air was added and the stirring started. The addition of small volumes of H_2O_2 130 V (2 mL after each sample), were also tested.

The autoclave tests were carried out using a Hastelloy C-276 autoclave (Parr, model 4843). In this case, 1000 mL of solution ($FeSO_4$ + H_2SO_4) was added to the reactor under stirring and the selected O_2 pressure. The first sample was collected when the selected temperature was reached.

The redox potential of the solution was monitored throughout the experiments with a silver/silver chloride reference electrode. The pH of the solution was also monitored during the tests. At pre-set time intervals, samples of 2 to 5 mL were withdrawn from the reactor and analysed for total and for ferrous iron.

4 Results and discussion

At atmospheric pressure, the oxidation of ferrous ions was performed by the addition of air and H_2O_2 130 V. The comparison between these two oxidizing agents is presented in Figure 1.

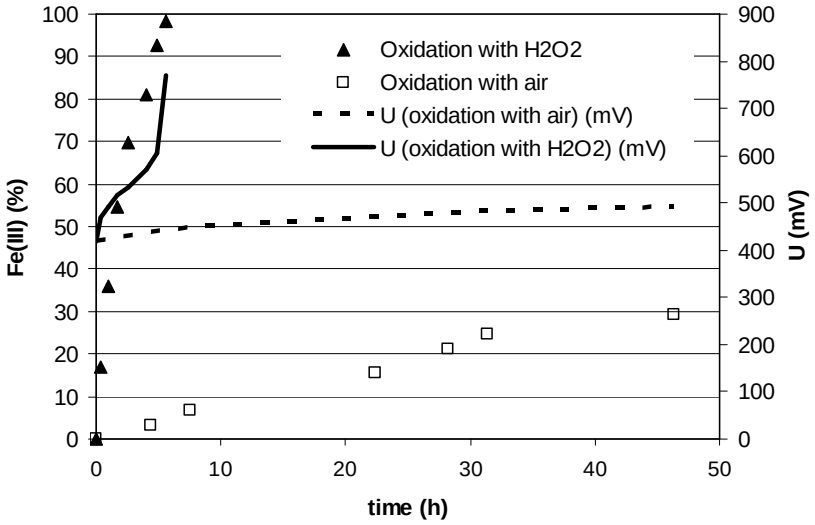

Figure 1: Effect of the addition of air and H_2O_2 on Fe(II) oxidation. Experimental conditions: solution with $[Fe(II)]_{initial}$=15 g/L, $[H_2SO_4]$=0.5 M, T=80 ± 3 ºC, stirring speed=500 rpm, air=64 L/h, V_{H2O2} =14 mL ($V_{solution}$=800 mL). Reference electrode: silver/silver chloride.

The results show that at atmospheric pressure, hydrogen peroxide was more effective than air. In fact, the addition of 14 mL of H_2O_2 130 V (addition of 2 mL after each sample) to 800 mL of solution allowed the complete oxidation of Fe(II), whereas after 46 h of air injection, only 30% of the ferrous ion was oxidized.

The autoclave tests were performed at two different O_2 pressures: 2 and 6 bar. Figure 2 presents the influence of the temperature in the oxidation rate of ferrous ion.

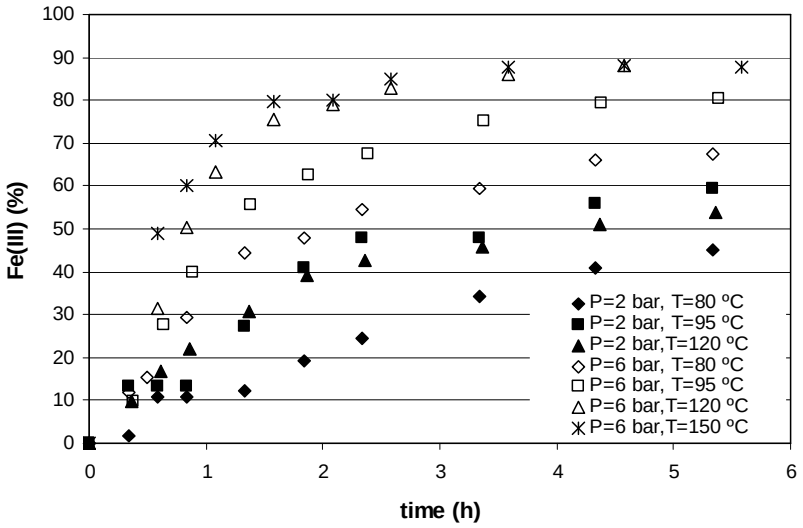

Figure 2: Autoclave oxidation of Fe(II). Experimental conditions: solution with $[Fe(II)]_{initial}$=15 g/L, $[H_2SO_4]$=0.5 M, stirring speed=500 rpm.

It is possible to conclude from Figure 2 that at 80 ºC and 2 bar of oxygen 44% of the ferrous ion was oxidized in 5 h. The results obtained were improved when the temperature was increased to 95 ºC. In fact, 60% of the ferrous ion was in its trivalent form after 5 h of reaction but there was no improvement of these results when the temperature was increased up to 120 ºC.

As expected, the kinetics of the oxidation reaction increased directly with the oxygen pressure and temperature, being the temperature effect more pronounced at 6 bar. Thus, for example, at 95 ºC and PO_2=2 bar, 40% of the ferrous ion was oxidized in 2 h, whereas this value increased to 63% at 6 bar. On the other hand, the temperature increase from 80 to 120 ºC allowed an augment of the amount of ferric ions in solution of about 30%.

The effect of the stirring speed on the oxidation rate of ferrous ion is presented in Figure 3. The results showed that, at 6 bar oxygen pressure, the oxidation rate was not significantly affected by the increase of the stirring speed. This result indicates that the rate controlling step of the ferrous ion oxidation is not the diffusion in the liquid phase. On the other hand, the effect of the temperature on the kinetics of ferrous iron oxidation presented in Figure 2 suggests a reaction rate control of the global process.

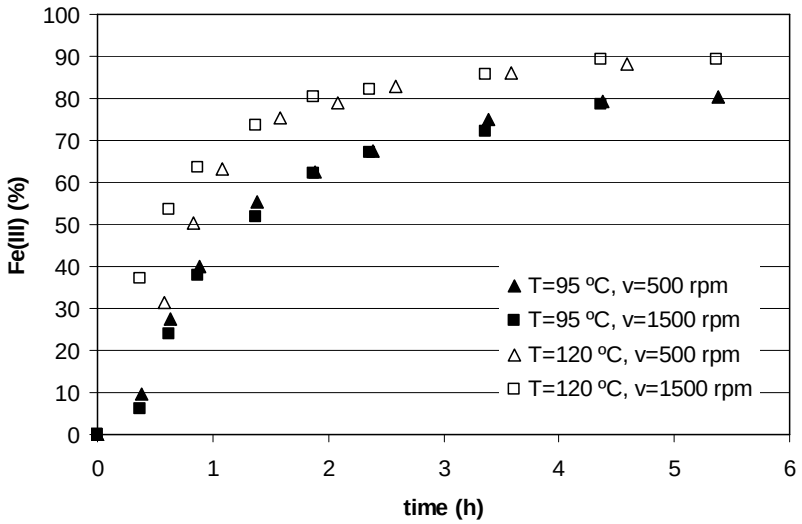

Figure 3: Autoclave oxidation of Fe(II). Experimental conditions: solution with $[Fe(II)]_{initial}$=15 g/L, $[H_2SO_4]$=0.5 M, $P(O_2)$=6 bar.

The activation energy value helps to identify the rate controlling step. Therefore, the kinetic constants for the experiments carried out at PO_2= 6 bar were calculated from the slope of the lines $[Fe(II)]^{-1}$ vs time and Figure 4 shows the correspondent Arrhenius plot. The value of the activation energy calculated for the reaction was E_a= 40 kJ/mol, which clearly suggests a reaction controlled process.

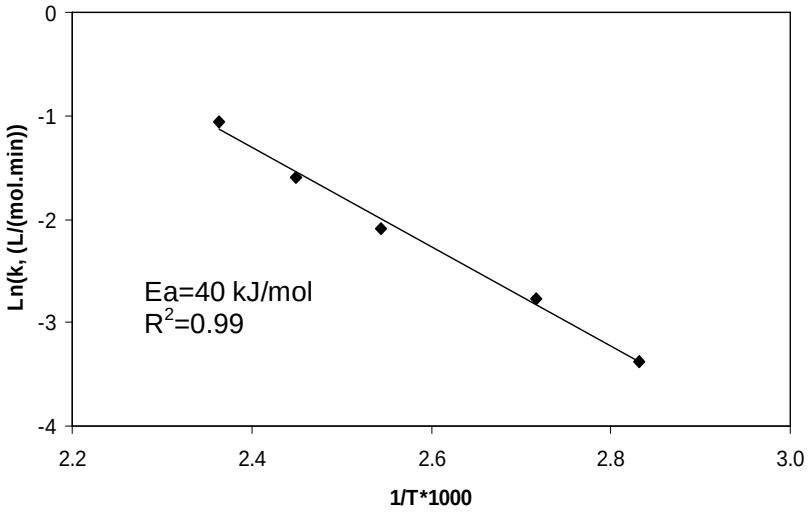

Figure 4: Arrhenius plot.

The above presented results are important in the optimization of the leaching conditions to be used in, for example, the leaching of the metals contained in a zinc sulphide concentrate. As shown in Figure 1, at atmospheric pressure, H_2O_2 was the most effective oxidant agent. However, its price may affect the economics of the hydrometallurgical process at industrial scale and, therefore, the autoclave leaching under an oxygen pressure should be used instead. In fact, Figure 5 clearly shows the benefits of carrying out the autoclave leaching described by the zinc leaching curves from a zinc sulphide concentrate with 45% of zinc. The change of the percentage of ferric ions in solution with time is also shown in this Figure.

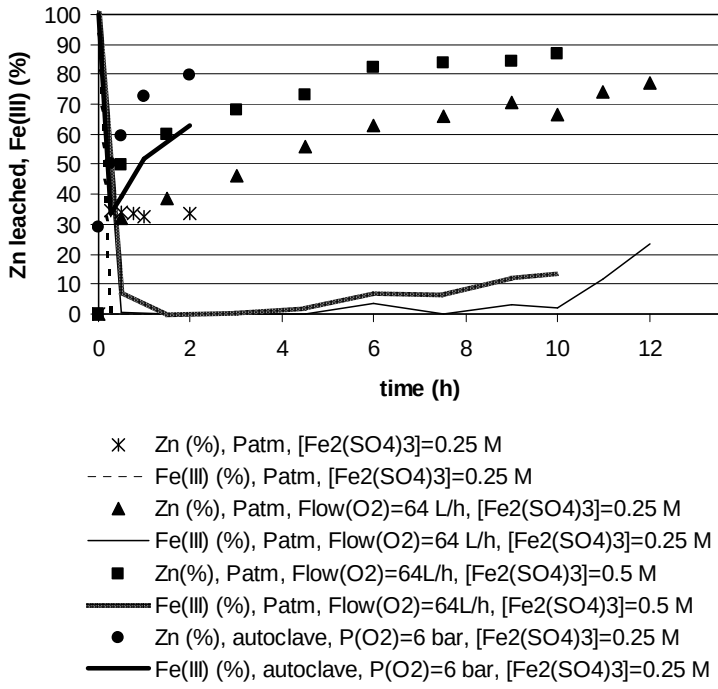

Figure 5: The effect of Fe(II) oxidation on Zn leaching. Experimental conditions: s/l=10% (w/v), T=80 ºC, solution with $[H_2SO_4]$=0.5 M, stirring speed=500 rpm.

As illustrated above, at atmospheric pressure and without iron oxidation, the maximum extraction of zinc (35%) was attained in 30 min and increasing the leaching time did not lead

to the increase of zinc extraction. Furthermore, after 15 min all the iron was in its ferrous form. At atmospheric pressure, the introduction of oxygen in the reactor allowed a slight improvment of the leaching results and the maintenance of a residual amount of ferric ions in solution for reaction times higher than 4 h. However, this effect was very slow. On the contrary, the resuls were improved significantly when the leaching was carried out in autoclave under an oxygen pressure of 6 bar. In this case, the ferrous iron was rapidly oxidated to Fe(III), allowing to maintain its percentage value higher than 35% during all the experiments and to leach in 2 h more than 80% of the zinc contained in the concentrate.

5 Conclusions

It was demonstrated that H_2O_2 at atmospheric pressure, as well as air/oxygen, may be used to perform the oxidation of ferrous ion. Whereas the reaction is very slow with air/oxygen, the price of hydrogen peroxide may not allow its application at industrial scale. As an alternative, ferrous ion oxidation may be carried out in an autoclave. In fact, the regeneration of the ferric ions in situ would allow a significant decrease of the consumption of fresh ferric oxidant, without decreasing the leaching efficiency. The results obtained in this work show that zinc leaching was considerably enhanced when the oxidation of the ferrous iron to the ferric state was performed during the leaching reaction and it was possible to leach in 2 h around 80% of the zinc contained in a zinc sulphide concentrate with 45% of zinc.

Topic: Advancing the chemical engineering fundamentals

Abstract

A study has been conducted on the performance of a draft-tube conical spouted bed for drying fine particles. Batch operation has been performed at several temperatures using different draft-tubes (non-porous and open-sided) in order to ascertain the influence of temperature and draft-tube configuration on the drying of fine particles. The open-sided draft-tube is the one with best performance and a maximum air temperature of 200 ºC is recommended for energy optimization. An open-sided tube that protrudes above the bed by at least 2/3 the stagnant bed height produces much lower and denser fountains.

1 Introduction

The applicability of the spouted bed technique lies in its ability to treat (drying, coating, encapsulation and so on) granular products that are too coarse for fluidized beds, or solids that are heat sensitive (Brennan, 1989; Ando and Maki, 2002; Rosiane et al., 2000). This is the case in the food and pharmaceutical industries. Thus, the spouted bed regime is an alternative contact method that is especially interesting when the conventional regimes have limitations imposed by the physical characteristics of the solid and by gas residence time (Rosiane et al., 2000; Olazar et al., 1992).

Spouted beds with fully conical geometry combine the features of the cylindrical spouted beds (such as the capacity for handling coarse particles, small pressure drop, cyclic movement of the particles and so on) with those inherent to their geometry, such as stable operation in a wide range of gas flowrates (Olazar et al., 1992). This versatility in the gas flowrate allows for handling particles of irregular texture, fine particles and those with a wide size distribution and sticky solids, whose treatment is difficult using other gas-solid contact regimes (Aguado et al. 1999). Moreover, operation in the dilute spouted bed can be carried out with short gas residence times (as low as milliseconds) (Olazar et al., 1997).

Conical spouted beds have low segregation (Olazar et al., 1994), which allows for handling particles with a wide size distribution without stability problems. This property is interesting for both physical operations, such as drying, and chemical operations, such as waste material pyrolysis, for improving the distribution of products and consequently increasing their commercial interest (Olazar et al., 2001).

A crucial parameter that limits the scaling-up of spouted beds is the ratio between inlet diameter and particle diameter. In fact, the inlet diameter should be no more than 20-30 times the average particle diameter in order to achieve spouting status. The use of a draft-tube is the usual solution to this problem. Nevertheless, solid circulation, particle cycle time, gas distribution and so on, are governed by the space between the bottom of the bed and the draft-tube, Moreover, minimum spouting velocity and operating pressure drop are also

* Corresponding author. Tel + 34-946012527. E-mail:haritz.altzibar@ehu.es

functions of the type of draft-tube used.

A conventional spouted bed with draft-tube has proven to be an efficient dryer of simple construction (Passos and Mujumdar, 1989). Thus, it provides a high interface area for gas and solid contact, high heat and mass transfer coefficients and high production rates.

In previous papers (Altzibar et al., 2008), a conical spouted bed provided with draft-tube has been studied to verify their potential application in the drying of fine particles. Batch runs have been carried out using non-porous, porous and open-sided draft-tubes at ambient conditions and their performance has been compared. In this paper, batch runs have been carried out in a conical spouted bed using non-porous and open-sided draft-tubes at different temperatures.

2 Experimental

The experimental unit used for drying, Figure 1, consists of the following components: feeding system, device for feeding nitrogen and/or air, preheater, the conical spouted bed reactor, cyclone and the filter.

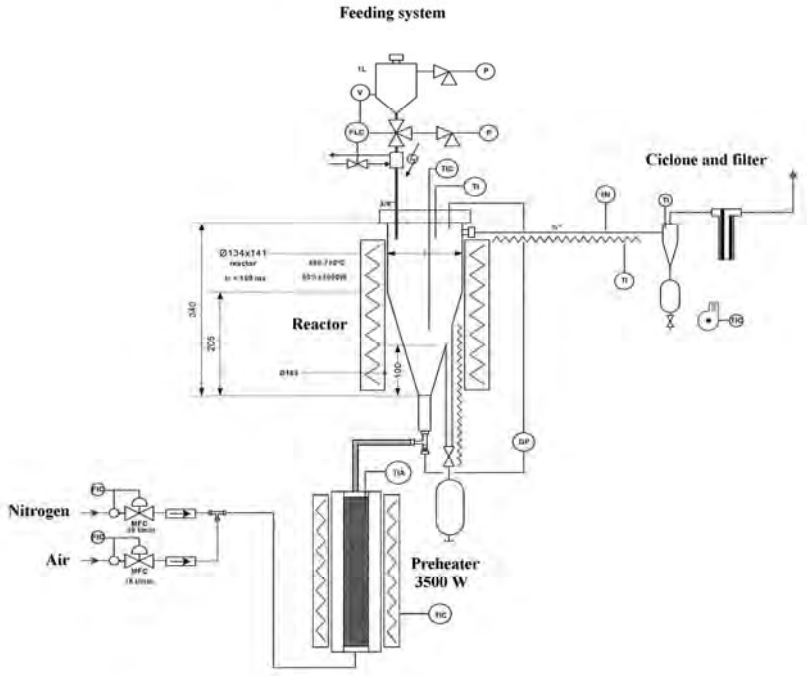

Figure 1. *Diagram of the experimental unit.*

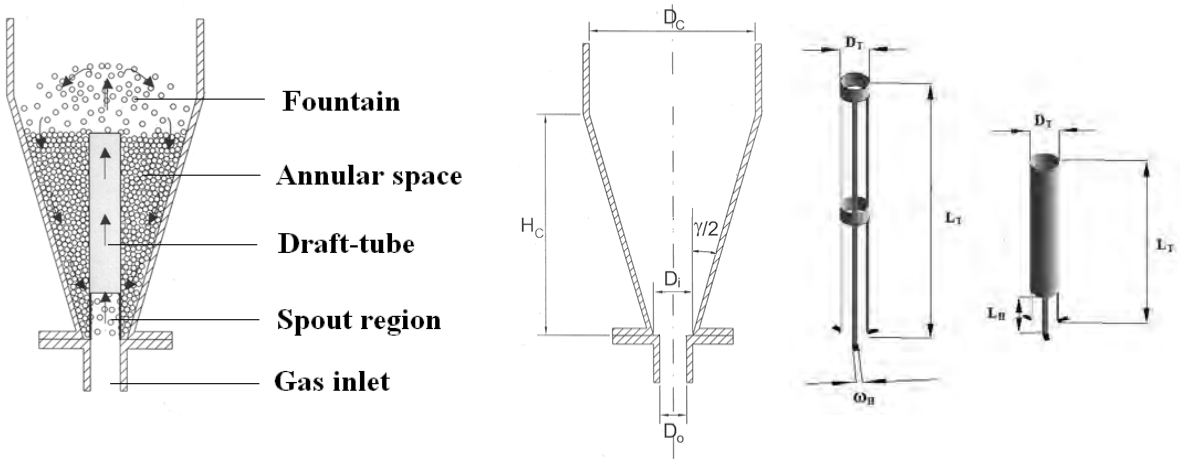
This experimental unit has been used previously in other operations, as a pyrolysis of waste plastics (Elordi et al., 2007), pyrolysis of biomass (Aguado et al., 2000) and pyrolysis of scrap tyres (Arabiourrutia et al., 2007).

The reactor is the main component of the unit and is of conical geometry provided with an upper cylindrical section. The reactor is made of 316-L stainless steel. Figure 2a shows the different zones in the bed with a standard non-porous draft-tube and particle movement. The geometric factors of the reactor, Figure 2b, are the following: height of the conical section, H_C = 0.205 m; angle of the conical section, γ = 28º; diameter of the cylindrical section, D_C = 0.123 m; base diameter, D_i = 0.02 m; inlet diameter, D_0 = 0.01 m. These dimensions have been established from previous hydrodynamic studies carried out in the spouted bed regime in conical contactors (Olazar et al., 1992) and bearing in mind the versatility of the equipment.

The reactor allows the insertion of draft-tubes. Two draft-tubes with different configurations have been used, Figure2c, which are open-sided and non-porous ones. The dimensions of

the open-sided draft-tube are the following: length of the tube, L_T = 0.16 m; width of the faces, W_H = 0.006 m; diameter of the tube, D_T = 0.01 m. In case of the non-porous draft-tube, the dimensions are: length of the tube, L_T = 0.115 m; height of entrainment zone (distance between the gas inlet nozzle and bottom of draft tube), L_H = 0.033 m; diameter of the tube, D_T = 0.01 m.



(a) (b) (c)

Figure 2. (a) *Zones in the conical spouted bed with draft-tube, (b) Geometric factors of the contactors, (c) Open-sided and non-porous draft-tubes.*

The unit is provided with two devices for heating the bed. A ceramic resistance for heating the gas that enters the reactor and another one that is coiled outside the reactor and covered with insulator. These resistances are controlled by means of measurements taken by several thermocouples, which are located at the bed inlet and at several positions in the bed.

Furthermore, there are thermal conductivity detectors (Alhborn MT8636-HR6) for measuring air moisture content at the bed inlet and outlet. Temperature and moisture contents are also stored in the Alhborn Almeno 2290-8 data logger, which allows for monitoring their evolution over time. The gas stream leaves the dryer and passes through a cyclone and a filter where fine solid particles are retained.

The gas flowrate is regulated by means of a mass flow controller that allows for a feed of up to 50 l min^{-1}, which is dosed by high sensitivity control valves that may be operated either from the computer or from the control panel. The gas used for operation is air.

The material used for drying is building sand. Table 1 shows the particle size distribution of this material.

Table 1. Particle size distribution of the sand.

Particle size (mm)	0.05	0.1	0.23	0.47	0.81	1.5	3	4	TOTAL
Weight (%)	0.172	3.974	20.210	31.476	26.793	16.852	0.489	0.034	100

Based on the values in Table 1, the average particle size (reciprocal mean diameter) has been calculated by means of the expression:

$$\overline{d_p} = 1/\left[\sum\left(x_i/d_{p_i}\right)\right] \quad (1)$$

The average size of the sand obtained using eq (1) is 0.5 mm and its density is 2358 kg m^{-3}.

3 Results

Batch runs have been carried out in a conical spouted bed with and without draft-tubes at four different temperatures: 25, 100, 200 and 300 ºC. The evolution of the air moisture

content with time has been monitored at the bed outlet. In the experimental study, an air flowrate 75% higher than the minimum one has been used in order to achieve a stable performance of the spouted bed.

In all runs, a bed with 200 grams of sand has been used. The initial moisture content of the sand is about 1%, and the specification is that it should be dried to approximately 0.005 kg of water/kg of dried solid for subsequent use. This solid is usually dried in rotary driers where mass transfer and efficiency are low.

Figure 3, 4 and 5 show the evolution of air moisture content with drying time at several temperatures with and without draft-tubes.

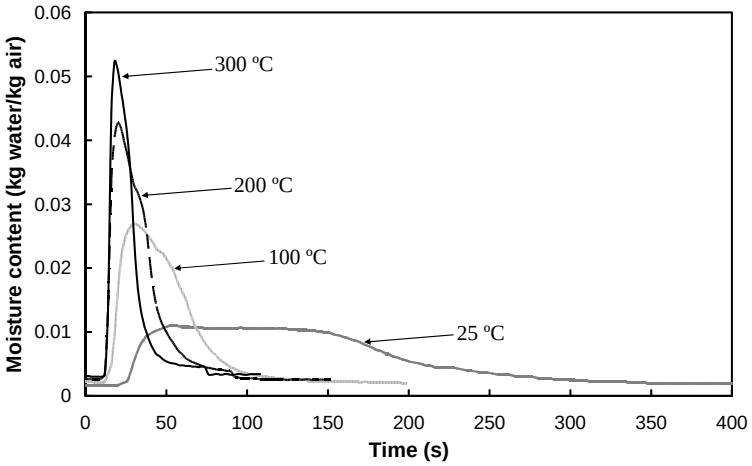


Figure 3. *Evolution of air moisture content with drying time at several temperatures without draft-tube.*

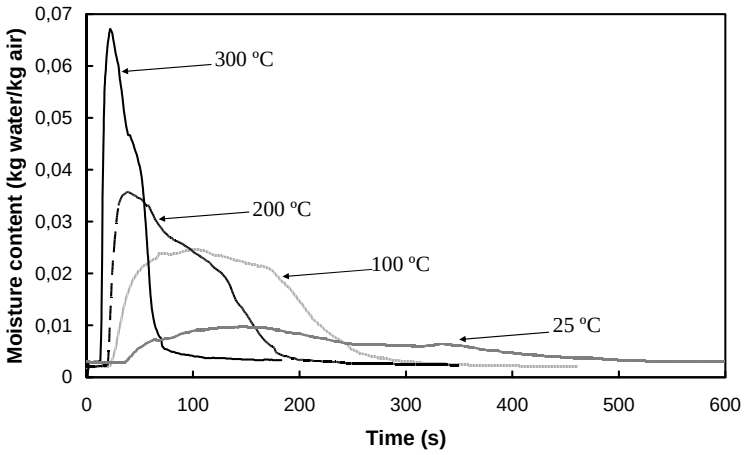

Figure 4. *Evolution of air moisture content with drying time at several temperatures using the non-porous draft-tubes.*

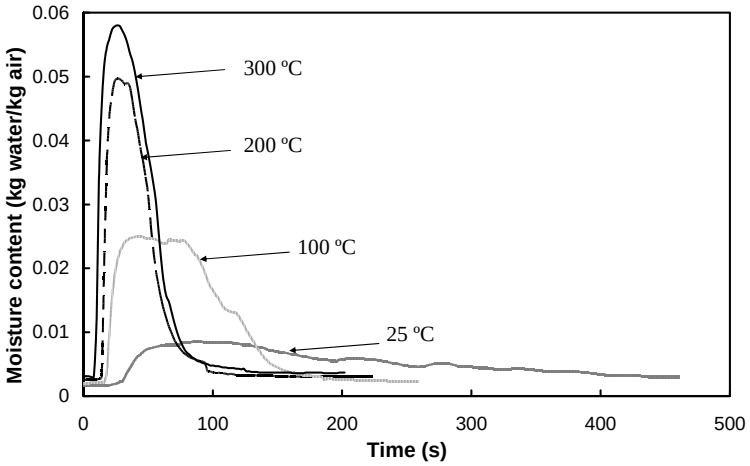

Figure 5. *Evolution of air moisture content with drying time at several temperatures using the open-sided draft-tubes.*

Figure 3, 4 and 5 show that the time required for drying the solid to the specification given decreases when the drying temperature is increased. As observed, the drying time required at ambient conditions (25 ºC) is significantly higher than that at high temperatures.

Furthermore, conical spouted beds are more stable at high temperatures than at ambient conditions, because under the latter conditions wet sand behaviour is much worse and the bed is more unstable.

In addition, it is also observed that without using any draft-tube and using open-sided draft-tube, the time required for drying above 200 ºC, Figures 3 and 5, is almost the same, which is evidence that the process is controlled by the internal diffusion in the particle.

Nevertheless, this is not the case when the non-porous draft-tube is used.Thus, the drying time required at 300 ºC is much higher than at 200 ºC. This is explained by the lower fraction of air rising through the annular space with the non-porous draft-tube and the resulting poorer gas-solid contact. Thus, when the non-porous draft-tube is used, until 300 ºC the process is not controlled by the internal diffusion in the particle.

On the other hand, Figures 3-5 show that the drying time required without using any draft-tube is shorter than using draft-tubes. The reason lies in the fact that the air required to achieve a stable spouted bed is much higher (2 or 3 times) and consequently the gas-solid contact is more vigorous. Consequently, energy efficiency for this operating procedure is low due to the excessive air flowrate required.

When draft-tubes are used, the drying time required with the open-sided draft-tube is shorter than with the non-porous draft-tube. The reason for that lies in the much higher solid circulation rate, which helps air percolation to the annulus and provides a better gas-solid contact. The only drawback of the open-sided draft-tube is that air flowrate required is slightly higher than with the non-porous draft-tube. Altzibar et al. (2008) proved that open-sided draft-tubes always require higher minimum spouting velocity and operation pressure drop than non-porous ones. This higher values are due to the solid-cross flow from the annulus into the spout along the whole length of the spout.

Despite these inconveniences, as proven by Altzibar et al. (2008), the solid circulation rate and the drying efficiency of the open-sided draft tube are superior to any other spouted bed configuration. Moreover, it allows for reducing the height of the fountain.

4 Conclusions

Conical spouted beds fitted with a draft-tube perform well in the drying of fine solids, given that they allow for stable operation in a wide range of operating conditions.

Conical spouted beds without any draft-tube require the shorter drying time, but the excessive air flowrate required does not advise this way of operation.

The non-porous draft-tube requires lower air flowrates but needs a longer drying time.

The open-sided draft-tube has the best performance on the drying of fine solids. Although the air flowrate required is slightly higher than the non-porous draft-tube, the time required for drying is much shorter. Besides the open-sided tube has the higher solid circulation rate. In addition, the open-sided tubes that protrude above the bed by at least 2/3 the stagnant bed height produce much lower and denser fountains. Consequently, the height required for the dryer is much shorter and particle entrainment will also be avoided.

Thus, conical spouted beds provided with open-sided draft-tubes have their best performance for drying sand at a temperature of 200 ºC. Higher temperartures do not have influence on the drying time and imply higher energy consumption.

Topic: Advancing the chemical and biological engineering fundamentals

Abstract

Three-level Box–Behnken factorial design with three factors and response surface methodology were used to optimize the colour removal of C.I. reactive red 180 by commercial laccase. A mathematical model was developed to study the effect of temperature, pH, enzyme concentration and their interactions on the decolourization. Enzyme concentration and pH as well as their interaction were the main factors that affected the decolourization. The dye degradation was independent of temperature. The model estimated that the highest decolourization (> 92 %) was obtained for pH 7.5 and 85 U l^{-1}. This predicted value was experimentally validated, obtaining dye colour removal (540 nm) of 93 ± 1.5 %.

1 Introduction

Reactive dyes are the principal class of dyes employed in textile industries to colour cellulosic fibres [1]. However, around 30 % of the applied reactive dyes are discarded causing serious environmental problems and the conventional treatments of wastewater are not efficient to completely remove the residual colour [2]. Classical treatments including adsorption, chemical precipitation, ozonation and flocculation have been reported for decolourization of effluents. However, in many cases they are inefficient and have a high cost. Conversely, biological processes such as biodegradation are an efficient alternative. Nevertheless, few studies involving enzymatic degradation of reactive dyes with commercial laccase are available [3].

Laccase is a copper-containing oxidoreductase (EC 1.10.3.2, *p*-diphenol:dioxygen oxidoreductase), which catalyzes the oxidation of phenolic compounds with reduction of oxygen to water [4]. However, the substrate range can be extended to non-phenolic compounds by the addition of a mediator [5]. Catalytic degradation of dyes with the laccase-mediator system (LMS) is an environmentally friendly technology which constitutes a promising alternative to conventional decolourization.

Experimental design and Response Surface Methodology (RSM) are useful statistical techniques that can be used in decolourization processes to identify and optimize the relevant factors that influence the colour removal. RSM can also be used to evaluate the relative significance of several factors and their possible interactions. It is an experimental strategy to obtain the optimum conditions for a multivariable system. Few reports are available to optimize reactive dyes degradation [6, 7].

In this study the RSM using the full Box-Behnken design of experiments was applied to optimize the decolourization conditions of C.I. reactive red 180 (RR180) by commercial laccase. A synthetic effluent containing the reactive dye was used to obtain a constant

composition in order to understand more easily the effects of the treatment.

2 Materials and Methods

Chemicals and enzyme

Textile dye: C.I. Reactive red 180 (Remazol Brilliant Red F3B), a monoazo dye, was kindly provided by DyStar (Porto, Portugal) and was used for degradation experiments without any further purification.

Enzyme: Commercial laccase formulation (DeniLite II S; 120 U g^{-1}) from genetically modified *Aspergillus* was kindly provided by Novozymes (Denmark). This formulation is used for indigo dye decolourization in denim finishing operations and includes a buffer and an enzyme mediator.

Box–Behnken Design of Experiments

A 3^3 Box–Behnken full factorial design was used to identify the factors having significant effects on RR180 decolourization by laccase. Three factors, i.e., temperature, enzyme concentration and pH were chosen. The experimental Box–Behnken design, analysis of variance (ANOVA) and 3D response surface were carried out using the software Statistica v.5.1 (Statsoft Inc.). Equation (1) describes the regression model of the present system, which includes the interaction terms:

$$Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \beta_3 X_3 + \beta_{12} X_1 X_2 + \beta_{13} X_1 X_3 + \beta_{23} X_2 X_3 + \beta_{11} X^2_1 + \beta_{22} X^2_2 + \beta_{33} X^2_3 \quad (1)$$

where Y is the predicted response, *i.e.* the colour removal; X_1, X_2 and X_3 are the coded levels of the independent factors temperature, pH and enzyme concentration. The regression coefficients are: β_0 the intercept term; β_1, β_2 and β_3 the linear coefficients; β_{12}, β_{13}, β_{23} the interaction coefficients and β_{11}, β_{22}, β_{33} the quadratic coefficients. The model evaluates the effect of each independent factor on the response.

Dye Decolourization Experiments

To study the decolourization of the reactive textile dye, 50 mg l^{-1} of C.I. RR180 were incubated in a 25 ml Erlenmeyer flask under stirring for one day. The dye degradation conditions are: laccase concentrations (24, 48 and 96 U l^{-1}), temperature (25, 35 and 45 ºC) and pH (6, 7 and 8). The pH values of dye solutions were adjusted with 50 mM phosphate buffer.

Determination of Dye Degradation

Dye decolourization was determined by monitoring the decrease in the absorbance peak at the maximum absorbance wavelength of RR180 (540 nm) (peak) or by calculating the total area under all the entire visible spectrum (area). UV-visible spectrophotometer (Thermo, model UV1) was used in all experiments. Decolourization is reported as: % decolourization = $(A_i - A_f)/A_i \times 100$, where A_i is the initial absorbance or total area under the initial spectrum and A_f is the final absorbance or total area under the final spectrum.

3 Results and Discussion

The most important factors, which affect the efficiency of enzymatic dye degradation,

are temperature and pH of the solution and enzyme concentration. In order to study the combined effect of these factors, experiments were performed for different combinations using factorial design methodology. The results show that the quadratic model, including linear interactions, fits adequately to the experimental data giving a coefficient of determination R^2 of 0.9306. Equation (2), which indicates the effect of factors on RR180 decolourization, is shown below, in terms of coded factors:

$$Y = 68.7 + 0.65X_1 + 10.5X_2 + 16.1X_3 + 0.5X_1^2 + 9.6X_2^2 + 6.7X_3^2 - 3.3\,X_1X_2 - 0.78X_1X_3 + 9.0X_2X_3 \quad (2)$$

Comparing the results of the dye decolourization by absorbance reduction at the maximum wavelength and results of the total decolourization based on the overall spectrum, the RR180 total decolourization (area) was always lower than decolourization at maximum wavelength (peak). The decolourization of RR180 causes a reduction of absorbance at the peak but not fully decolourization considering the entire visible spectrum.

The model was found to be adequate for prediction within the range of factors chosen. The optimum operating conditions for RR180 decolourization can be predicted from the second order polynomial function. The Pareto chart displays the statistically relevant effect of each factor on the response and it is a practical way to view the results. These are sorted from the largest to the smallest, and the effects to the right of the divisor line are significant. From Figure 1, the enzyme concentration (X_3) and pH (X_2) and their interaction $X_3 \times X_2$ showed to have effect on RR180 decolourization whilst the temperature did not affect the decolourization.

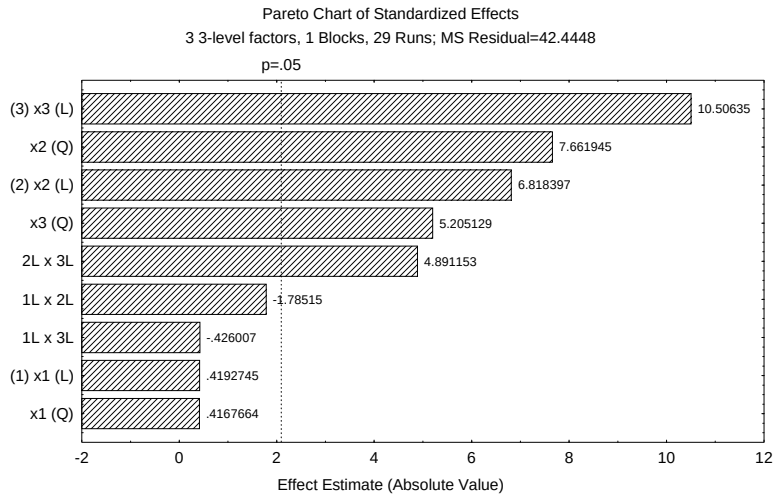

Figure 1 – Pareto chart of standardized effects for 3^3 Box-Behnken factorial design. (1) Temperature; (2) pH; (3) enzyme concentration.

The significance of the estimated effects was tested by analysis of variance (ANOVA). The ANOVA (Table 1) test indicates that the model adequately describes the decolourization of RR180 by commercial laccase. The significance of each coefficient was determined through a *p* value test considering 95 % of confidence in which low *p* values ($p < 0.05$) indicate high significance of the corresponding coefficient. The effect of pH and enzyme concentration and their interaction on RR180 decolourization is significant whilst the temperature did not influence the decolourization.

The response surface plots, generated from Box–Behnken design, are showed in Figure 2 a-c. The plots represent the decolourization of RR180 over changes in two independent factors (temperature, pH or enzyme concentration) while a third one was kept constant. Figure 2a shows the response surface of interactions between pH and temperature at 55 U l^{-1}. Decolourization increases with pH up to 7.5, and then decreases. The decolourization was practically independent of temperature changes as observed in Figures 2a and 2c. Figure 2b represents the effect of changes in enzyme concentration and pH at 35 ºC. It clearly shows that the optimum conditions for obtaining the maximum decolourization are within the experimental ranges tested. The decolourization increased with increasing pH and enzyme concentration up to approximately 7.5 and 85 U l^{-1}, respectively. Then the decolourization decreased slowly. Maximum decolourization was observed at those conditions and dye degradation above 92 % was predicted by the response surface metodology.

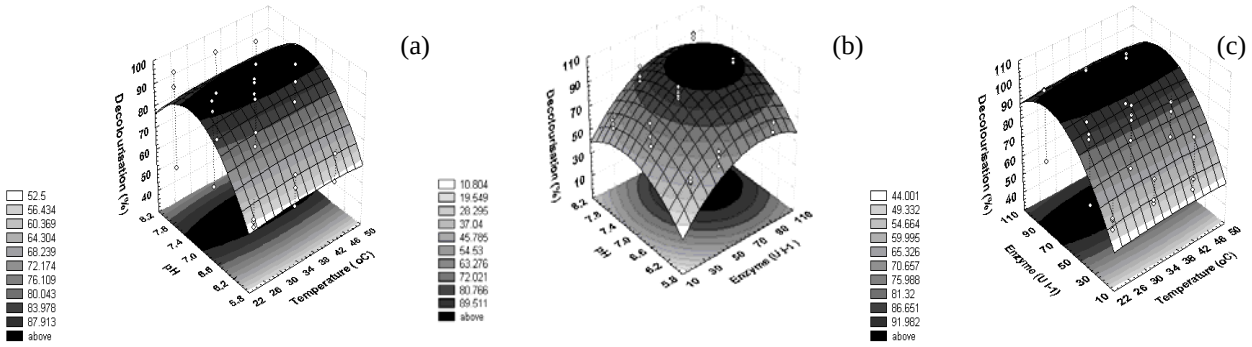

Figure 2 – Response surface plots of the reactive red 180 decolourization by commercial laccase: (a) effect of temperature (X_1) vs pH (X_2) at 55.4 U/l; (b) effect of enzyme concentration (X_3) vs pH (X_2) at 35 ºC; (c) effect of temperature (X_1) vs enzyme concentration (X_3) at pH 7.0.

The adequacy of the regression model for RR180 decolourization by laccase was checked by using the calculated optimum conditions: 85.4 U l^{-1} and pH 7.5 in triplicate experiments. Under these conditions, 93 ± 1.5 % of RR180 decolourization was obtained which is in good agreement with the predicted value (above 92 %).

DeniLite II is a commercial laccase with great potential to decolourise textile dyes. However a few studies regarding the use of this commercial laccase on the treatment of effluents containing dyes and especially with reactive dyes (RR 180) are available. It is a formulation containing laccase, mediator and a non-ionic surfactant used in the finishing process for indigo stained clothes [8]. In this study DeniLite II was used for decolourization of RR180 and the obtained results prove that pH and enzyme concentration play an important role on decolourization. Recent reports showed that a mediator is necessary for the decolourization of dyes by laccase [9, 10]. To confirm these findings, some experiments were carried out with pure commercial laccase (DeniLite Base) and no degradation of RR180 was detected (data not shown). Apparently, mediator is necessary for its degradation by laccase in order to complete the mechanism of electron transfer from the substrate to the enzyme. It seems that the mediator acts as an electron carrier, an intermediate substrate for the laccase [11]. The overall catalytic cycle is the reduction of the oxygen molecule to water molecule with the concomitant oxidation of the substrate.

4 Conclusions

Commercial laccase (DeniLite II S) was tested for decolourization of RR180. 3^3 Box–Behnken full factorial design was found to be an efficient tool for optimisation of RR180 decolourization. Enzyme concentration and pH were the factors that influenced the decolourization whilst the temperature changes did not affect the dye degradation. Validation experiments were carried out in order to check the suitability of the model. The results showed that the predicted decolourization was in agreement with the experimental value. Dye degradation by commercial laccase proved to be an efficient alternative treatment for decolourization of RR180 (> 92 %).

5 Acknowledgments

Financial support for this work was in part provided by LSRE financing by FEDER/POCI/2010, for which the authors are thankful. The authors wish to thank Novozymes (Denmark) for commercial laccase and DyStar (Porto, Portugal) for C.I. reactive red 180. R. Cristóvão acknowledges her Ph.D. scholarship from Fundação para a Ciência e a Tecnologia (FCT) (SFRH/BD/28529/2006) and A.P.M. Tavares acknowledges her Post-Doc scholarship from FCT (SFRH/BPD/22697/2005).

Modeling Orange II Azo Dye Degradation by Fenton's Reagent

J. Herney Ramirez, Filipa M. Duarte, F. G. Martins, Carlos A. Costa and Luis M. Madeira*

Keywords: Orange II, Kinetics, Fenton's Reagent, Hydrogen Peroxide, Oxidation.
Topic: Advancing the chemical and biological engineering fundamentals.

Abstract

A semi-empirical kinetic model was used to study the degradation of the azo dye orange II (OII) using Fenton's reagent, in the Fenton-like stage. The effect of temperature and initial concentrations of OII, hydrogen peroxide and ferrous ion catalyst on the degradation rate has been investigated in a batch reactor. The apparent kinetic constants (k_{ap}) were determined in a wide range of experimental conditions, using a pseudo-first-order reaction rate with respect to OII concentration. Besides, k_{ap} depends on the initial conditions following a power-law dependency. This equation, without further fitting parameters, was then successfully used to validate experiments performed in a continuous stirred tank reactor.

1 Introduction

Some azo dyes and their precursors have shown to be, or are suspected to be, human carcinogens as they form toxic aromatic amines (Brown et al., 1993). In particular, orange II (OII), also called acid orange 7, is a molecule with N=N bonds that is widely used in the dyeing of textiles and cosmetics, and thus found in the wastewaters of the related industries (Méndez-Paz et al., 2005). The processes used to decontaminate such wastewaters are physical, biological and chemical. Recent progress in this field has led to the development of advanced oxidation processes (AOPs). Among them, the oxidation using Fenton's reagent has proved to be a promising and attractive treatment method for the effective decolourization and degradation of dyes, as well as for the destruction of a large number of hazardous and organic pollutants (Lin et al., 1997; Malik et al., 2003). Moreover, the process is simple, taking place at low temperatures and atmospheric pressure (Bigda et al., 1995).

Oxidation with Fenton's reagent is based on ferrous ion and hydrogen peroxide and exploits the very high reactivity of the hydroxyl radical produced in acidic solution by the catalytic decomposition of H_2O_2. The $HO^{\bullet}$ species produced through these reaction will then attack the organic matter present in the reaction medium, because the hydroxyl radical is a powerful inorganic oxidant that reacts non-selectively with numerous compounds.

A main goal of the present work is to find a simple semi-empirical equation that describes the degradation of Orange II in a batch reactor by the Fenton's reagent. Several operational parameters, such as OII concentration, H_2O_2 dosage, Fe^{2+} concentration and temperature, which affect the degradation efficiency, were investigated. Finally, the kinetic law obtained was used to validate experiments carried out in a continuous reactor. To the best of the author's knowledge, there are available only a few studies about Fenton's reagent application in continuous reactors (e.g., Rivas et al., 2004), and none was found for the OII dye. Studies dealing with the modelling of such continuous process are also scarce.

2 Materials and methods

Chemical oxidation of azo dye Orange II aqueous solutions was conducted in two stirred jacketed glass reactors: a batch and a continuous stirred tank reactor (CSTR), with 0.30 L

and 0.92 L capacity, respectively. In both cases, temperature was controlled through a Huber thermostatic bath (Polystat CC1 unit). The absorbance and the pH were continuously monitored using a Philips PU8625 UV/VIS spectrophotometer and a pH-meter from EDT instruments (RE 357 TX), respectively. More details about the apparatus can be found in Ramirez et al. (2005).

In all batch experiments initial pH was adjusted to 3.0 through addition of 1 M NaOH or 0.1 M H_2SO_4 solutions, this optimal pH value being chosen based on our previous work (Ramirez et al., 2005). After pH adjustment, solid iron sulphate ($FeSO_4.7H_2O$, from Panreac) was added to the reactor, followed by the hydrogen peroxide solution (30% w/w, from Merck), which corresponds to the initial instant of the runs.

Orange II concentration was obtained from a calibration curve at the characteristic dye wavelength (486 nm), because this corresponds to the maximum of absorption and in this range interference by oxidation products does not occur (Ramirez et al., 2007a).

For operation of the CSTR, a Watson-Marlow 5055 peristaltic pump was used to feed two streams: one acidic containing the dye solution with the dissolved iron catalyst and another with the H_2O_2 solution. Both flow rates were carefully measured so that the concentration of each species, at the reactor inlet, was known. The exit stream flowed through the spectrophotometer flow-through cell until a steady dye concentration was measured. All experiments were carried out at pH ~3.0. In experiments carried out in duplicate, conversion varied by less than 10% (Ramirez et al., 2008).

3 Results and Discussion

3.1 Batch Reactor - Kinetic study

In the Fenton's process the formation of hydroxyl radicals has been demonstrated by several researchers and suggested to be the main oxidant species. In spite of the oxidation kinetics complexity, it is often assumed that, under certain conditions, the mechanism of the process can be significantly simplified, being of particular relevance the reaction between the organic matter and such radicals (Sun et al., 2007). The corresponding kinetic equation, assumed to be elementary, can thus be expressed as follows:

$$\left(-r_{OII}\right) = kC_{HO^{\bullet}}.C_{OII} = k_{ap}C_{OII} \qquad (1)$$

where k_{ap} is an apparent pseudo first-order kinetic constant that involves the radical HO concentration (assumed to remain constant along one experiment, due to the hypothesis of a pseudo steady-state concentration of hydroxyl radicals). The value of this rate constant depends therefore on the initial reactants concentrations (H_2O_2 and Fe^{2+}), on the temperature and also on the concentration of scavenger species present in the reaction mixture (such as intermediates, $HO_2^{\bullet}$, etc.) (Sun et al., 2007). On the other hand, these scavenger species concentrations depend on the initial orange II concentration, and for this reason k_{ap} is a function of all these variables: $k_{ap} = f(C_{OII_o}, C_{H2O2_o}, C_{Fe^{2+}{}_o}, T)$.

The dependence of k_{ap} from the operating conditions can be found by performing independent experiments, changing each factor at a time, after appropriate linearization of the data. On the other hand, the k_{ap} values in each run can be obtained from the mass balance in the batch reactor ($dC_{OII}/dt = -k_{ap}.C_{OII}$), thus yielding:

$$\frac{C_{OII}}{C_{OII_o}} = exp\left(-k_{ap}t\right) \qquad (2)$$

However, the reaction exhibits a change on its kinetics, which is a consequence of the complexity of the mechanism. This has been widely reported in the literature associated with the Fenton's process, and for that reason the k_{ap} values were calculated from experimental data covering only the Fenton-like phase of the process, this means where most of the Fe^{2+} has been converted into Fe^{3+} ($Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + HO^- + HO^{\bullet}$). Actually, it is known that the Fenton's process is divided in two stage-reactions. In the first stage the organic compounds

are decomposed rapidly and somewhat less rapidly in the second one (Malik et al., 2003). Because the above-mentioned reaction in which Fe^{2+} is converted into Fe^{3+} is very fast, the first stage is short and afterwards the process enters into a so-called pseudo steady-state, wherein Fe is mainly in the 3+ oxidation state (although it regenerates to Fe^{2+}).

3.2 Batch Reactor – Effect of the main operating conditions

3.2.1 Effect of the initial orange II concentration

The effect of the initial dye concentration was tested at constant initial H_2O_2 and Fe^{2+} concentrations and temperature. Results are shown in Fig. 1A, with the corresponding fitting lines (in the second Fenton's stage), and the obtained apparent kinetic constants are shown in Fig. 1B. Results show that the degradation rate decreases for increasing initial dye concentrations. The apparent rate order for Orange II was then determined to be -0.67 from the slope of a ln k_{ap} vs. ln C_{OIIo} plot (Fig. 1B). The negative effect of the parent organic compound on the apparent kinetic constant was also reported by other authors (e.g., Sun et al., 2007). Because the amount of hydrogen peroxide molecules available is the same, this indicates that the higher the dye concentration in the reactor, the smaller is the hydroxyl radicals concentration at the pseudo steady-state.

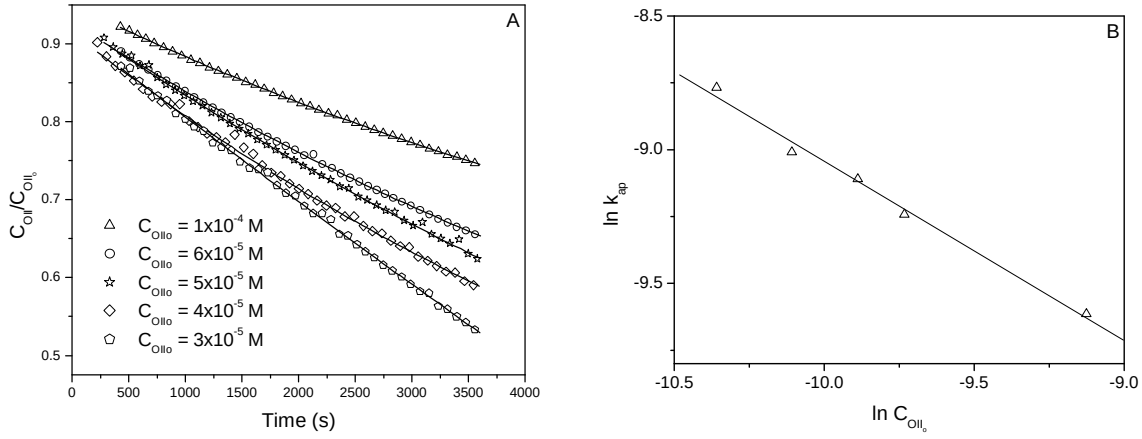

Fig. 1 – (A) Plot of the normalized dye concentration over time in the second Fenton stage at different initial OII concentrations and respective model fitting. (B) Effect of the initial OII concentration on the apparent rate constant of OII degradation. T = 30°C, $C_{H_2O_2}$ = 2.0×10^{-4} M, $C_{Fe^{2+}}$ = 5.0×10^{-6} M.

3.2.2 Effect of the initial hydrogen peroxide concentration

The effect of the initial hydrogen peroxide concentration on k_{ap} evidenced that the degradation rate increases for increasing hydrogen peroxide loads, in the range studied (data not shown). This trend was expectable. The apparent rate order for initial H_2O_2 concentration was determined to be 0.77 from the slope of a ln k_{ap} vs. ln $C_{H_2O_{2_o}}$ plot.

3.2.3 Effect of the initial ferrous ion concentration

The procedure described above was also applied to analyze the effect of $C_{Fe^{2+}_o}$. Data obtained put into evidence that the degradation rate is very sensitive to the iron concentration, because it acts as catalyst in the Fenton or Fenton-like process. The rate order for initial Fe^{2+} dose was determined to be 1.43.

3.2.4 Effect of the temperature

It was observed that the temperature has a strong positive effect on the OII degradation rate, due to an increment in the pseudo-first-order rate constant. The data exhibit Arrhenius-type behaviour, with an apparent activation energy of 58.1 kJ mol^{-1}, calculated from the usual ln k_{ap} vs. 1/T plot. The value obtained is very similar to that previously reported by the authors for a Fe-impregnated activated carbon (56.1 kJ mol^{-1}) (Ramirez et al., 2007b).

3.2.5 Rate equation for the degradation of OII in a batch reactor

The rate equation can be expressed in a simple way, as shown in Eq. (1), wherein k_{ap} depends on the initial conditions as follows:

$$k_{ap} = 4.06\times10^{13} C_{OIIo}^{-0.67} C_{H_2O_2o}^{0.77} C_{Fe^{2+}o}^{1.43} \exp(-58092/RT) \qquad (3)$$

It is noteworthy that the pre-exponential coefficient indicated was calculated by regression, minimising the sum of the square residues between the k_{ap} data obtained from Eqs. (2) and (3), for each experiment.

Up to now a first-order rate law for OII degradation was established, which can be useful for predicting the pseudo steady-state (i.e., when Fe is essentially at the 3+ oxidation state) in a chemical reactor. Obviously, in a batch system this can fail, depending on the initial conditions and extension of the initial (Fenton) phase, which in most experiments performed is short. However, it can be valuable to predict the behaviour of open reactors, operating at steady-state conditions, if the residence time is enough so that Fe^{2+} is almost completely converted into Fe^{3+}.

3.3 Continuous stirred tank reactor (CSTR) experiments

In an ideal CSTR, the contents are well-stirred and uniform throughout; therefore the exit stream has the same composition as the fluid within the vessel. Tracer experiments have confirmed that the reactor used in this work closely matches these ideal mixing conditions (Ramirez et al., 2008).

In Figs. 2 to 6, is shown the effect of the reagents concentrations (at the reactor inlet), temperature and residence time on the outlet concentration of OII. In all of them, closed symbols refer to conditions within the batch range, whereas open symbols to values out of it. It can be concluded that the effect of each parameter on the OII outlet concentration is similar to that observed in the batch reactor. First, C_{OIIout} increases when the dye concentration in the reactor feed increases (Fig. 2). It is evident that when the H_2O_2 concentration is increased in the feed, a decrement in the OII outlet concentration is noticed (Fig. 3), because more hydroxyl radicals are available for oxidation, in the range studied. The same behaviour is observed when the ferrous iron is changed, as showed in the previous figures and also in Fig. 4. In the latter, an increase in the Fe^{2+} load fed to the reactor from 5×10^{-6} to 6×10^{-5} M lead to a significant increase in the steady-state OII conversion, however runs carried out at higher Fe^{2+} doses ($1\text{-}2\times10^{-4}$ M) resulted in no appreciable differences in terms of OII removal. Temperature effect was investigated in the range 283 to 336 K, showing to be an important parameter in the Fenton process (Fig. 5), particularly when low catalyst doses are employed. Finally, when the residence time was incremented, better results were obtained in terms of OII removal, as expected (Fig. 6).

3.4 Validation of the model in the continuous reactor

Since the reaction is of a pseudo first-order type, the outlet concentration of OII can be predicted by the CSTR mass balance, which yields (Fogler 1999):

$$C_{OII_{out}} = \frac{C_{OII_{in}}}{1 + k_{ap}\,\tau} \qquad (4)$$

where τ = V/Q is the space-time, V is the reactor volume (0.92 L) and Q is the total flow rate. k_{ap} is obtained by Eq. (3), based on the concentration of each species at the reactor inlet, because these are the conditions that determine the steady-state radicals concentration. This issue can also be rationalized from the well known total segregation model (Fogler 1999, Rodrigues 1981). Actually, the computation of conversion/exit concentration in a continuous reactor by the total segregation model makes use of an expression for a “micro” batch reactor that is based on the reactor feed conditions. Figures 2 to 6 show the model predictions (Eq. (4)) for all the experiments performed.

In what concerns the effect of the inlet OII concentration (Fig. 2), it is remarkable the adherence of the model to experimental data in which iron concentrations within the range used in the batch runs have been employed (closed symbols). However, even when catalyst doses one order of magnitude higher are employed, the model is able to predict the negative

effect of increasing dye concentrations, related with a decrease in the number of oxidant molecules (or radicals) available per dye molecule (lower H_2O_2/OII ratios). The model fits also reasonably the data obtained in experiments where increasing oxidant dosages were employed (Fig. 3), particularly for low iron loads. The model adherence is however worst when the catalyst concentration approaches the upper limit employed in the kinetic study.

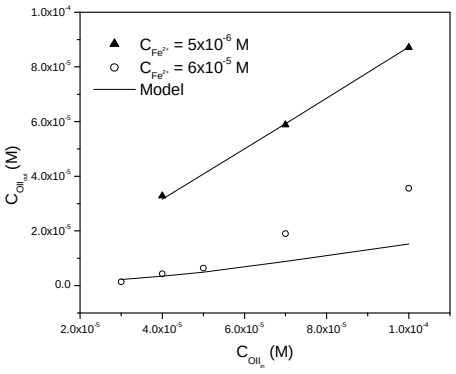

Fig. 2 – Effect of the inlet dye concentration on the OII outlet concentration in the CSTR $\left(C_{H_2O_2} = 4.0\times10^{-4}\ M, T = 30\ ^oC\right)$.

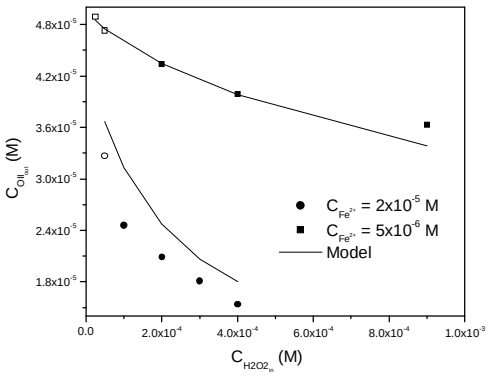

Fig. 3 – Effect of the inlet H_2O_2 concentration on the OII outlet concentration in the CSTR $\left(C_{OII} = 5.0\times10^{-5}\ M, T = 30\ ^oC\right)$.

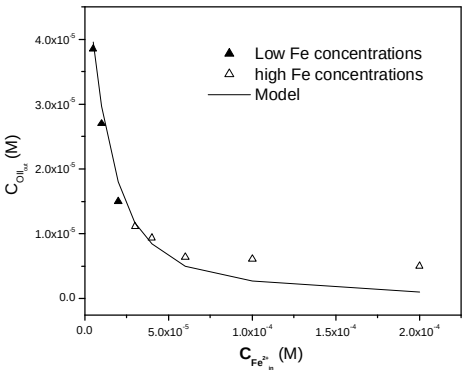

Fig. 4 – Effect of the inlet Fe^{2+} concentration on the OII outlet concentration in the CSTR $\left(C_{H_2O_2} = 4.0\times10^{-4}\ M, C_{OII} = 5.0\times10^{-5}\ M,\ T = 30\ ^oC\right)$

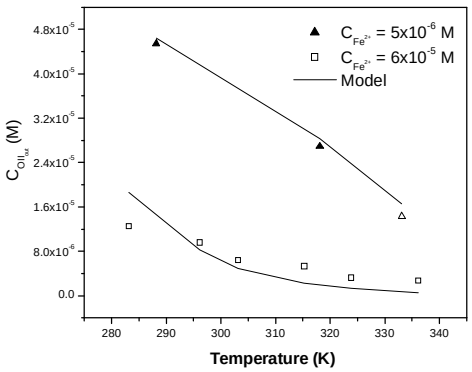

Fig. 5 – Effect of the temperature on the OII outlet concentration in the CSTR $\left(C_{H_2O_2} = 4.0\times10^{-4}\ M, C_{OII} = 5.0\times10^{-5}\ M\right)$.

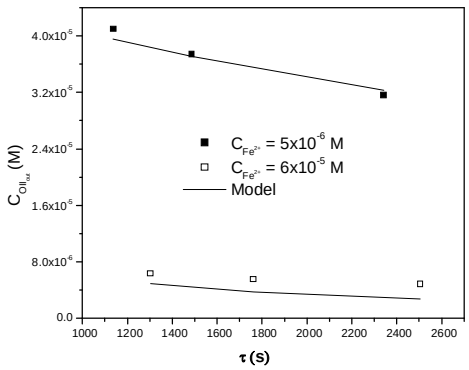

Fig. 6 – Effect of the space time on the OII outlet concentration in the CSTR $\left(C_{H_2O_2} = 4.0\times10^{-4}\ M, C_{OII} = 5.0\times10^{-5}\ M, T = 30\ ^oC\right)$.

Fig. 4 reinforces what was said in the previous paragraph, i.e., the good adherence of the

model to experimental data when using conditions (now iron concentrations) within those employed when establishing the rate equation. However it has some difficulties to predict the scavenging effect, i.e., the parallel and undesirable reaction that occurs between the catalyst and the hydroxyl radicals at high Fe loads. The results obtained when the temperature and residence time were changed (Figs. 5 and 6, respectively) show that the model also predicts well the positive effect of both parameters.

Conclusions

In this study, and particularly in the batch reactor experiments, low initial concentrations of hydrogen peroxide and ferrous ion were applied to eliminate the useless use of excessive reagent doses, commonly found at high Fe^{2+} and/or H_2O_2 doses. Experiments carried out in the batch reactor evidenced the positive effect of increasing the reaction temperature, H_2O_2 or Fe^{2+} concentrations, and the negative effect of increasing dye concentrations, trends that were corroborated with experiments in the CSTR.

The dye history concentration showed a change in the kinetics, typical of this process, being initially very rapid (Fenton stage) and afterwards the slower Fenton-like stage proceeds, where iron is mostly in the 3+ oxidation state. For the longer and last stage, a pseudo steady-state approach was employed to deduce the reaction rate, which was found to be of the first-order type with respect to OII concentration. The dependence of the apparent kinetic constant on the initial operating conditions was then deduced, leading to a power-law rate equation with Arrhenius dependency.

This rate equation revealed to be useful to predict the steady-state OII outlet concentration in the CSTR, in a wide range of operating conditions. In all cases, it was observed a reasonably good agreement between experimental and model results, even for experiments performed out of the range used in the batch kinetic study.

Topic: Advancing the chemical and biological engineering fundamentals

1. Introduction

The oil and its derivatives are complex mixtures that must be characterized by special methods to determine their chemical composition and other properties. As these experimental methods are expensive, and at times, insufficient, several empirical methods of calculation are applied, which easily allow estimating the composition basic properties of the substance. Among these characterization properties, the one that differentiates the description of the oil and its fractions is the viscosity, due to its easy and fast determination, and its possibility of use for heavy fractions.

The field of applications of viscosity characterization for oils and fractions is vast, especially for the heavy ones. The production and processing of heavy crude oil is constantly increasing as more heavy and viscous oil resources are being exploited to satisfy the rising world demand for petroleum. The viscosity correlations are important, in evaluating the performance in all operations and processes to which the oil and its derivatives are subjected, so that the method with the best performance of its production, refining, transport and storage can be selected.

There are several correlations and methods in literature that predict the viscosity of pure hydrocarbons and their mixtures, as well as estimate the viscosity of oil and its derivatives, which takes in to consideration the composition of the mixture. Almost all of them are of empirical nature, since there isn't a basic theory that predicts fluid transport properties.

The mixture can be modeled as a homogeneous solution or as a non-homogeneous mixture with a dispersed phase made of heavier components. This study aims at selecting a simple model that can quantify the dilution and the reduction of viscosity, as well as getting a good correlation between the viscosity of the mixture with temperature and the concentration of the diluent. We measured the kinematic viscosity of solutions of two atmospheric and one vacuum residues of distillation in toluene for different concentrations of diluent at several temperatures. The kinematic viscosity of a naphthenic crude oil was also measured for a wide temperature variation.

2. The Viscosity Prediction Models

2.1. Viscosity Prediction of the crude oil with temperature variation

The correlation usually used in petroleum industry proposed initially by Walther (1931), and later modified by ASTM (1982), where the parameters are a function of the kinematic

* Corresponding author. raja@eq.ufrj.br <mailto:raja@eq.ufrj.br>

viscosity (ν) and can be seen in the reference:

$$\log(\log(z)) = A - B \times \log(T)$$

$$z = \upsilon + 0{,}7 + C - D + E - F + G - H$$

The Eyring model (1936) shows that the dynamic viscosity decreases exponentially with the increase of temperature, depending on each substance, for example the presence mainly of aromatic hydrocarbons and little for the presence of paraffins. The viscosity, which is related with the energy necessary to initiate the draining of a substance, varies depending on the type and the form of molecules, besides being dependent on intra and intermolecular forces. Therefore, the parameters to predict the dynamic viscosity (μ) depend on the size of the molecule, its molar density and its activation energy.

$$\ln \mu = A + \frac{B}{T}$$

2.2. Viscosity Prediction of Residues in Toluene Mixtures

The viscosity prediction of these mixtures of residue in the solvent, toluene, can be obtained considering two kinds of models: those, in which the sample concentration is low, defined as less than 10%; and those in which the residue concentration is higher, defined as less than 50%. The first type of mixture was defined as dilute solution and the second type, as emulsions.

2.2.1. Dilute solutions

Dilute suspensions can be treated as if a particle were alone in an infinite liquid. Most of the existing models estimate the relative viscosity of the solution (η_r), defined as the ratio between the viscosities of the solution (η) to that of the continuous phase (η_C).

Taylor (1932) has considered the influence of the viscosities of both the dispersed and continuous phase and proposed an expression valid for emulsions with low concentration of dispersed spherical drops. His model is a function of volumetric fraction of the dispersed phase *(ϕ),* and the parameter *k*, which is the ratio of the viscosity of the dispersed phase (η_D) to that of the continuous phase (η_C).

Mooney (1951) has developed an equation based on Einstein's model, but for a suspension at a finite concentration, which is a function of an agglomeration factor defined by the value of null fluidity and the volumetric fraction of the dispersed phase *(ϕ).*

Roscoe (1952) has proposed a correlation for micro emulsions, modifying the Einstein's equation, using just the volumetric fraction of the dispersed phase *(ϕ).*

Choi and Schowalter (1975) and Yaron and Gal-Or (1972) have proposed correction factors to take into account the deformation of droplets. Both factors $f(\phi^{1/3})$ depend on the volume fraction (ϕ) and the ratio (k), given in the references.

Phan-Thien and Pham (1997) have developed a correlation based on the Taylor model, for a band of particles size above of which the Brownian movement is not so important anymore. Their model is a function of the parameter *k* and the volumetric fraction of the dispersed phase *(ϕ).*

2.2.2. Emulsions

An emulsion is a dispersed system in which the phases are immiscible or partially miscible liquids. Theoretical studies in the oil emulsions area have been limited to the case of suspensions of rigid spheres, especially for semi-dilute suspensions, in which the interactions between the pairs are dominant. For concentrated suspensions there are some semi-empirical models that can be used in the calculation of viscosity.

Guth and Simha (1936) have extended the results of Einstein to another concentration band, involving the interaction between particles, just applying the volumetric fraction of the dispersed phase *(ϕ).*

Brinkman (1952) has proposed a correlation especially recommended for high concentration samples, just as a function of the volumetric fraction of the dispersed phase *(ϕ).*

Richardson (1953) has observed an exponential increase of the relative viscosity also as a function of the volumetric fraction of the dispersed phase.

Krieger and Dougherty (1959), based in the model of Taylor, have considered a model where the concentration of the dispersed phase depends on the size of the drops. The correlation, restricted to Newtonian fluids, is a function of maximum volumetric fraction of the dispersed phase (ϕ_m), that is the limit of fluidity above of which the system is not in a liquid state to behave as an elastic solid. The correlation is also a function of intrinsic viscosity ([η]), which takes in consideration the ratio between the viscosity of the dispersed phase and the one from the continuous phase.

All these models only describe the variation of viscosity as a function of dispersed phase volume fraction or the ratio between the viscosity of dispersed phase and that of the continuous phase. The significant effect of temperature on the viscosity is not considered in any of these models.

3. Materials and Methods

For this study a stable medium heavy naphthenic crude oil (**OIL**), a very light atmospheric residue similar to several heavy oils (**AR I**), a typical atmospheric residue (**AR II**) and a typical vacuum residue from same oil (**VR II**) were selected . The samples were characterized by chemical analysis (elemental and SARA) and several relevant physical properties were measured. Table 1 lists molecular weight obtained by cryoscopy, density by Anton-Paar densimeter and molal average boiling point obtained by simulated distillation. Toluene was chosen as diluent as it dissolves all the asphaltenes present in chosen residues. Toluene high purity "HPLC / Spectra grade " was purchased from TEDIA Inc of United States and was used with out further purification.

Table 1 – Samples characteristics

	Oil	**AR I**	**AR II**	**VR II**
Molecular Wt.	340	565	604	1037
Density (ºAPI)	20,2	26,7	12,6	7,9
Molal Avg. Boiling Point	373,3	490	383	518

The kinematic viscosity is determined experimentally by the method ASTM D 445 (Brazilian standard MB-293), where a given volume of liquid sample is introduced into a standard viscometer and viscosity is determined by the time of flow by gravity through a capillary, under precise and reproducible control of temperature. We used calibrated Cannon-Fenske reverse flow viscometers for opaque fluids. The calibration factor was obtained by the standard procedure ASTM 446. This analysis takes about 60 minutes, with a reproducibility of approximately 0,35% of the average value, and a repeatability of 0,7% of average.

4. Results and Discussion

4.1. Viscosity prediction of Crude Oil

To obtain kinematic viscosity of the crude oil, 37 experiments were performed, each one with 2 repetitions. A temperature range of 20 to 200° C, with steps of 5° C was studied. The empirical result for the viscosity experiment for the oil showed an exponential decrease of the property by the increase of the temperature, as was expected.

Next it can be seen in the results for the kinematic viscosity prediction of the crude oil where the ASTM method and the Eyring's correlation is applied, both of which are extensively used in oil industry, a graph with the comparison of both methods, where the calculated results of the prediction are plotted against the experimental kinematic viscosity of the heavy crude oil. Values of the R-square coefficient from the observed figure, standard deviations and average absolute deviations of the experiments are presented in Table 2 and Figure 1.

Table2 – Crude oil viscosity prediction

Model	R2	SD	AAD
ASTM	0.9967		3.21614
Eyring	0.9582		20.05004

When the kinematic viscosities obtained experimentally are compared against the generated values from Eyring's correlation, an average absolute deviation (AAD) of 20 cSt, with a correlation coefficient (R^2) of 0.9582, is observed which makes it clear that this correlation is not well applied to the heavy crude oil. On the other hand, the same analysis for the ASTM method using the parameters obtained for this oil shows an average absolute deviation of 3 cSt and a correlation coefficient of 0.9967.

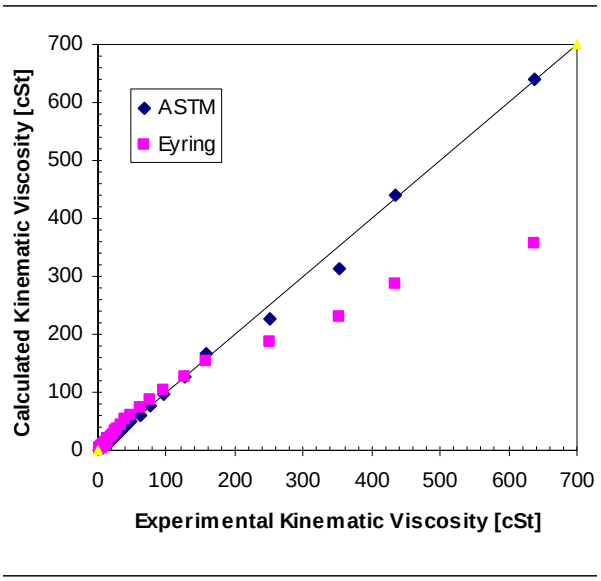

Figure 1 – Crude oil viscosity prediction

As a result, it can be concluded that when the Eyring's correlation is applied to heavy crude oils, it is noticed that this is only well adjusted at low temperatures, whereas when the ASTM method is applied, the results are perfectly adjusted for all temperatures, including high temperatures. These satisfactory results were already expected, since ASTM method is vastly applied to oils, while the Eyring's correlation is better adjusted to dilute solutions.

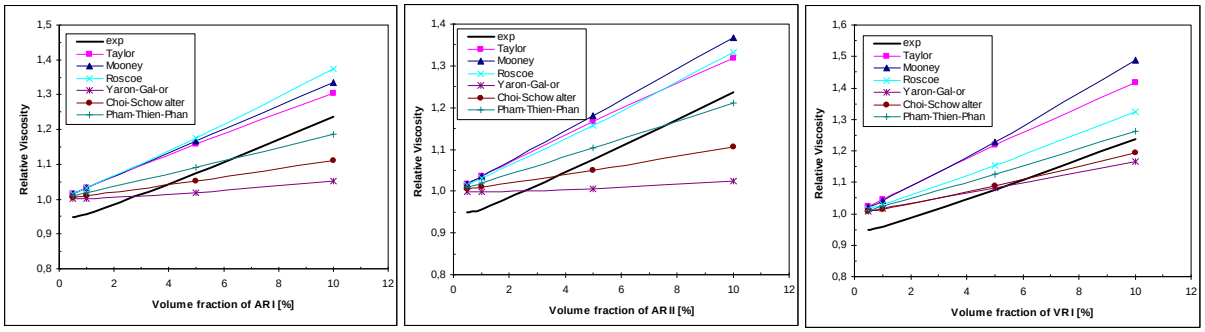
4.2. Viscosity prediction of Dilute Mixtures

The variation with concentration of residues correlates accurately with literature correlations for colloids and emulsions. Results of the average absolute deviation of the predictions of relative viscosity of residues at low concentrations mixed in toluene using literature correlations at a standard temperature of 20º C are presented in Table 3 and Figure 2. Dilute mixtures were prepared using volumetric fraction from 1% to 10% of the dispersed phase.

Table 3 – Average Absolute Deviations (AAD) of dilute mixtures

Correlation	AR I	AR II	VR II
Taylor	0.0737	0.0991	0.0985
Mooney	0.0833	0.1146	0.1186
Roscoe	0.0952	0.0982	0.0529
Yaron - Gal-or	0.0841	0.0965	0.0843
Choi - Schwlater	0.0645	0.0691	0.0762
Phan-Thien - Pham	**0.0465**	**0.0588**	**0.0586**

Figure 2 – Dilute mixtures relative viscosity prediction



Deviation results for all residues studied were satisfactory when all correlations were applied. As it can be observed, the lighter the residue is, the better the deviation results are. At low concentrations, the relation of Phan-Thien and Pham best correlates the viscosity data effectively. By the information given above, it can be affirmed that dilute mixtures of residues of oil can be treated as pure ones.

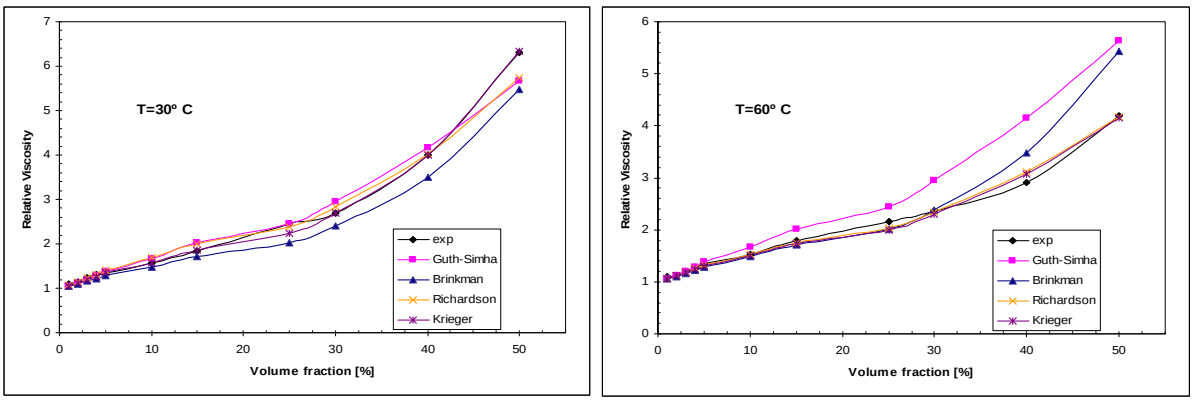
4.3. Viscosity prediction of Emulsions

Results of the average absolute deviation of the predictions of relative viscosity of one residue at high concentrations mixed in toluene using literature correlations with temperature variation are presented in Table 4 and Figure 3. Concentrated solutions can be treated as emulsions. Those were prepared using volumetric fraction from 1% to 50% of the dispersed phase, a light atmospheric residue called AR I. Relative viscosity was obtained varying temperature from 30º to 60º C, with a 10º C step.

Table 4 – Average Absolute Deviations (AAD) of emulsions

Correlation	***30º C***	***40º C***	***50º C***	***60º C***	***Temp Avg***
Guth - Simha	0.1462	0.1372	0.3191	0.3683	*0.2427*
Brinkman	0.2316	0.2894	0.1583	0.2064	*0.2214*
Richardson	0.1131	0.0886	0.0444	0.0462	*0.0731*
Krieger	0.0417	0.1054	0.0344	0.0593	*0.0602*

Figure 3 – Emulsions relative viscosity prediction



Results of average absolute deviations above show that the higher the temperature the higher the deviation results, which can be better observed on the figures. Krieger correlation best correlates all concentrations of the residue at all temperatures. The parameter used in this correlation depends linearly on temperature, which explains this best fit to even higher temperatures. Therefore, these correlations were well adjusted to residue in toluene, even in high concentrations, what confirms the hypothesis that this synthetic mixture behaviors as an emulsion.

5. Conclusions

From the measured kinematic viscosities of heavy naphthenic crude oils over a wide temperature range, it was concluded that the Eyring's correlation is accurate only at low temperatures, whereas ASTM results are perfectly adjusted in all temperatures. This was expected since ASTM method is widely applied to oils, while Eyring's correlation is better adjusted to dilute solutions.

The relative viscosity of residues mixed in toluene at low concentrations were correlated using several literature correlations. It was observed, that the lighter the residue, the better the deviation results. At low concentrations, the relation of Phan-Thien and Pham correlated the viscosity data most effectively.

Finally, predictions of relative viscosity of one residue at high concentrations mixed in toluene were obtained using literature correlations for viscosities of emulsions at several temperatures . The results showed that the deviation increases with the temperature. Krieger correlation best correlated the viscosity at all concentrations of the residue and at all temperatures. Therefore, these correlations, in general, were well adjusted to residue in toluene, even in high concentrations, which confirms the hypothesis that synthetic mixtures behave as emulsions.

Solving population balance models in precipitation using orthogonal collocation and stochastic optimization

Raluca Isopescu, Vasile Lavric*
University Politehnica of Bucharest, Department of Chemical Engineering,
RO-011061, 1-7 Polizu Street, Bucharest, Romania

Keywords: population balance, precipitation, orthogonal collocation, genetic algorithms
Topic: Advancing the chemical and biological engineering fundamentals.

Abstract

The present work focuses first on modeling the semi-continuous precipitation using the population balance (PB) technique, considering homogenous nucleation, size dependent growth and agglomeration, then on estimating the parameters that describe the crystallization kinetics. The mathematical model includes the reaction kinetic characterization together with the mass and particle number conservation laws. Additional novel relations characterizing the crystallization processes like nucleation, growth and agglomeration are defined. The method of choice to solve the integral-differential PB equation is the orthogonal collocation. The parameter estimation was performed using genetic algorithms (GA) throughout minimization of the sum of squares of the residuals experimental - calculated density function in the collocation points. The methodology was applied using data obtained for the precipitation of $CaCO_3$ by pouring into a given volume of $CaCl_2$ solution, initially placed in a well-stirred vessel, an equivalent volume of K_2CO_3 solution during a specified time.

1 Introduction

The precipitation of sparingly soluble salts as a result of a homogeneous reaction in semi-batch crystallizers is a common procedure in industrial fabrications of chemicals. This procedure is experimentally very convenient but entails a lot of problems especially when the final product has to be carefully controlled from morphological and particle size distribution (PSD) points of view. The homogeneous nucleation induced by the fast chemical reaction generates new particles all over the reaction time. Besides nucleation, particle growth and side processes such as agglomeration act concomitantly to establish the final PSD; this overlap of mechanisms worsens the control of PSD (Jones *et al.* 2005). The PB technique is widely used to model crystallization and precipitation processes as it captures the changes in PSD seen as the result of four basic processes acting upon the particles within a control volume: birth, growth, break-up and agglomeration (Qamar *et al.*, 2006). Considering the characteristic particle size as the internal co-ordinate of the solid phase that is formed, denoted by *L*, the dynamic population balance equation (DPBE) can be written as:

$$\frac{\partial n(L,t)}{\partial t} + \frac{\partial \left[G(L,t) \cdot n(L,t) \right]}{\partial L} = r\left(L,t,n\right) \tag{1}$$

where *n(L,t)* is the population density function, *G(L,t)* is the growth rate function and *r(n,L,t)* is a complex functional, with integral terms, agglutinating generation and/or death functions that model nucleation, agglomeration and/or breakage processes. Several numerical methods are proposed in literature to solve the DPBE, among them the methods of classes' moments, line characteristics and pivot being the most used, while the collocation methods are seldom taken into consideration. In the present work the DPBE for the precipitation of calcium carbonate in semi-batch crystallizer was built and solved by orthogonal collocation with Legendre polynomials.

* Corresponding author. E-mail:v_lavric@chim.upb.ro

Applying orthogonal collocation to equation (1) transforms it into a system of ordinary differential equations (ODEs) with respect to time written for the collocation points which are the roots of the considered orthogonal polynomials. The overlapping of homogenous nucleation and agglomeration could render the ODEs stiff for some periods of the integration time, implying to switch the integration methods from non-stiff to stiff and back accordingly.

2 Experimental

The precipitation was carried on in a 0.5 L crystallizer at 30°C. A volume of 0.250 L of 0.1 M $CaCl_2$ solution was initially placed in the vessel. An equivalent volume of 0.1 M K_2CO_3 solution was added at a flowrate of 1 L/h. Suspension samples were taken at different feeding moments and PSD was measured on a laser beam particle analyzer, in terms of mass distribution. Concomitantly, Ca^{2+} ion concentration was measured in solution using a volumetric method. The precipitated solid phase was identified as pure calcite according to *IR* spectra analysis.

The population density function *n(L)* was computed from the final experimental PSD using the common transformation of first order approximation:

$$n(L) = \frac{\left[M(L_i) - M(L_{i-1})\right] \cdot m_T}{\bar{L}_i^3 \cdot \rho_S \cdot k_v \cdot (L_i - L_{i-1})} \tag{2}$$

where *M(L)* is the cumulative mass distribution, m_T is the solid mass in the unit volume of suspension, evaluated from Ca^{2+} concentration measurements, ρ_s is the density of calcite and k_v the volumetric shape factor which, for calcite, takes the value of 1.

3 Mathematical model

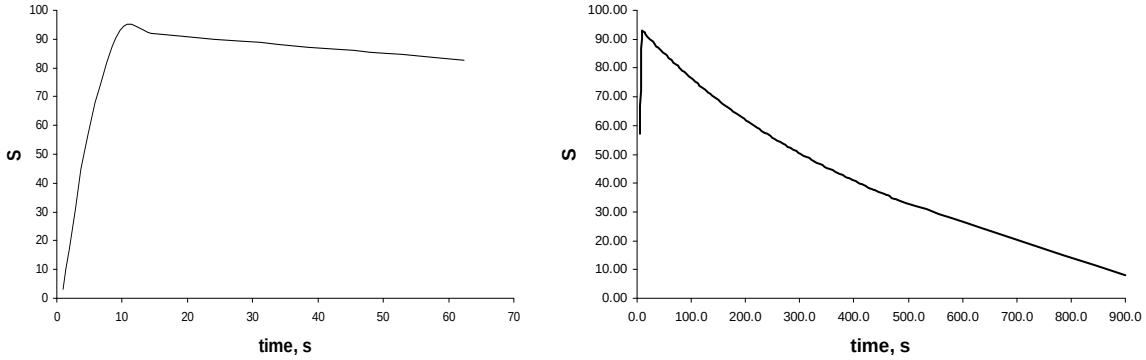
The supersaturation is generated by the chemical reaction:

$$CaCl_2 + K_2CO_3 \rightarrow CaCO_3 + 2KCl \tag{3}$$

The resulted calcium carbonate has a very low solubility and precipitation occurs almost instantaneously. The relative supersaturation is calculated according to the general mass action law for the ionic reactions and assuming perfect mixing of the reaction system:

$$S = \sqrt{\frac{\left[Ca^{2+}\right] \cdot \left[CO_3^{2-}\right]}{K_{sp}}} \tag{4}$$

where the solubility constant, K_{sp}, has the value of $3.4 \cdot 10^{-9}$ $(mol/L)^2$ for calcite. The concentration of Ca^{2+} and CO_3^{2-} ions are calculated from mass balances at the given flowrate. The variation of the calculated supersaturation is presented in Figure 1.



a) variation of relative supersaturation in the first minute

b) variation of relative supersaturation during the reagent addition

Figure 1. Time profile of the calculated relative supersaturation: (a) details, (b) whole time

As Figure 1 shows, the computed supersaturation increases very rapidly to rather high values; this is common in precipitation where supersaturation is created by a fast chemical reaction and the solubility product is very small. After less than 10 s from the beginning of the second reactant's addition, the supersaturation reaches a maximum value. During this period the nuclei are formed faster than the precipitation rate of the solid phase. After this short period the supersaturation starts decreasing till the end of the reaction time as Ca^{2+} ions are consumed.

Nucleation and growth (primary mechanisms) are mainly influenced by supersaturation. The relations assumed in this work to define nucleation and growth rates are of power low type:

$$B^0(t) = k_B\left[S(t)\right]^{n_B} \tag{5}$$

$$G(L,t) = G_0(t)\cdot(1+a\cdot L)^b \tag{6}$$

$$G_0(t) = k_G\cdot\left[S(t)\right]^{n_G} \tag{7}$$

where $B^0(t)$ is the nucleation rate depending only on supersaturation and $G(L,t)$ is the crystal growth rate depending on the crystal characteristic length, L. $G_0(t)$ is the growth rate at zero nucleus-size while a and b are the parameters of the size dependent growth model. The zero nucleus-size growth rate depends on supersaturation, and hence on time, according to equation (7).

The general DPBE for precipitation describes the time variation of the number based density function $n(L, t)$ when several possible antagonist mechanisms are present:

$$\frac{1}{V(t)}\frac{\partial\left[n(L,t)\cdot V(t)\right]}{\partial t}+\frac{\partial\left[G(L,t)\cdot n(L,t)\right]}{\partial L}=B^0\delta(L-L_0)+B(L,t)-D(L,t) \tag{8}$$

where $V(t)$ is the reaction volume while $B(L,t)$ and $D(L,t)$ represent the *birth* (two combining crystals) and *death* (growth beyond the current crystal characteristic length) functions characterizing the agglomeration process.

$$B(L,t)=\frac{1}{2}\int_0^L\beta(L,y,t)\cdot n(L-y,t)\cdot n(y,t)\cdot dy \tag{9}$$

$$D(L,t)=\int_0^\infty\beta(L,y,t)\cdot n(L,t)\cdot n(y,t)\cdot dy \tag{10}$$

where β is the agglomeration kernel representing the rate constant for the agglomeration process. Like for chemical processes, this constant can be also expressed as:

$$\beta(L,y,t)=\beta_0(t)\cdot\beta'(L,y) \tag{11}$$

In this study, since the experiments were performed at intense agitation and for moderate concentrations, the time dependency of the agglomeration kernel was defined throughout supersaturation:

$$\beta_0(t)=k_\beta\left[S(t)\right]^{n_\beta} \tag{12}$$

Agglomeration accompanies the primary mechanisms all over the precipitation process. As one of the reagents is continuously fed new nuclei are generated which can either grow or attach to the already formed crystals. At high supersaturation, bridges can form between particles that collide and larger particle could be generated. In the assumed crystal growth mechanism we included a size dependency that, formally, could be responsible for a faster growth of larger particles due to the addition of newly formed nuclei. Thus, we model the agglomeration process introducing a correction factor that reduces the contribution of the agglomerates formed throughout the collisions between very large and very small particles; the

agglomeration kernel therefore includes a particle size dependency. The value of this correction factor has to be established from experimental data fitting.

4 Numerical integration of the population balance equation

The DPBE was rendered dimensionless using the notations $\xi = \frac{L}{L^{\max}}$ and $\nu(\xi,t) = \frac{n(\xi,t)}{n^{\max}}$:

$$\frac{\partial \nu(\xi,\tau)}{\partial \tau} + \frac{\partial\left[G(\xi,\tau)\cdot\nu(\xi,\tau)\right]}{\partial \xi} + \frac{\nu(\xi,\tau)}{(1+\tau)} = \\ = B^{*}\cdot\delta(\xi-\xi_0) + \frac{1}{2}\int_0^{\xi}\beta^{*}(\xi,\zeta,\tau)\cdot\nu(\xi-\zeta,\tau)\cdot\nu(\zeta,\tau)\cdot d\zeta - \nu(\xi,\tau)\int_0^{1}\beta^{*}(\zeta,\xi,t)\cdot\nu(\zeta,t)\cdot d\zeta \tag{13}$$

The equation (13) is transformed throughout orthogonal collocation into a set of ODEs defined on the N interior collocation points (*j=1,N*; *j=0* and *j=N+1* represent de boundary conditions):

$$\frac{d\nu(\xi_i,\tau)}{d\tau} + \sum_{j=0}^{N+1} A_{ij}\left[G^{*}(\xi_j,\tau)\cdot\nu(\xi_j,\tau)\right] + \frac{\nu(\xi_i,\tau)}{(1+\tau)} = \\ = B^{*}\cdot\delta(\xi_i-\xi_0) + \frac{1}{2}\beta^{*}\int_0^{\xi_i}\nu(\xi_i-\zeta,\tau)\cdot\nu(\zeta,\tau)\cdot d\zeta - \nu(\xi_i,\tau)\cdot\beta^{*}\int_0^{1}\nu(\zeta,t)\cdot d\zeta, \quad i = 0,N+1 \tag{14}$$

In equation (14) the elements in matrix A depend on the collocation point (Finlayson, 1972). The significance of *B**, *G** and β^{*} is the following:

$$B^{*} = \frac{B^{0}\cdot\delta(\xi-\xi_0)\cdot\bar{t}}{n^{\max}} \tag{15}$$

$$G^{*} = \frac{G(L,t)\cdot\bar{t}}{L^{\max}} \tag{16}$$

$$\beta^{*} = \frac{\beta_0(\tau)\cdot\bar{t}\cdot n^{\max}\cdot L^{\max}}{2} \tag{17}$$

The function chosen for the correction factor to reflect the particle size dependency of the agglomeration kernel, as mentioned above, is:

$$\beta^{*}(\zeta,\xi,\tau) = \beta^{*}\cdot\sqrt{\zeta}\cdot(1-\zeta^{2})\cdot\sqrt{\xi}\cdot(1-\xi^{2}) \tag{18}$$

The system of ODEs was integrated for the initial and boundary conditions:

$$\tau = 0, \quad \nu(\xi,0) = 0 \tag{19}$$

$$\zeta = 0, \quad \nu(0,\tau) = \frac{B^{0}(\tau)}{G^{0}(\tau)} \tag{20}$$

The model parameters are k_B, n_B, k_G, n_G, *a*, *b*, k_β, n_β. These parameters were estimated by fitting the computed values for population density function with experimental data. The objective function used in the search for the optimal vales of the parameters was:

$$Fob = \min\sum_i\left[\frac{\ln\nu(\xi_i)_{comp}}{\ln\nu(\xi_i)_{\exp}} - 1\right]^2 \tag{21}$$

The minimization was carried out using GA which is expected to give good results due to its capability to explore a wide range of parameter variation and find the global optimum even for multimodal objective functions which is the case when 8 kinetic parameters are to be simultaneously identified. Inspired from the natural selection of biological organisms (survival

of the fittest), GA have several specific features: (a) the representation of parameters on chromosome-like structure, either binary encoded or directly stored for a faster retrieval and processing – the later is the method we used in the present study; the restrictions are dealt with simply eliminating the individuals violating them; (b) the optimal value is searched for within a group of candidate solutions, assimilated to a population; (c) the objective function is used to compute a fitness value, for each individual, measuring its adequacy; there is no need to employ derivatives or other additional information regarding the problem. Several probabilistic rules, known as genetic operators (selection, crossover, mutation and cloning), are used to create new offspring from best fitted individuals. Two important improvements are implemented into the standard GA, making it converging more rapidly: 1) when a large part of the population has too bad fitted individuals, preventing them to participate at multiplication, apply cloning by selecting randomly from the better fitted individuals and 2) if elitism is sought, the individuals from the new population not born through crossover are generated randomly around the best fitted individual, using a shrinking standard deviation (Răducan *et al.*, 2004).

5 Results and discussions

The mathematical model was solved for a period of 480 s from the beginning of reagent addition and fitted to the experimental distribution data using equation (21) as objective function. In this time interval about half of the reagent quantity was added. We tried several ortogonal collocation interior points from 7 to 19 – the lower the value the approximation error increases, while for high numbers the solution starts oscillating. In our case, 15 interior points was a good compromise. The values of kinetic parameters obtained regressing the mathematical model over the experimental data set are presented in Table 1.

Table 1. The values of the parameters implied in the mathematical model

k_B, no·m^{-3}	n_B	k_G, ms^{-1}	n_G	a, m^{-1}	b	β_0, m^3·s^{-1}	n_β	*Fmin*
$4.844 \cdot 10^{14}$	1.115	$1.009 \cdot 10^{-9}$	0.167	$1.67 \cdot 10^{6}$	0.862	$3.782 \cdot 10^{-17}$	0.959	0.022

The quality of the fit is also represented in Figure 2. As it can be seen analyzing Figure 2, the computed and experimental values are in a rather good agreement, although at very small particle sizes the distance model – experiment is fairly high. Experimental data show a more important small particle sizes population that could not be reproduced by the model, although a very high nucleation rate was identified (see Table 1 for details). An explanation can be the fact that in this range of particle sizes the experimental data are not very reliable as they were obtained on a laser beam particle size analyzer which do not include information for particles below 0.5 μm. Another source of errors could come from equation (2) which uses backward finite differences to compute the first derivative of the cumulative mass distribution with respect to the characteristic length of the crystal. In the very small particle domains, this means zero extrapolation, with the unavoidable attached errors. At the same time, the lack of dense experimental point on the last five μm makes the model fluctuate, although being close to the experiments in the range 18 – 27 μm.

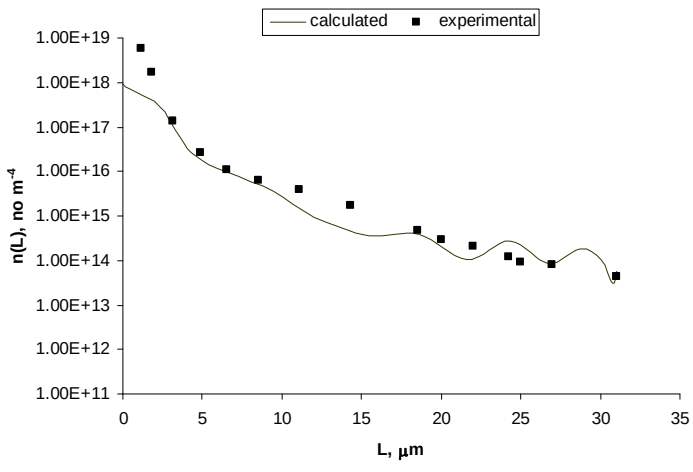


Figure 2. Computed and experimental distribution of the population density function

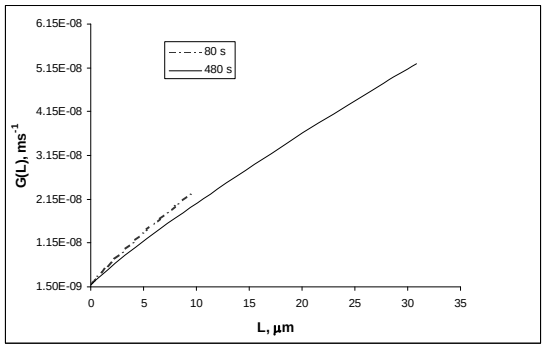
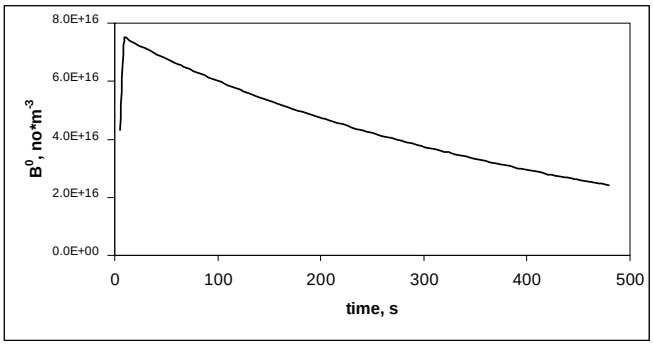
Under the experimental conditions investigated, nucleation is very important all along the reaction





a) b)

Figure 3. Variation of the crystal growth rate with the characteristic length of the crystal (a) and time profile of the nucleation rate (b) during the precipitation process

time (Figure 3b). Following supersaturation, it almost doubles during the first 10 s then asymptotically decays due to the decrease of Ca^{2+} ion concentration. The crystal growth rate significantly increases with the particle size (Figure 3a), with a higher slope at the beginning of the process, when only small crystals are present (dashed line), and a lower one towards the end (solid line), when the nuclei growth rate, $G_0(\tau)$ decreases due to the supersaturation decrease – see equations (7).

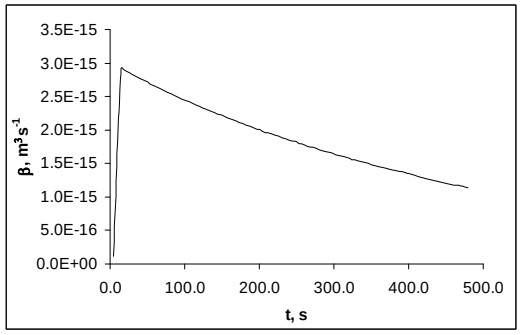


Figure 4. Time profile of agglomeration kernel

The agglomeration kernel (Figure 4) has quite significant values, meaning that agglomeration mechanism is important all along the precipitation process. The value of n_β parameter obtained in the regression analysis step proves that supersaturation strongly influences the solid bridge formation between particles that collide. Due to its dependency upon supersaturation – see equation (12) – its shape closely follows the supersaturation time profile. The agglomeration kernel should change profile after the second reactant adding will cease (the ageing period) when the supersaturation is very low but an important mass of solid phase is formed.

6 Conclusions

A mathematical model describing precipitation was built based upon PBE and using as basic mechanisms solely homogenous nucleation, crystal growth and agglomeration. Some additional novel relationships characterizing these crystallization processes have been proposed, relating them to relative supersaturation and crystal size. Satisfactory agreement between the mathematical model and the experiment was observed. Improvements could be sought changing the way the experimental distribution of the population density is computed, replacing in equation (2) the backward finite difference with a more appropriate formula.

Analyzing regimes in chemical reactors with allowing for the multistage kinetics and non-perfection of a system

Brener A.M.*, Tauasarov B.R.
State University of South Kazakhstan, Tauke Khan av. 5, Shimkent, Kazakhstan

Keywords: s, Reactor, Multistage Kinetics, Non-perfect Systems, Stability, Wave Front
Topic: (Bio) Catalysis & reaction engineering.

Abstract

The paper deals with problems of dynamical systems describing reaction-diffusion systems distinguishing by multistage and non-perfect kinetics. We consider main types of dynamical behaviour of such systems using two characteristis examples.

As a result of investigations we conclude that multistage and non-perfect kinetics can essentially affect reactor regimes and change their important characteristics. Moreover we submit the set of parameters controlling the regime stability and describing the regime bifurcations. The main types of possible dissipate structures induced by these factors as well as conditions of their formation have been determined. The results of investigations are likely to be useful for calculating intensity of mass transfer processes in chemical reactors.

1 Theoretical details and discussion

Multistage kinetics and non-perfection of reaction-diffusion systems have an essential influence on the process regime in chemical reactors. At the same time engineers often don't give due attention to these aspects of chemical processes and apparatuses design. In our work this problem has been theoretically investigated and illustrated by means of two model auto-catalytic reactions as examples.

Firstly we consider the following model scheme with main reagents X, Y and intermediate products A, C, despite the first stage is supposed to be an auto-catalytic reaction (Saul and Showalter, 1985):

$$X + Y \xrightarrow{k_1} X\,,\; X \xrightarrow{k_2} A,\; Y \xrightarrow{k_3} C\,, \tag{1}$$

where k_1, k_2, k_3 are the reactions rate constants.

Let's assume that the component Y enters the reactor continously with constant supply rate q, and the reagent X is the initial priming-tube.

Thus the system of kinetic equations for main reagents reads

$$\begin{aligned} \frac{dX}{dt} &= k_1 XY - k_2 X\,, \\ \frac{dY}{dt} &= q - k_1 XY - k_3 Y. \end{aligned} \tag{2}$$

[1]Here $X \geq 0$ and $Y \geq 0$ denote concentrations of reagents X and Y.

Provided the rate q satisfying the inequation

$$q < \frac{k_2 k_3}{k_1} \tag{3}$$

there is the only stable rest point of the system (2)

$$X_{01} = 0;\ Y_{01} = \frac{q}{k_3}. \tag{4}$$

But when this rate exceeds the critical value

$$q > q^* = \frac{k_2 k_3}{k_1} \tag{5}$$

the system acquires yet another rest point:

$$X_{02} = \frac{q k_1 - k_2 k_3}{k_1 k_2}\ ;\ Y_{02} = \frac{k_2}{k_1}. \tag{6}$$

Jacobians of the linearized system of kinetic equations at the rest points have the following

$$J_{01} = \begin{pmatrix} -k_2 + \dfrac{k_1 q}{k_3} & 0 \\ -\dfrac{k_1 q}{k_3} & -k_3 \end{pmatrix}, \tag{7}$$

$$J_{02} = \begin{pmatrix} 0 & \dfrac{q k_1 - k_2 k_3}{k_2} \\ -k_2 & -\dfrac{q k_1}{k_2} \end{pmatrix}. \tag{8}$$

Provided $q > q^*$ the rest point (4) becames unstable. And the springing up rest point (6) becomes stable on the contrary and it has a type of stable node or stable spiral.

The regimes analysis gives the folowing results:

1) for $(k_3/k_2) \geq 1$ at any q the rest point (6) is a stable node, and oscillations don't exist;

2) for $(k_3/k_2) < 1$ at q exceeding the critical value q^* rest point (6) can be a spiral.

At $(k_3/k_2) < 1$ we have

* Corresponding author. Tel 007-725-2210933. E-mail:amb_52@mail.ru

$$q^* < \frac{2k_2^2}{k_1}\left[1-\sqrt{1-\frac{k_3}{k_2}}\right]. \tag{9}$$

From this it follows that provided $(k_3/k_2)<1$ and $q > q^*$ the rest point (6) is a stable spiral, and appropriate transition regime goes on in the form of oscillations at the rate range

$$q_1 < q < q_2\,, \tag{10}$$

where

$$q_1 = \frac{2k_2^2}{k_1}\left[1-\sqrt{1-\frac{k_3}{k_2}}\right], \tag{11}$$

$$q_2 = \frac{2k_2^2}{k_1}\left[1+\sqrt{1-\frac{k_3}{k_2}}\right]. \tag{12}$$

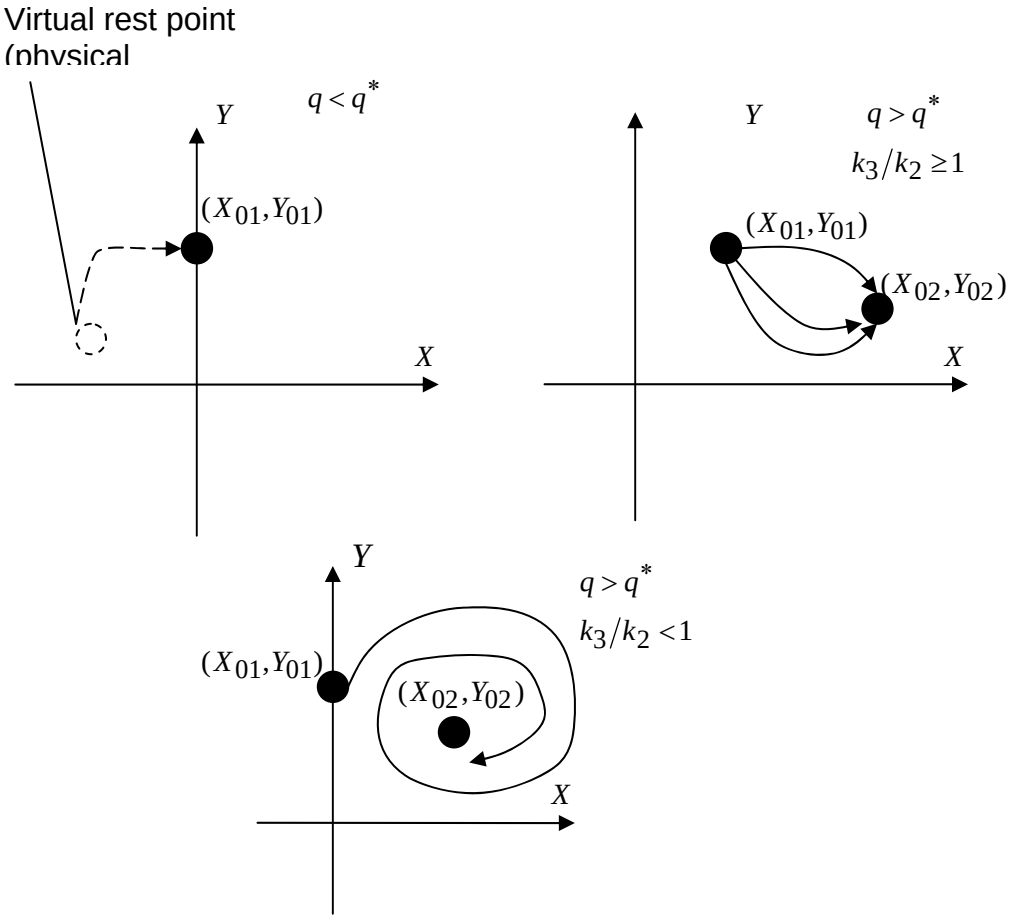

Figure 1- Phase curves near rest points of the system (2)

Thus the system has the control parameter

$$\alpha = \frac{k_3}{k_2}. \tag{13}$$

The value $\alpha = \alpha^* = 1$ is the bifurcation point, and for the transition regime we can obtain the frequency of oscillations ω and the logarithmic fading decrement ν :

$$\omega = \sqrt{\frac{2q}{k_3} - \frac{2k_2k_4}{k_1k_3} - \frac{k_3k_4^2}{4}}, \tag{14}$$

$$\nu = -\frac{k_4}{2} \tag{15}$$

The second example is the auto-catalytic reaction of the following type (Saul and Showalter, 1985; Kudryavtsev, 1987):

$$A + X \underset{k_2}{\overset{k_1}{\rightleftarrows}} 2X + C. \tag{16}$$

In the perfect thermodynamic system the following relation is true

$$\mu = \mu^* + RT \ln X, \tag{17}$$

where μ is a chemical potential and μ^* - its standard value, R is gas constant, T is a temperature.

Let's consider the case of non-perfect reaction-diffusion system, where the chemical potentials of reagents read (Karapetianz, 1975; Jou et all, 2001).

$$\mu = \mu^* + RT \ln X + \omega_{AX} (1 - X)^2. \tag{17}$$

Here

$$\omega_{AX} = \kappa[2\varepsilon_{AX} - (\varepsilon_{AA} + \varepsilon_{XX})], \tag{18}$$

and ε_{AX}, ε_{AA}, ε_{XX} are energies of an interaction between molecules of reagents, κ is a parameter depending on the model of liquid state.

Supposing $X << 1$ we obtain the following approximate relation

$$\mu = \mu^* + RT \ln X + \omega_{AX} (1 - 2X). \tag{19}$$

According to thermodynamics of diluted solutions the diffusion coefficients determine by the derivatives of chemical potentials over the concentrations.

Thus we obtain:

$$\frac{\partial \mu}{\partial X} = \frac{RT}{X} - 2\omega_{AX} = \frac{RT}{X}(1 - 2\omega_{AX} X), \tag{20}$$

From this it follows

$$D = D_i\left(1-2\omega_{AX}X\right), \tag{21}$$

where D_i is the diffusion coefficient in perfect system, D is the one in a real system.

And so, the mass transfer equation for the reaction (15) proceeding in a tubular through-reactor can be written as follows

$$\frac{\partial X}{\partial t}+q\frac{\partial X}{\partial z}=\frac{\partial}{\partial z}\left(D_i\left(1-2\omega_{AX}X\right)\frac{\partial X}{\partial z}\right)+f\left(X\right), \tag{22}$$

where

$$f\left(X\right)=k_1AX-k_2X^2. \tag{23}$$

Using method of an auto-model variable the equation (22) can be reduced to the following ordinary differential equation

$$\frac{d^2X}{ds^2}-\frac{q-c}{D_i\left(1-2\omega_{AX}X\right)}\frac{dX}{ds}-\frac{2\omega_{AX}}{1-2\omega_{AX}X}\left(\frac{dX}{ds}\right)^2+\frac{f\left(X\right)}{D_i\left(1-2\omega_{AX}\right)}=0, \tag{24}$$

where $s=x-ct$, c is a phase velocity or a velocity of wave front.

Equations of the appropriate dynamical system read

$$\begin{cases} \dfrac{dX}{dt}=Y, \\ \dfrac{dY}{dt}=\dfrac{q-c}{D_i\left(1-2\omega_{AX}X\right)}Y+\dfrac{2\omega_{AX}}{1-2\omega_{AX}X}Y^2-\dfrac{f\left(X\right)}{D_i\left(1-2\omega_{AX}X\right)}=0 \end{cases} \tag{25}$$

There are two rest points of the system

$$X_{01}=0,\quad X_{02}=A\frac{k_1}{k_2}. \tag{26}$$

Jacobians of the linearized system (25) at the rest points (26) read

$$J_{01}=\begin{pmatrix} 0 & 1 \\ -\dfrac{k_1A}{D_i} & \dfrac{q-c}{D_i} \end{pmatrix}, \tag{27}$$

$$J_{02} = \begin{pmatrix} 0 & 1 \\ \dfrac{k_1 A}{D_i(1-\gamma)} & \dfrac{q-c}{D_i(1-\gamma)} \end{pmatrix}. \quad (28)$$

where

$$\gamma = 2\omega_{AX} A \frac{k_1}{k_2}. \quad (29)$$

As for diluted solutions $\omega_{AX} << 1$ the following inequation is correct

$$\gamma < 1. \quad (30)$$

From detail analysis which is analogous with the analysis of system (2) we conclude that non-perfect kinetics in the case of high diluted solutions doesn't change types of rest points and reactor regimes. At the same time concrete values of regimes characteristics have undergone changes.

Particularly, the velocity of wave front which generates from transient oscillatory regimes differs from the velocity of wave front in a perfect system. The appropriate relation reads

$$c_{0r} = c_0 + \gamma\sqrt{k_1 D_i A}\ . \quad (31)$$

Here c_0 is the wave front velocity calculated for the perfect system:

$$c_0 = \left| q - 2\sqrt{k_1 DA} \right|, \quad (32)$$

and $\gamma < 1$ is the special amendment coefficient for which we obtain the following relation

$$\gamma = 2\omega_{AX} \frac{k_1}{k_2} A. \quad (33)$$

2 Conclusion

It can be concluded that rate of reagents supply not only controls an output of the reactor but also can essentially change a set of stationary and transition process regimes. Usually engineers connect such transformations with heat phenomena. At the same time the mentioned above factors can also cause regime transitions.

As regards the non-perfection of systems its influence for high diluted solutions manifests only in increasing the wave front velocity under transition regimes.Incidentally, transition regims theirself are determined by a system non-linearity. However in the case of strong solutions the situation may be different. This problem needs an additional study.

Optimisation of a package production process for the implementation of a "Total Productive Maintenance"

Ana Rita Seita, Rui Alves[2], M.Mercedes Esquível[1*]
[1]Centre for Biological and Chemical Engineering, IBB, DEQB, Instituto Superior Técnico, Av. Rovisco Pais, 1049-001 Lisboa, Portugal

Topic: Multi-scale and/or multidisciplinary approach to process-product innovation

Abstract

This research consists of the detailed study on the powder detergent packages production process, focusing especially on optimal control variable levels' selection and stipulation, with the purpose of minimising the number of defective board boxes. Although the production process has four stages, this study focuses mainly on the second stage, where the laminated board boxes are produced.

Among the several defects these boxes may have, one in particular was studied, as it is responsible for the major problems that have happened since the company started producing these boxes. This defect is the curling of the laminated board boxes, which, when reaching the third stage, cause the machine to stop, as well as a high level of waste. By using a factorial design, the conclusion is that the variables which influence the boxes curling the most are: paper's tension (tp); the position of the fibre breakers 2 (QF2); and the interactions among board box grammage and wax's temperature (Gc.Tw) and (tp.QF2).

1 Introduction

One of today's companies' primary concerns is the increase of global productivity, including the production tasks, as well as the technical activities and all the other company's functions. This high production's increase can only be obtained by increasing work efficiency, constituting the company's economical and social progress thrust.

In this context, the Seda Ibérica S.A. Company, where this study took place, is in the middle of a TPM's implementation process around the factory, which will represent a change in its organisation's culture. One of TPM's goal is to "achieve zero stops, zero malfunctions, zero accidents and zero defects" and in order to succeed all the processes must be known in detail. This means a deep knowledge of each process, the flaws must be identified and formally recognised, their causes discovered and attempts have to be made to eliminate them. In this context, it is essential to keep the process controlled so that it can be adjusted, later on, obtaining the expected results. This way, to implement TPM, a multi-departmental team in each process of the factory is constituted so that all the workers are involved in improving production.

* Corresponding author. Tel + 351-218417312. E-mail: mercedes.esquivel@ist.utl.pt

After a detailed knowledge of the process, optimal values are to be found for each parameter and, so that the maximum efficiency of the manufacturing process is obtained, increasing production, increasing the quality and the costumers' satisfaction and reducing waste.

Therefore, this process control was achieved through the following steps: i) a corrective control – to study the best environmental conditions in which the board boxes must be subjected after leaving the machine, and which is the best way palletization can be made so that deformation doesn't increase during the waiting period, before beginning the following stage; ii) a preventive control – in order to discover the machine's working parameters optimal values for each format, so that the board boxes deformation can be reduced.

TPM

Japan introduced TPM around 1971. At that time, industries were trying to improve the preventive maintenance techniques, system production maintenance and trustworthy engineering, to achieve zero failure and zero equipment malfunctions, as well as zero defective products and zero losses in the process. TPM is a program of continuous improvement, which requires the cooperation of all workers: from the equipment handler, to the maintenance workers, to the intermediate managership, to the higher levels of management. In this sense, the five TPM main goals are: (a) to guarantee the global installation efficiency, (b) to implement a maintenance program that optimises the equipment life-cycle, (c) to call for every department involved in the increasing of the installed capacity plan, (d) to request data and information about all the workers of the company and (e) to encourage the team-work principle, in order to consolidate actions of continuous improvement.

2 Description of the conditioning powder detergents packages manufacturing process

This process consists of four stages. During the first stage, the paper is printed through rotogravure printing, by entering and leaving through the paper rolls. That being said, we can consider this to be a continuous production. The printing is done with gravure cylinders, immersed in paint so that when the paper is pressed against them, the printing stays in the paper. The paper goes through several gravure cylinders printing each colour at a time.

During the second stage, the printed paper and the board are united. This union is achieved through microcrystalline wax that is applied in one of the board sides and by pressing it with a system of rolls. This operation is called lamination and is accomplished with a special machine in a continuous production. The board and the printed paper enter the machine through paper rolls and are glued together, using a hot melt lamination, followed by the tear strip application. After the lamination process, the glued material is diecutted, according to the specific format, so that in the end of stage two, the boxes are ready to go to the third stage of the process.

During the third stage, the laminated detergent boards are folded, glue is applied to the sides of the box and a corrugated cardboard support is pasted inside the box, providing the endurance needed to support the powder detergent. In this stage, the laminated detergent boards are shaped and glued overall, although its bases and tops are left unglued. They then proceed to the final stage, to a machine where the handles are placed, to ease transportation.

At the end of the process, the laminated detergent boards are conditioned inside board boxes, stacked and stored up, and this is a process that can produce boxes with diverse formats and has the ability to produce 3000 boxes per hour.

3 Problem description

In the process of making laminated detergent boards, some problems such as decentralized printing, incorrect folding or curling can occur. From all these, only the one which causes stops at the third stage of the process was studied. This problem is the boxes' curling and is responsible for 25% of the total registered defects.

Performance's Characteristic is defined as the deformation height, in centimetres, from the upper and lower left corners (y_1 and y_2), exhibited by the laminated board boxes. The maximum deformation height to considerer the product conform is $2X10^{-2}$ m

Only 7 parameters out of the usual registered 20 were considered critical. Chosen as critical factors are: *velocity* (v) because it represents the process' yield; *paper's tension* (tp) because it is applied near the laminating area and it influences the boxes' curling; the *fibre breakers' position 1*(QF1) and *2* (QF2), because they make sure the board box is stretched; the *wax's temperature* (Tw); The board box *grammage* (Gc) as it affects its resistance; and the *board box's humidity* (Hc) because it influences most of the board box mechanic characteristics, such as resistance and elasticity.
The factorial design was applied on two levels and in two stages to optimize the working conditions. The optimization strategy used, in which factors vary simultaneously, reduces the number of trials in comparison to the classical approach in which only one factor varies. In table 1 the values considered for the selected factors are presented.

Table 1- Variables' levels

Variables	**High level (+1)**	**Low level (-1)**

QF1 (%)	61	18
QF2 (%)	95	0
Tw (ºC)	200	100
Gc (g/m^2)	430	378

4 Results and Discussion

On the first stage a factorial 2^{7-3} was applied corresponding to a total of 16 trials with the objective to quickly identify the set of factors with significative effect on the deformation of the boxes. The obtained data confirmed that the *fibre breaker's position* (QF1) and the *board box humidity* (Hc) did not have any influence in the cardboard box deformation.
On a second stage of the work a factorial 2^{5-1} was applied to the remaining 5 factors according to the matrix presented on table 2.

Table 2: 2^{5-1} matrix and its resulting data

Trial Nº	Factors					Results ($\times 10^2$ m)	
	A(v)	B(tp)	C(QF2)	D(Gc)	ABCD (Tw)	y1 (Upper Left)	y2 (Lower Left)
1	-1	-1	-1	-1	1	1	1,5
2	1	-1	-1	-1	-1	0,5	1
3	-1	1	-1	-1	-1	0,5	3
4	1	1	-1	-1	1	0	0,5
5	-1	-1	1	-1	-1	1,5	4
6	1	-1	1	-1	1	2	1,5
7	-1	1	1	-1	1	0	0
8	1	1	1	-1	-1	0	0
9	-1	-1	-1	1	-1	0	0
10	1	-1	-1	1	1	0	0
11	-1	1	-1	1	1	0	0,5
12	1	1	-1	1	-1	0	0
13	-1	-1	1	1	1	2,5	5
14	1	-1	1	1	-1	1	1
15	-1	1	1	1	-1	0	0
16	1	1	1	1	1	1,5	3

The factor effects were calculated by measuring the difference between the average of the trials, were the factor is in the + level, and the average of the trials, were the factor is in the level – (eq.1).

$$Effect_{Factor} = \bar{y}_{Factor^+} - \bar{y}_{Factor^-} \qquad \text{eq. 1}$$

In figure 1 a graph of the probability of the effects is shown. All the effects that fall on the line are negligible while the significant effects are represented further form the line. The important effects from this analysis are paper's tension (tp) the position of the fibre breakers (QF2) and the interactions tp.Qf2 and GC.Tw.

The two principal factors tp and QF2 and the interactions tp.QF2 and Gc.Tw are those which may produce the most deformation on the boxes.

In figure 2 a geometrical representation of factorial design 2^{5-1} is shown, in which vertices of the cubes the values of the answer variables y_1 and y_2 are written between brackets. The shaded areas represent the combination of the variables for which the box deformation is minimized.

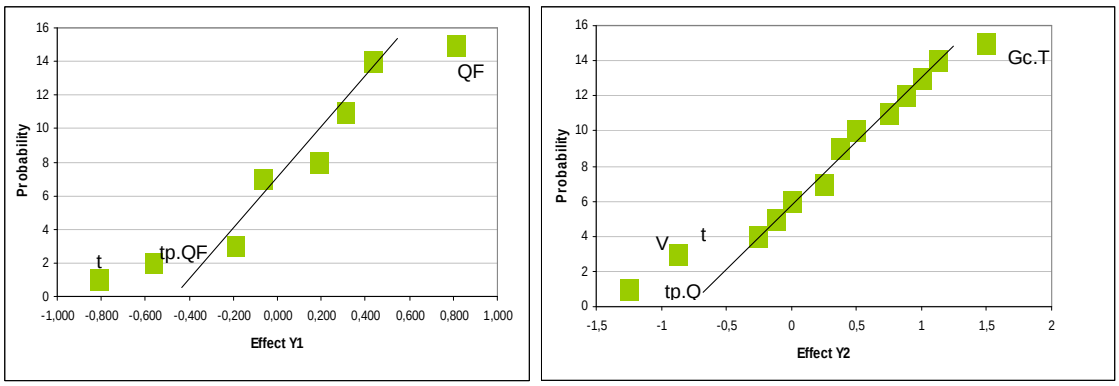

Figure 1 - Graph of the normal probability of the effects for factorial 2^{5-1}

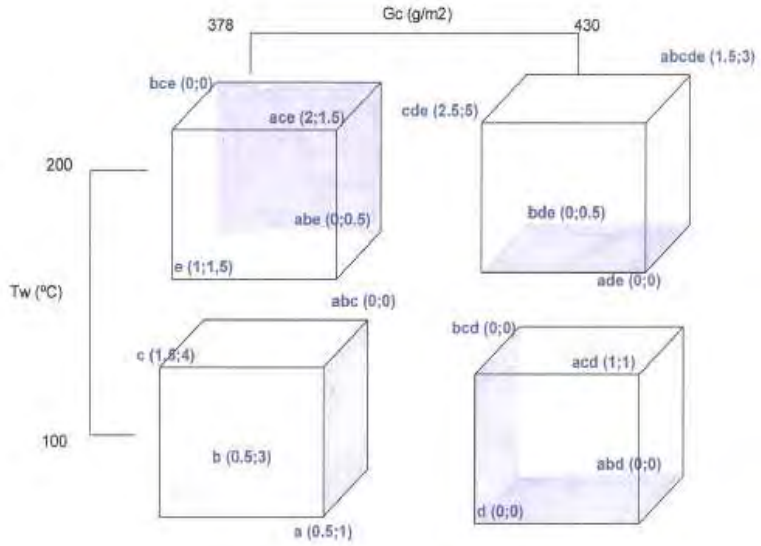

Figure 2: Geometrical representation of factorial design 2^{5-1} and its respective results y_1 and y_2 (between brackets)

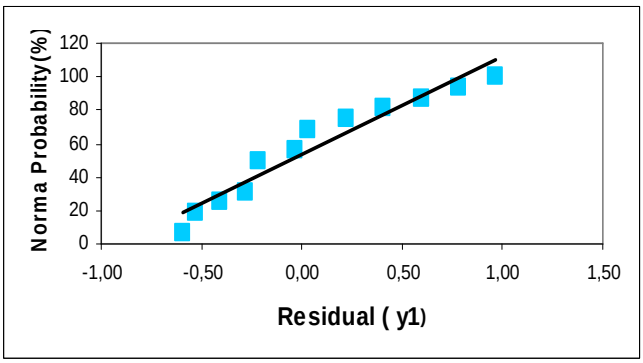
First order model building

For the four variables mentioned before, a first order model was made, as exemplified in the equation 2 and 3. Figure 3 shows the normal probability for y1 and y2 residuals. The points in the graph are reasonably located over a straight line confirming the hypothesis that the factors tp, QF2, tp.QF2 and Gc.Tw are the only ones with significative effect in the process being studied.

$$\hat{y}_1 = 0.656 - \frac{0.813}{2}x_2 + \frac{0.813}{2}x_3 - \frac{0.563}{2}x_2x_3 + \frac{0.313}{2}x_4x_5 \qquad \text{eq. 2}$$

$$\hat{y}_1 = 1.313 - \frac{0.875}{2}x_2 + \frac{1.000}{2}x_3 - \frac{1.250}{2}x_2x_3 + \frac{1.500}{2}x_4x_5 \qquad \text{eq. 3}$$

$$x_i = \frac{Factor - (Factor_{low} + Factor_{high})/2}{(Factor_{high} + Factor_{low})/2} \qquad \text{eq. 4}$$



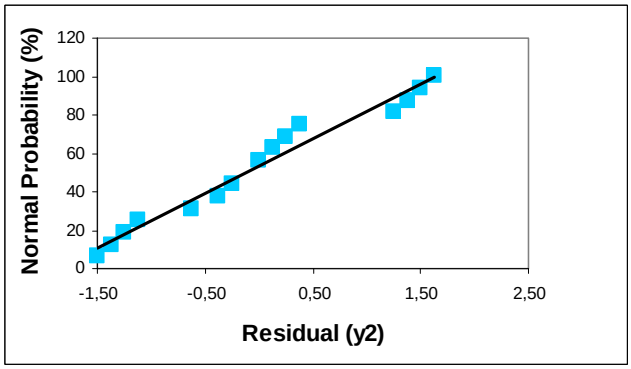


Figure 3- Normal probability graph of the residues

5 Conclusions

The purpose of this research was to select the control variables and to calculate its effects on the “RPL” machine during the laminated board boxes production process.

From the seven critical variables pointed out, it was determined that only the paper’s tension (tp), the fibre breaker’s position (QF2), the interactions (tp.QF2) and (Gc.Tw) cause the board boxes to curl.

From the data shown on figure 2 a decision diagram was constructed which allows, depending on cardboard grammage (Gc) and wax temperature (Tw), to select the remaining conditions of the process towards minimal cardboard deformity.

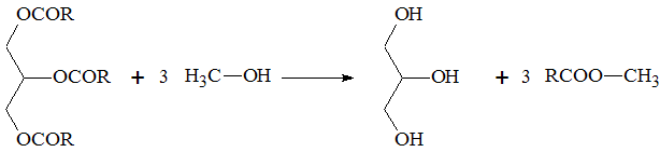
Rheological and thermodynamic study on a biodiesel production process

Álvaro F. C. Vaz[1], Andreia C.S. Fial[1], Ana P. R. Gomes[2], Rogério M. S. Simões[1]

[1] DCTP – Department of Paper Science and Technology, [2] Optics Center
University of Beira Interior, Rua Marquês d'Ávila e Bolama, 6200–001 Covilhã, Portugal.

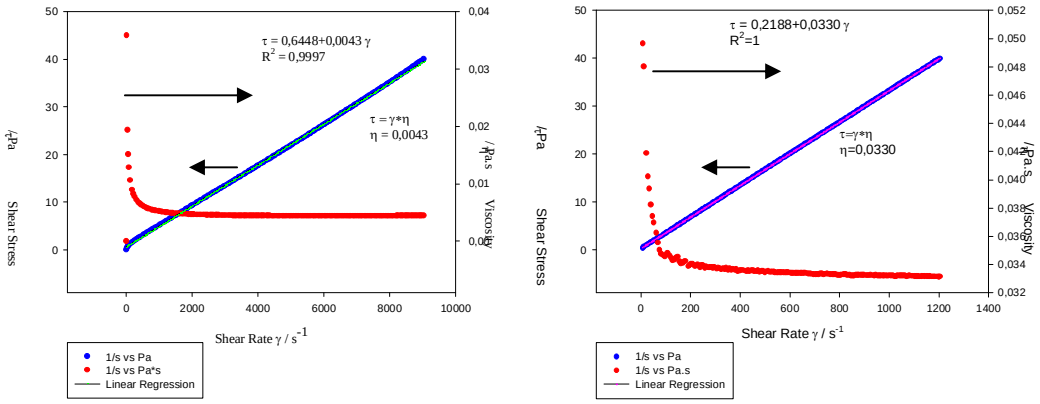
Keywords: Biodiesel, Rheology, Surface Energy, Thermogravimetry, Differential Scanning Calorimetry.
Topic: Multi-scale and/or multi-disciplinary approach to process-product innovation.

Most of the world energy consumption is based on oil, coal and natural gas. The rise in energy demand related with new global players resulted in a surge of the conventional energy sources prices. The global concern on environmental issues such as greenhouse effect and threats related with future supply shortage have opened the way for new sustainable alternatives based on renewable sources, and the conversion of natural oils into biodiesel. Biodiesel is a fatty acid mono-alquil esther derived from vegetable oils and animal fats obtained by a transestherification process with an alcohol (methanol or ethanol), as represented by the equation (Knothe et al.):



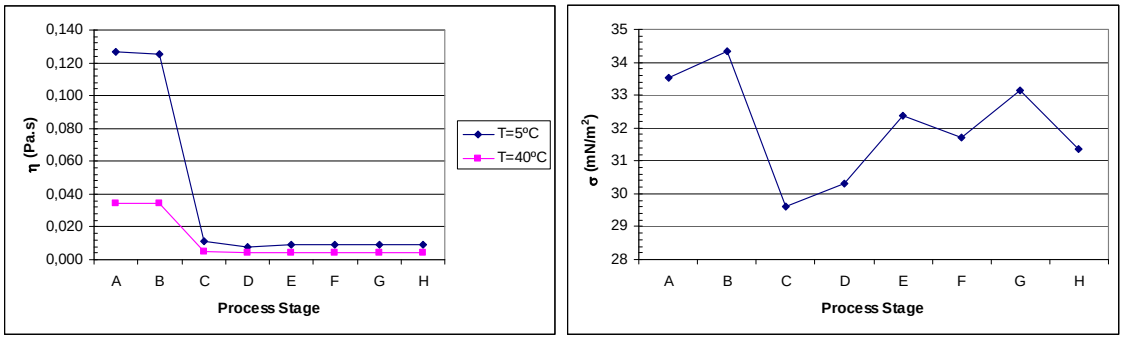
(Equation 1)

The oil in the industrial process passes trough a pre-treatment (such as filtering, degumming, free fatty acids removal and catalyst mixing), a transestherification reaction, a phase separation from glycerol, a washing step, a purification step and a drying step. This work characterizes different vegetable oils such as rape seed, sunflower seed and soybean, and biodiesel produced industrially by methanolic via. All samples were furnished by PRIO, from an industrial site. The scope of this study embraces rheological and surface tension characterization and a thermodynamic study on thermogravimetry and differential scanning calorimetry (DSC). The reason behind these options is the importance of these itens on the biodiesel flow, atomization and proper combustion through the injector (Ejim et al.). The evolution throughout a PRIO industrial process was the goal of this study, represented by steps A trough H.



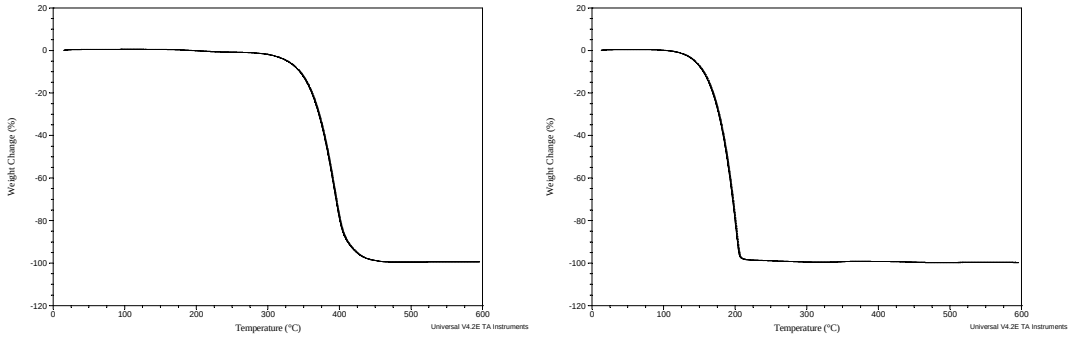
Graphic 1: Oil and Biodiesel pseudoplastic responses.

The oil and biodiesel viscosity evaluation was made on a HAAKE RS150 rheometer with baths at 40ºC and 5ºC. The surface tension was made using a DATAPHYSICS Contact Angle System OCA. Both oils and biodiesel have shown pseudoplastic responses, as exemplified in Graphic 1. It shows the values of shear stress (kPa) in the left vertical axis, and apparent viscosity (Pa.s) in the right vertical axis, as a function of shear rate in s^{-1}. The value of the apparent viscosity can be considered constant for high shear rates.



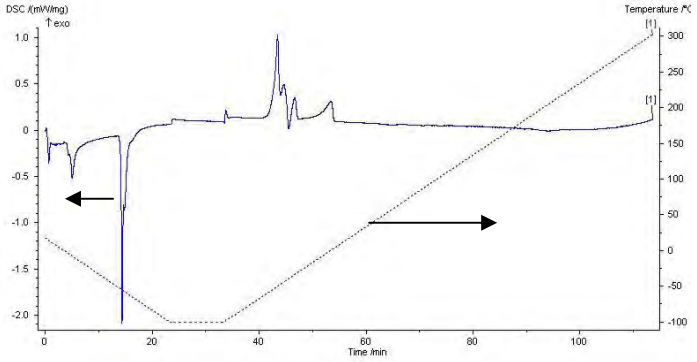
Graphic 2: Process viscosity (Pa.s) at 5ºC and 40ºC and surface tension (mN/m^2) evolutions.

Graphic 2 shows the evolution during the process of the apparent viscosity (at 5ºC and 40ºC) and surface tension. It can be seen that there is a steep viscosity reduction after the transestherification step. This can be justified by the molecular length reduction and a more linear structure in the biodiesel. The surface tension similarly reduces after the transestherification step, but it increases regularly in the subsequent steps.



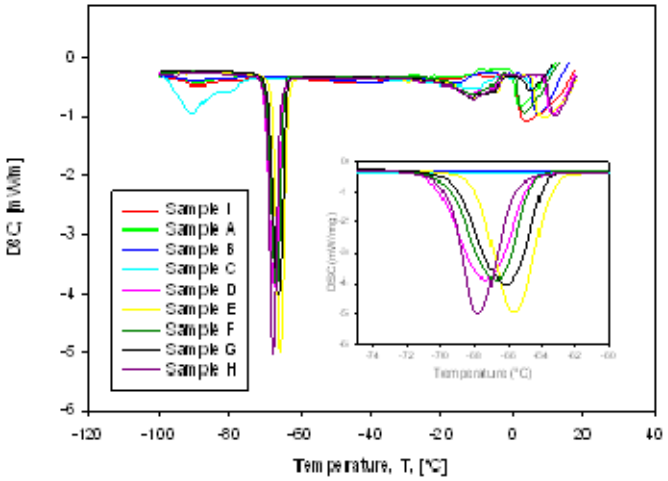
Graphic 3: Oil and biodiesel thermogravimetric evolution.

Thermogravimetry is a technique which obtains a sample mass variation as the temperature increases regularly. Graphic 3 represents thermogravimetric results for a sample of oil and sample of biodiesel, where the maximum evaporation rate took place at close to 375ºC for the oil and close to 175ºC for the biodiesel.



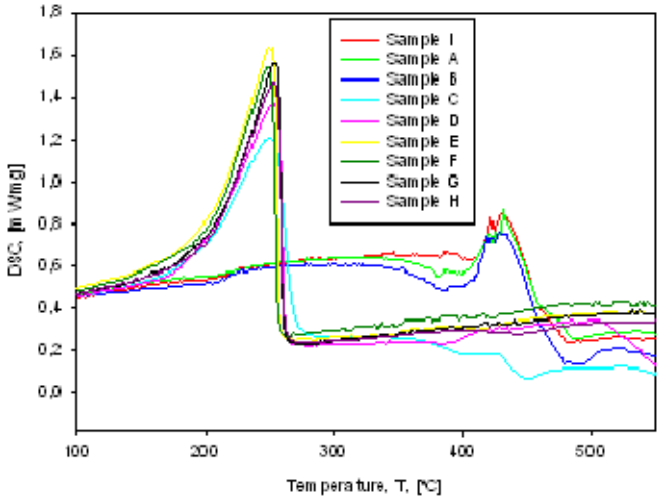
Graphic 4: Differential scanning calorimetry for a biodiesel sample.

Differential Scanning Calorimetry compares the heat flow to a sample and a standard material, with a programmed temperature evolution. It permits to study phase transitions and reactions. A study has been made between -100ºC and 300ºC in a nitrogen inert atmosphere. As seen in Graphic 4, two significant phase transitions where obtained in the -100ºC–20ºC interval. The first one, close to 0ºC, corresponds to wax crystallization, being the crystallization onset temperature (or Cloud Point). The latter results from a crystallization/solidification step (Pour Point) (Knothe et al.). Further studies with non-inert air atmosphere were already made and are being prepared for publication.



Graphic 5: DSC for all samples from 20ºC to -100ºC.

Graphic 4 5 show the DSC diagram for the different samples throughout the process from 20ºC to -120ºC. It can be seen two exothermic peaks, the first one in the -80ºC—60ºC range and the second one in the 0ºC-20ºC. The first one is the Pour Point, being the lowest temperature at which the biodiesel can be poured. The second one, as explained above, is the temperature at which the waxes begin to crystallize (Cloud Point). It can be seen in the graphic that a reduction in the Cloud Point occurs in steps F trough H, being then in the range -20ºC–0ºC.



Graphic 6: DSC for all samples from 100ºC to 550ºC.

Graphic 6 shows the DSC diagram for the different samples in the 100ºC–550ºC range.

An endothermic step is observed, as in the thermogravimetric results. Anyway, vaporization temperatures are comparatively slightly higher, being around 430ºC for the oil steps (I, A and B) and around 230ºC for the biodiesel steps (C trough H). This corresponds to the final evaporation temperatures in the thermogravimetric plots.

Subsequent studies will focus on establishing the relationship between the process operation and biodiesel composition, and how it determines the evolution of physical, rheological and thermodynamic properties.

Keywords: bioethanol, lignocellulosic biomass, steam explosion, ozonolysis, straw
Topic: Multi-scale and/or multi-disciplinary approach to process-product innovation. Energy and environment

Abstract

In this work ozonization and steam explosion of wheat straw have been compared as adequate pretreatments in the bioethanol production process from lignocellulosic materials. The pretreatment stage is necessary before enzymatic hydrolysys in order to leave cellulose accesible to enzymes when lignocellulosic raw material is employed. For both selected pretreatments, the influence of the main process variables was analysed and operation conditions were optimized. Hydrolysis tests for each pretreated sample were performed in order to determine the improvement produced in the enzymatic saccharification under the different pretreatment conditions used. From the statistical treatment of the obtained experimental results, it can be concluded that the maximum yields (87.1 % on glucose) on enzymatic hydrolysis were obtained when wheat straw is ozonized, operating with 40 % of solid moisture, 3-5 mm of particle size and 90 L/h of ozone, whereas a 80,9 % of glucose after enzymatic hydrolysis was obtained when the raw material was steam exploded at 210 ºC, 20 mm of particle size and 10 min of residence time.

1 Introduction

Locomotion is a key factor in the present economy progress representing around 20-25% of total world energy consumption. Therefore, its integration in a sustainable development is decisive. Among the whole renewable fuels one of the best to reduce the present dependence on crude oil is bioethanol. The reason for worldwide interest in bioethanol lies in its numerous advantages. It's a renewable combustible, non toxic, highly soluble and quickly biodegradable. Ethanol can be used as fuel for automobiles either alone or blended with gasoline to reduce the consumption of petroleum fuels. The National Renewable Energy Laboratory in the USA establish that the use of bioethanol blended gasoline results in fall of around 1.85-2.65 Kg CO_2 emissions /L of gasoline. It can also be used as an additive for standard gasoline as ETBE (ethyl tertiary butyl ether), being a replacement for MTBE (methyl t-butyl ether), the most common additive, which use is being limited in the United States owing to its probed groundwater contaminant effect.

Nevertheless, despite the efforts made to decrease the production cost of ethanol, this is still too high compared with petroleum derived fuels. Moreover, the production of bioethanol from the traditional raw materials (starch and carbohydrates) must compete with the food market, so the development of process employing new raw materials is an important challenge in this area. To reduce this cost, lots of researchers have focused on the exploitation of lignocellulosic materials which abundance and low prices would guarantee process self-sufficiency (Sánchez y Cardona, 2007).

However, the main obstacle for the better use of lignocellulosic materials to produce ethanol is their low digestibility because of the tight association between their components: cellulose,

* Corresponding author. Tel + 34 983 423237. E-mail:maite@iq.uva.es

hemicellulose and lignin. It is well known that lignin content have a large impact in enzymatic hydrolysis of lignocellulosic biomass (Palonen, 2004; Mosier, 2005). Vidal and Molinier (1988) shown that the accessibility to the enzyme was inversely proportional to the lignin content. Therefore delignification appears to be necessary to enhance enzymatic saccharification. Cardona and Sánchez (2007) reviews and compare the use of different mature and developing technologies leading to an improvement on the global process.

The different alternatives tested for lignocelluloses pretreatment involve the use of physical, chemical, physicochemical and/or biological methods, e.g. steam explosion, ammonia fiber explosion (AFEX), ozonolysis and wet oxidation (Sun and Cheng, 2002; Silverstein et al., 2007). This research compares ozonization and steam explosion as adequate techniques to the removal and/or degradation of lignin structure, leaving cellulose accessible to enzymes and avoiding toxic wastes which can inhibit the subsequent enzymatic hydrolysis and fermentation processes.

2 Material and Methods

Raw material. Wheat straws were kindly donated by Institute of Technological Agriculture of Castilla y León. The straw was ground in a blender, sieved to obtain the size desired and kept in an oven at 45ºC. The composition range (% w/w) of wheat straw is shown in Table 1.

Table 1. Composition of wheat straw

Composition (% w/w)	
Moisture	9.0 – 6.0
Cellulose (as glucose)	34.2 – 26.7
Hemicellulose (as xilose)	20.1 – 17.5
Acid Insoluble Lignin	17.1 – 23.8
Acid Soluble Lignin	5.2 – 3.8

Ozonolysis Pretreatment. Experimental work was designed to examine the influence of the initially proposed main operation factors [Moisture (M), particle size (S), air/O_3 flow rate (C), ozone concentration (O) and type of biomass (L)] on the percentage of lignin removal during ozone pre-treatment. The ozonolysis was performed in a fixed bed reactor under room conditions. Ground material was firstly hydrated to the required moisture value and exposed to an ozone/air gas stream in the fixed bed reactor (glass column 50 cm in heigh and 2.7 cm in diameter). The ozone production was controlled by varying either the oxygen flow rate or the electrical power supply and its concentration was measured according to the iodometric method (Standard Methods, 1995). Reactor's outlet went past through a 2% KI solution in order to remove the unreacted ozone from the gas stream. The resulting ozone-treated substrate was dried in an oven at 45ºC, stored in a freezer and used for enzymatic hydrolysis and analysis. The experiments were programmed through a 2^{5-1} factorial design in which the variables were evaluated at two levels (Table 2). The study of the influence of main operating factors and their interactions were calculated and exposed in a normal probability plot to draw the most significant process variables. The estimation of the effect is defined as the change in the response that is produced by a change in the level of the parameter.

Table 2. Experimental levels of the parameters studied in ozonation experiments

Factor	Level value	
	Lower (-1)	Upper (1)
Moisture (M) (%w/w)	20	40
Particle size (S) (mm)	<1	3-5
Air/ozone flow rate (C) (L/h)	60	90
Ozone concentration (O) (%w/w)	2.7	3.0

Steam explosion Pretreatment. The steam explosion was carried out in a 5L stainless steel batch reactor in which the straw was loaded at the top and heated to the desired temperature with saturated steam. When the pre-set residence time was concluded, the steam-treated biomass was released from the reactor by rapid depressurization of the vessel. After the pre-treatment, the product was washed with warm water and the residual solid was separated by filtration. Both, solid and liquid portions were dried in an oven at 45ºC, stored in a freezer and used for enzymatic hydrolysis and analysis. The experiments arranged as a 2^{4-1} factorial design. The main process variables selected for this pretreatment being temperature (T), residence time (R), particle size (S) and the use or not of 4,5% w/w SO_2 as acid catalyst (A) as it is shown in Table 3. Results were statistically studied as indicated in ozonolysis experiments.

Table 3. Experimental levels of the parameters studied in steam explosion experiments

Factor	Level value	
	Lower (-1)	Upper (1)
Temperature(T)(ºC)	180	210
Residence time (R) (min)	4	10
Particle size (S) (mm)	3	20
Catalyst (4.5%w/w SO_2) (A)	no	yes

Enzymatic Hydrolysis. The enzymatic hydrolysis was carried out using a mixture of cellulose complex (NS50013) and β-glucosidase (NS50010), both enzymes kindly donated by Novozymes (Denmark). The tests were performed with 0.3 g of freeze stored biomass suspended in 5 mL acetate buffer 0.1 M (pH 4.8), containing 10 FPU g-1 and 10 CBU g-1 of substrate (dry basis) at 50 ºC for 96 h. The flasks were shaken in a rotary incubator at 150 rpm. After the hydrolysis, liquid portion is analyzed for carbohydrates.

Analytical methods. Acid insoluble lignin, acid soluble lignin and carbohydrates were estimated according to NREL laboratory analytical procedures Lap 003, 004 and 002 respectively (NREL, 1995), except that a Bio-Rad HPX-87H ion-exclusion column was used to measure sugar concentration. The mobile phase was 5 mM H_2SO_4 at a flow rate of 0.6 mL min-1 at 60 ºC. The detector was based on the refraction index measurement. Carbohydrates after enzymatic hydrolysis were analyzed by HPLC with the same method indicated before.

3 Results

Ozonolysis Pretreatment. The statistical treatment of the results is collected in Table 4. Capital letters refer to upper level and lower case letters refer to lower level of the analysed variables, the moisture variable presents the most significant effects from the studied parameters working always with identical operation time (2.5 h). According to the factorial design, as the percentage of water content increased, it was observed an increase in the removal of acid insoluble lignin for wheat straw. The rest of the studied parameters didn't have major importance from the point of view of delignification yield and digestibility. However, these parameters have to be taken into account to make this pretreatment feasible from an economical point of view.

Figure 1 represents the normal probability plot, in which the moisture effect gets off from the line that goes through the rest of the points. The content of acid soluble lignin increased after the ozonolysis pre-treatment and some times the total acid lignin content decreased, showing that exist a lignin fraction refractory to the ozonation pre-treatment, as suggested by Neely (1984).

Table 4. Results obtained in the 2^{5-1} experimental design for ozonolysis.

Variables	% AIL (% w/w)	% ASL (% w/w)	Effect estimation		% glucose hydrolyzed (% w/w)
			Parameter	% AIL removed	
msco	11.8	7.3	M	13.9	81,0
MSco	13.5	8.8	MS	-8.3	63,2
MsCo	12.2	10.4	MC	2.1	75,9
msCo	13.5	8.6	C	-0.6	69,3
MscO	11.8	8.6	MO	-4.3	74,8
mScO	14.4	7.1	SO	-8.9	81,3
msCO	13.9	9.7	CO	-16.1	56,4
MSCO	11.2	8.4	MSCO	-0.6	87,1

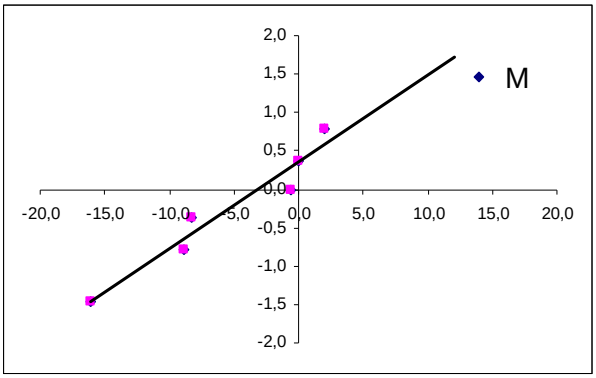

Figure 1. Normal probability plot of the effects of parameters in the ozonation experimental design for AIL variation

The yield obtained after enzymatic hydrolysis of the pretreated samples defined as the percentage of glucose hydrolyzed is shown in Table 4. There is a correlation between the % of glucose hydrolyzed and the acid insoluble lignin concentration. In all cases, when the ozonated materials were hydrolyzed, the yield obtained increased compared with the untreated straw. The enzymatic hydrolysis yield improved from 29% corresponding to untreated raw material to 56.4 – 87.1 % for pretreated wheat straw as the acid insoluble lignin content decreased from 17.1% to 13.9% and 11.7% respectively.

The operating conditions leading the maximum yield on enzymatic hydrolysis were: 40 % of moisture, 3-5 mm of particle size, 90 L/h of ozone and a ozone concentration corresponding the 76% of ozonizator power. These values agree with the higher lignin removal observed.

Steam Explosion Pretreatment. The statistical treatment of the results is shown in Table 5. Capital letters refer to upper level and lower case letters refer to lower level of the analysed variables. At this moment, there are not available results of experiments using the acid catalyst. The residence time variable has the higher influence on acid insoluble lignin removal but however it is not statistically important. The other analysed parameters didn't show major influence from the point of view of delignification yield and digestibility. The acid insoluble lignin values obtained in the different experimental conditions are very similar, no relevant differences are found. The same behaviour has been observed by Cullis et al (2004).

The variation in the content of acid insoluble lignin after steam explosion, in the operating conditions tested, was not significantly different. There is not a clear relationship between %AIL in the steam exploded straw and the yield of the further enzymatic hydrolysis stage.

Table 5. Results obtained in the 2^{4-1} experimental design for steam explosion

Variables	% AIL (% w/w)	% ASL (% w/w)	% glucose hydrolyzed (% w/w)	Effect estimation		
				Parameter	% AIL variation	% glucose hydrolyzed
Trsa	18.6	2.4	48.5	T	5.9	58.1
tRsa	19.4	2.7	23.4	R	-3.8	0.4
trSa	19.7	25.3	23.5	S	1.7	23.5
TRsa	19.5	2.5	34.8	TR	-2.1	10.8
TrSa	17.9	3.7	56.0	TS	5.9	30.1
tRSa	19.4	2.7	23.4	RS	2.9	22.6
TRSa	18.4	1.3	80.9	TRS	-1.3	16.0
trsa	18.7	2.5	31.9	-	-	-

Figure 2 represents the normal probability plot for acid insoluble lignin removal and enzymatic hydrolysis. The effect on %AIL removed did not indicate a clear influence of none of the parameters considered in the experimental design, as it is inferred on the results of %AIL. The effect on the yield of enzymatic hydrolysis is greater and always positive and the temperature seems to be the more influent parameter.

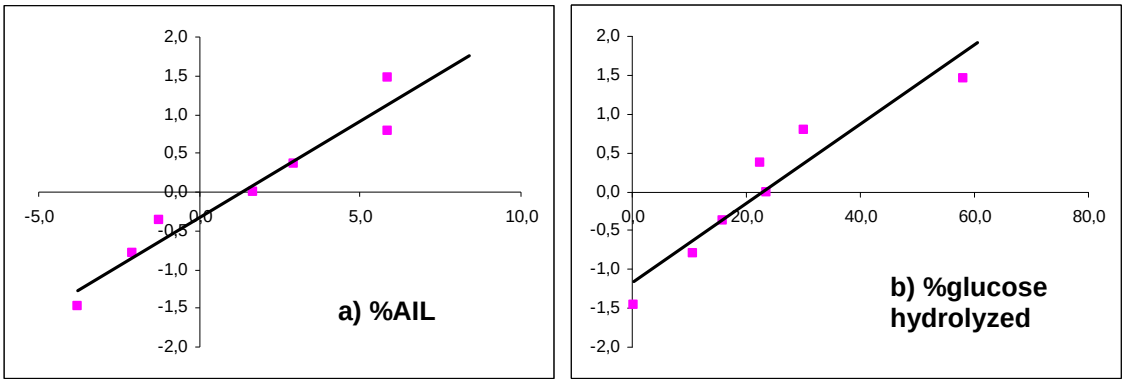

Figure 2. Normal probability plot of the effects of parameters in the steam explosion experimental design for a) AIL variation and b) % glucose hydrolyzed

On the other hand, higher temperature and size particle leads in a higher extent on enzymatic hydrolysis, in accordance with results obtained by Ballesteros et al (2002). The influence of residence time is also positive (higher the time, higher the yield of enzymatic hydrolysis). The enzymatic hydrolysis yield for this pre-treatment ranged in a largest interval from 23.4 – 80.9 % whereas the acid insoluble lignin content varies only from 19.4% to 18.4%.

The operating conditions leading the maximum yield on enzymatic hydrolysis were: temperature of 210 ºC, reaction time of 10 min and particle size of 20 mm.

4 Conclusions

It can be concluded that the maximum yields (87.1 % on glucose) on enzymatic hydrolysis were obtained when wheat straw is ozonized, operating with 40 % of solid moisture, 3-5 mm of particle size and 90 L/h of ozone, whereas a 80.9 % of glucose after enzymatic hydrolysis

was obtained when the raw material was steam exploded at 210 ºC, 20 mm of particle size and 10 min of residence time.

Results derived from the experimental designs reveal different mechanisms to improve cellulose accessibility to enzymes. The ozone degrades and solubilizes the acid lignin content in the biomass, whereas steam explosion seems to open the lignocellulosic structure without significant changes in the lignin composition.

Moreover, ozonolysis has demonstrated to be a very suitable pre-treatment for wheat straw to be used for bioethanol production. More research must be done in this way, in order to have a costly effective pretreatment.

The vegetative cycle of *Lavandula luisieri* – influence on essential oils and antioxidants

Ana Rita B. Mancelos Beirão, M. Gabriela Bernardo-Gil, Humberto E. Ferreira

Centre for Biological and Chemical Engineering, IBB, DEQB, IST,
Av. Rovisco Pais, 1049 – 001 Lisboa, Portugal

Keywords**:** *Lavandula luisieri*, essential oil, antioxidant, Rancimat, peroxide value
Topic: Multi-scale and/or multi-disciplinary approach to process-product innovation

Abstract

The *Lavandula luisieri* was studied in terms of yield and composition of essential oil and antioxidant activity during the vegetative cycle of life. The essential oil was obtained by hydrodistillation (Clevenger apparatus), and the liquid and the solid residues were solvent extracted to obtain extracts, which were studied in terms of antioxidant activity. The composition of essential oils was determined by gas chromatography and confirmed by GC-MS. The main components found included α-pinene, 1,8-cineole and α-terpineol. The antioxidant activity was determined in terms of induction time by the Rancimat method and the peroxide value. The highest value of essential oil yield was 0.59 %, obtained from the plant harvested in September. The extracts with the highest antioxidant activity were obtained from the plant harvested in May.

1. Introduction

A number of reasons point to the need of an in-depth study of the mechanisms of oxidation (rancidity), not only on fats, but more generally in food. Among them, nutritional problems caused by changes in modern life, accompanied by changes in our diet, the evidence of the existence of degenerative diseases in the developed countries caused by a longer but more stressed live, a complex food production market accompanied by a higher quality demand, are some of the reasons that explain the public consumers demands upon scientists ("When do they finally dominate the issue and give some concrete answers?"). But the issues raised are not easy to answer, and seem to become more and more complicated. Antioxidants of synthetic origin introduced in the industry over the last 50 years have become notorious not only to the public, but to some of the scientists. There is growing concern about the safety of synthetic antioxidants, despite their superior efficacy and high stability (Kiokias, Sotirios *et al.*, 2008). Discussion is centered around the advantages and disadvantages of natural and synthetic antioxidants (Pokormý, Jan, 2007), the need to use them, and the ability to resolve the actual anxiety of the public *vis-a-vis* a longer shelf life, but above all a longer human life. In the meantime, antioxidants of plant origin, known since the earlier days of man's culture, regained the right to be restudied and understood, in their composition and plant production technics, with the help of higher resolution scientific instruments of our days, such as liquid and gas chromatography and others related technics. Extraction methods have also been improved, and new methods invented (Esquivel, 1999), so that a new scientific horizon has been created. It joins nutritionists, chemists, pharmacologists, toxicologists, medicinal doctors and agronomic scientists, as well as technical and instrumental engineers, in providing new insights into one of the most ancient puzzles of the world: food science and human health.

The term antioxidant is not restrained by any international accepted definition. However, an antioxidant can be defined as "any substance that in small quantities, normally in concentrations much lower than the oxidizable materials to be protected, is able to prevent or greatly delay its oxidation".

Antioxidants are applied to foods for two different purposes:

- To suppress lipid oxidation and the formation of free radicals under conditions of prolonged storage, heating, frying or deodorization;
- To reduce the concentration of free radicals *in vivo* after food ingestion.

Antioxidants can be of synthetic or natural origin. The use of synthetic antioxidants is restricted in several countries, because of their undesirable long-term toxicological effects, including carcinogenicity (Branen, 1975; Barlow, 1990, Gazzini et al., 1998). As a result, there is a great interest in finding antioxidants from natural sources for food and medicinal applications.

As previously mentioned, the extraction of natural substances with antioxidant activity, to replace synthetic food preservatives has gained great importance (Economou et al, 1991, Esquivel et al., 1999, Ribeiro et al., 2001, Reddy et al., 2005). Extensive research has been dedicated to the identification of antioxidant compounds obtained from natural sources, and the antioxidant activity of many plants has been investigated. However, only rosemary and sage are commercially available as flavourless, odourless, and colourless antioxidant extracts. Previous work shows that the majority of active antioxidant substances occurs in extracts, but some essential oils were also studied to analyze their antioxidant activity, namely essential oil containing thymol and carvacrol, and other phenolic compounds, which exhibit high antioxidative activity. However, these compounds are highly volatile and, when high temperatures are involved, they provide scarce antioxidative protection.

There are several methods for the evaluation of antioxidative action on fats and oils (Frankel and Meyer, 2000; Becker et al, 2004). Some methods are used for the assessment of early oxidative changes (loss of reactants – active oxygen, unsaturated fatty acids; formation of free radicals – ESR detection of spin adducts; and formation of primary oxidation products – peroxide value (POV), hydroperoxides) and late oxidative changes (formation of secondary oxidation products – hydrocarbons, aldehydes, ketones, acids, p-anisidine value, trolox value, TBARS; protein damage – carbonyls, cross-linking). In the Rancimat method the conductivity caused by short-chained acids is measured, after a process of acceleration of oxidation. Rancimat method has some advantages such as being fast and able to study stability at high temperatures, which are important for the use of the antioxidants in food processing (frying). However, the oxidation analysis under these conditions is also pointed out as the principal disadvantage, as significant losses of volatile antioxidants may occur. Furthermore, at high temperatures, marked differences in energies of activation may result in overestimated oxidation levels.

Lavandula luisieri is an aromatic *Labiatae* endemic of the Iberian Peninsula, common in the South of Portugal and in the Southwest of Spain. Sanz et al. (2004) found 1,8-cineole, lavandulol, linalool and their acetates and necrodane derivatives in essential oils of this *Lavandula*, harvested in Spain.

2. Materials and Methods

2.1. Materials

Wild *Lavandula luisieri* was collected from August 2003 until July 2004 in Alentejo (South of Portugal) and was air-dried. Before extraction, leaves and/or flowers were coarsely cut. The particle diameter after size reduction was estimated by using a sieving machine Retsch KS 1000 (Retsch, Haan, Germany), being the medium particle diameter calculated as 0.3 mm. All the chemicals were obtained from several suppliers, but they were of the highest purity available.

2.2 Methods

2.2.1 Extraction of essential oil

The essential oils of *Lavandula luisieri* were obtained by using a modified Clevenger apparatus. About 100 g of dried plant powder (leaves and/or flowers) were used and the distillation was conducted for 4h. The amount of recovered oil was measured gravimetrically.

2.2.2. Solvent extraction

Both the solid residue and the liquid residue of Clevenger distillation were used for preparation of extracts with eventual antioxidant activity by using the method described by

Ribeiro et al. (2001). The ground solid residues were boiled with distilled water for about 2 h, and then filtered through a coffee filter paper. The collected filtrate was acidulated with a solution of HCl 25% to a pH 2.5 and filtered. The aqueous phase was shaken with diisopropilether (10:3) and allowed to separate. The upper aqueous layer was extracted twice more with diisopropilether. The organic phases were combined, dried with anhydrous $MgSO_4$, filtered, and evaporated using a rotary evaporator (Heidolph VV2000).

2.2.3. Analysis of essential oils

The essential oils were analysed by gas chromatography (GC) on a Hewlett-Packard 5890 Series II chromatograph equipped with a FID detector and a DB5 column (5% phenyl, 95% dimethylpolysiloxane), 0.32 mm id x 50m, film thickness 0.17 μm. The column oven temperature was programmed to hold at 60 ºC for 10 minutes, then heated to 180 ºC at a slope of 2 ºC/min, with a final isothermal hold at 180 ºC for 30 minutes. Injector and detector temperatures were 200 and 250ºC, respectively. Nitrogen carrier gas was adjusted to a linear velocity of 2 ml/min. Aliquotes of 0.2 μl were injected using the split mode (split ratio 1:20).

The sample components were identified by comparing the retention times with those of chromatographic standard of the compounds (Sigma-Aldrich, Madrid, Spain). Peak areas were determined using a Hewlett-Packard 3396 Series II integrator. For quantitative analyses, the peak areas were converted to absolute values using response factors estimated from the calibration curves of the standard compounds. Results were compared to those obtained by GC-MS.

2.2.4. Rancimat method

Rancimat method (Metrohm Rancimat 679) was used for detection and estimation of the antioxidant activity. Sample extracts dissolved in sunflower oil (7.0 g), with concentrations varying from 0 to 4000 ppm, were heated at 110 ºC. A continuous air stream (20 L/h) was passed through the heated samples, and the volatile compounds were absorbed in a conductivity cell. Conductivities were continuously monitored until a sudden rise appears. The oxidative stability was determined as the time corresponding to the inflection point of the curve, named the induction time (IT). Protection factor (PF) was determined by the ratio between the induction period found for the sunflower oil with a certain quantity of extract and the induction time obtained for sunflower oil with no addition of extract.

2.2.5. Peroxide value

The peroxide value (PV) was expressed as mEq of oxygen / kg of fat, and was determined by the iodine titration method. Extracted oil samples (2 g) were weighed into test tubes. The oxidation of the potassium iodide, in acetic medium, by the active oxygen of the fat is followed by titration of the free iodine with sodium thiosulphate, using starch as an indicator. The evolution of the peroxide value with storage time was studied.

2.3 Results and Discussion

2.3.1 Essencial oils

Table 1 summarizes the major components of the *Lavandula luisieri* essential oil obtained from plants harvested in May 2004. The yields obtained, in terms of grams of essential oil per 100 g of plant were 0.12 % from flowers and 0.3 % from leaves + flowers. The main antioxidative component present is α-Terpineol, either when the essential oil was obtained from flowers only or from flowers + leaves. The content in 1,8-Cineole and α-Pinene is higher in leaves than in flowers. On other hand, the content of viridiflorol is higher in flowers than in leaves. Figures 1 and 2 show seasonal variations of the major antioxidative components in essencial oil.

Components	Mass percentage	
	Flowers	Flowers + Leaves
α-Pinene	2.85	8.47
α-Terpinene	1.22	2.51
Limonene	0.33	0.43
1,8-Cineole	4.00	16.6
Linalool oxide	0.96	1.76
Fenchone	1.91	3.67
Terpinolene	0.79	1.16
Camphor	8.92	1.91
Borneol	2.24	2.16
Menthol	2.15	2.01
Dihydrocarveol Acetate	1.63	1.60
Lavandulil Acetate	1.71	1.31
Eucarvone	5.00	4.41
Menthatriene	2.15	1.84
α-Terpineol	13.85	17.15
Carvacril Acetate	1.21	1.07
Eugenol	2.01	0.74
β-Caryophyllene	1.48	0.84
Viridiflorol	6.77	2.97

Table 1. Some components of essential oils obtained from flowers and flowers + leaves of *Lavandula luisieri* harvested in May.

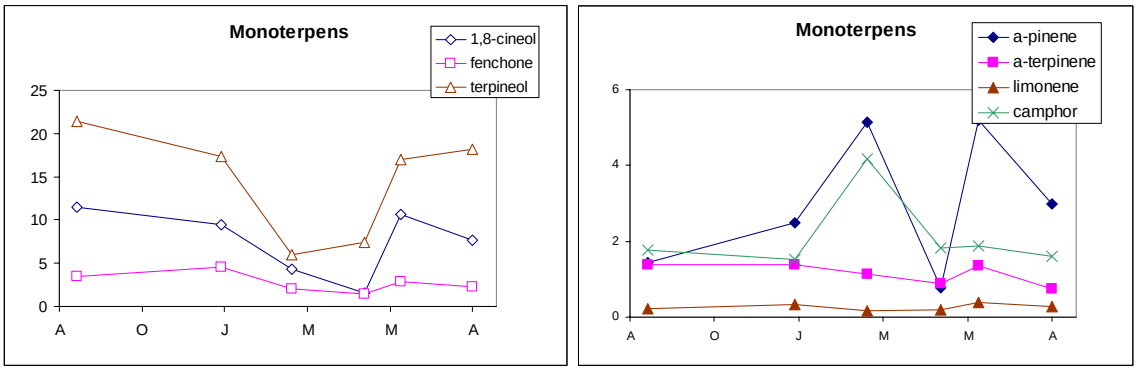

Figure 1 and 2 – Variation of monoterpene composition along the vegetative cycle. From left to right, the months represented are August, October, January, March, May and August again. Amounts are expressed as mass percentage of the extract.

2.3.2 Diisopropylether Extracts

After the solvent extraction of essential oils by 'Clevenger distillation' the liquid and solid residues left were extracted with diisopropilether. Yields, in terms of grams of antioxidative extract per 100 g of plant were 2.10 % and 0.39 %, respectively for the extraction from liquid and solid residues. The yields obtained from the plants harvested in June 2004 were 2.7 % for the extraction from the Clevenger distillation' liquid residue, and 0.24 % for the solid residue.

Figures 3 and 4 show the protection factor results of extracts, obtained from solid and liquid residues of Clevenger distillation, of plant harvested in May and June, respectively. In general, liquid residues presented higher antioxidant activity than solid residues, although the differences in results are not statiscally significant.

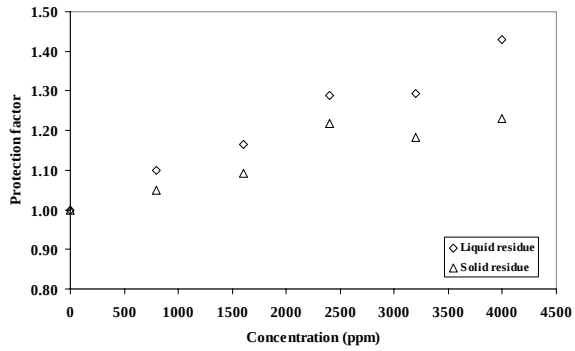

Figure 3. Protection factors of extracts obtained from liquid and solid residues of Clevenger distillation of *Lavandula luisieri* harvested in May.

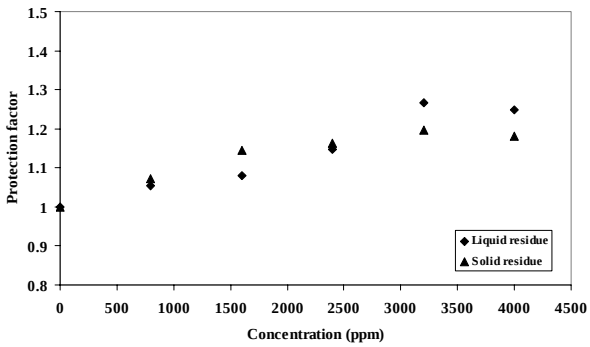

Figure 4. Protection factors of extracts obtained from liquid and solid residues of Clevenger distillation of *Lavandula luisieri* harvested in June

The evolution of the oxidation process (peroxide value) of the sunflower oil was followed in 4 different storage conditions: under direct sunlight exposure at room temperature, simulating shelf exposure; in the dark at 4ºC (refrigerator); under indirect natural light at room temperature (20-22ºC); and under artificial light at room temperature (15-18ºC). For each one of these 4 storage conditions, 3 essays were conducted in parallel: one with sunflower oil only (reference, blank essay); another with sunflower oil spiked with 4000 ppm of the antioxidative plant extracts (*Lavandula luisieri)*; and a third with sunflower oil spiked with butylated hydroxytoluene (BHT, 4000 ppm). Several aliquotes of these 3 essays were taken over time, and titrated as described previously under section 2.2.5 to obtain the peroxide value. Similar essays were conducted with extracts obtained from plants harvested during March, May, June. The results of the June extracts are presented in Figures 5 to 8.

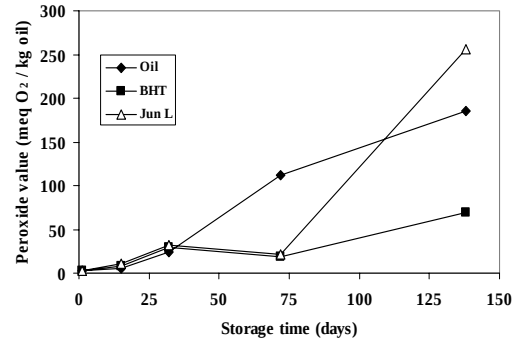

Figure 5. Peroxide values of sunflower oil (Oil), of sunflower oil with BHT, and sunflower oil with *Lavandula luisieri* extract, obtained from plant harvested in June, during storage at sun exposure.

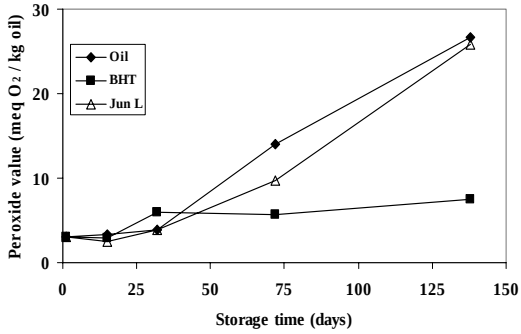

Figure 6. Peroxide values of sunflower oil (Oil), of sunflower oil with BHT, and sunflower oil with *Lavandula luisieri* extract, obtained from plant harvested in June, during storage in refrigerator.

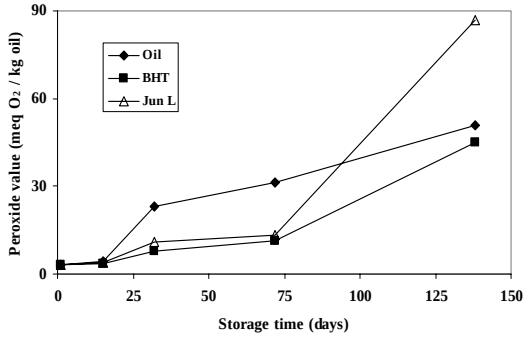

Figure 7. Peroxide values of sunflower oil (Oil), of sunflower oil with BHT, and sunflower oil with *Lavandula luisieri* extract, obtained from plant harvested in June, during storage at natural light.

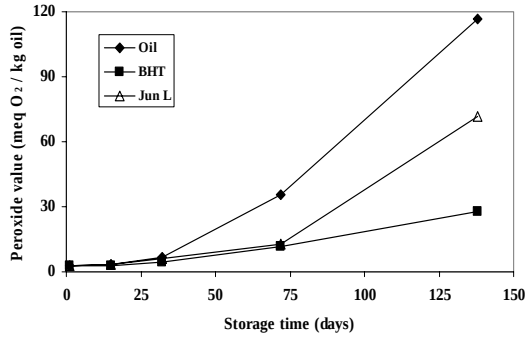

Figure 8. Peroxide values of sunflower oil (Oil), of sunflower oil with BHT, and sunflower oil with *Lavandula luisieri* extract, obtained from plant harvested in June, during storage at artificial light.

As it was expected, the oil samples stored under direct sunlight exposure at room temperature, presented higher peroxide values than all the other storage conditions, since the oxidative process occurs through radical formation, a process known to be enhanced by UV light. Furthermore, direct sun exposure seems to alter the plant antioxidative molecules that are supposed to reduce oxidation, as can be seen in Figure 6 above 75 days. The peroxide value of the oil plus *Lavandula luisieri* extract increased its oxidation drastically, from the 75th day onward, supplanting the peroxide value of the oil alone, in the conditions of storage at sun exposure.

Storage under artificial light at room temperature (15-18ºC) showed that the *Lavandula luisieri* extract prevented the oil oxidation as well as BHT, until, at least, 75 days of storage (Figure 8).

2.3.3 Plant extracts obtained under new alternative experimental conditions

Components of the plants of May, June and July were extracted with alcohols under a sonication protocol and analysed by HPLC (Wang *et al*, 2004) to identify fenolic acids. Using comparisons with standards, it was possible to identify the presence and quantitate rosmarinic and caffeic acids(Figure 9). A correlation has been found between Protection Factor of the samples and the quantity of rosmarinic acid present in extracts (Figure 10).

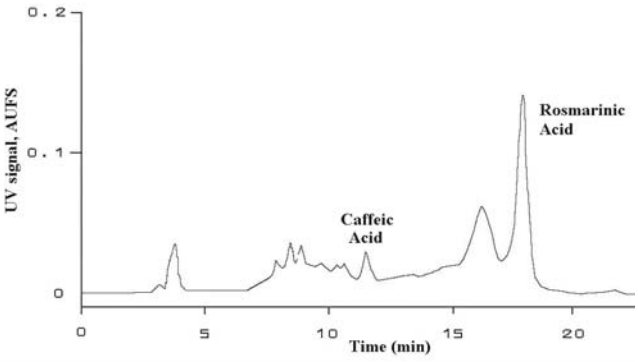

Figure 9 –HPLC chromatogram of the June extract

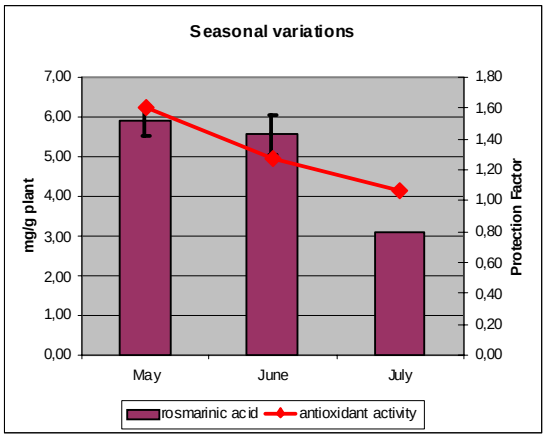

Figure 10 – Correlation between quantity of rosmarinic acid and Protection Factor

This result highlights the possibility that rosmarinic acid may be one of the substances responsible for the antioxidant activity of *Lavandula luisieri*. Further efforts are required to confirm the results, and to improve the analytical method, both in terms of increasing the antioxidant extraction yield and to better resolve and identify de various unknown components of the extract by HPLC-MS-Electrospray.

Topic: Multi-scale and/or multi-disciplinary approach to process-product innovation. Integration of life sciences & engineering.

Abstract

Extraction of natural hydrocolloid carbohydrate polymers, such as pectin, from de surplus of the crop of fruits becomes interesting commercially. Thus, the extraction of pectin from guavas pulp and pulp with peel was carried out in an aqueous acid medium under different concentrations using a experimental design for two extraction parameters (acid concentration and time). Considering the efficiency, the economization of energy and the feasibility of experiment, the optimum conditions of pectin extraction were extraction time 60 min and citric acid solution 5%, getting up yield of extracted pectin from guavas pulp and pulp with peel the range of 12–13.65% and pectin of low degree of esterification.

1 Introduction

Pectin is a polysaccharide composed of molecules of acid galacturônico united by glycosidic alpha-(1.4) and neutral sugars that contribute to the structure of the fruit. Pectins obtained have different characteristics, which vary according to their origin, allowing for wider use in industry (Willats; Knox; Mikkelsen, 2006).

The raw material commonly used is the citrus peel or apple pomace (May, 1990). Studies of new sources have been the target of several searches, particularly of fruits and agro-industrial waste. The guava (*Psidium guajava* L.), considered a source of pectin, is a fruit with high rates of post-harvest loss (Linhares et al., 2007), allowing its use for that purpose.

The process of extraction of pectin covers the steps of extraction, separation and drying. The extraction can be performed with acids, bases or enzymes, and the most common procedure acid. The factors that influence the efficiency of extraction are the type and concentration of acid, temperature and time of extraction (May, 1990). However the use of inorganic acids, as HCl and HNO_3, generate waste pollutants. A viable alternative could be the use of organic acids such as citric acid.

The research aimed to extract pectin from the pulp and the pulp with peel of flour of red guavas *cv* Pedro Sato, and characterized by degree of esterification.

2 Materials and methods

2.1 Materials

Red guavas (*Psidium guajava* L.) *cv* Pedro Sato were acquired in the district of Santa Terezinha, Itaporã city, MS state, Brazil.

The fruits were washed and sanitized with dichloro s. dicloro s. triazinatriona sodium dihydrate (Sumaveg), the concentration of 0.66% per 10 min. Then the fruits were separated into two lots and broke up pulp and pulp with peel for further drying in stove. The fractions

* Corresponding author. Tel + 55-67-34681169. E-mail:clmunhoz@yahoo.com.br

were dried in stove with forced movement of air at 55 ºC for 72 hours until moisture of 12.55 and 13.24% for pulp and pulp with peel, respectively. The fractions were ground into mill knives (Marconi), to obtain the flour and stored in glass containers tightly closed. All reagents used in the analyses were analytical grade.

2.2 Experimental design

The composed central rotational design 2^2 with four axial points and three replicates in the central point was applied to obtain the yield on the extraction of pectin (Table1). The independent variables were the concentration of citric acid (g $L)^{-1}$ and the time of extraction (min). Tests were conducted with two repetitions and random.

Table 1. Matrix of experimental design.

Test	Variables coded		Variables original	
	Acid (%)	Time (min)	Acid (%)	Time (min)
1	-1	-1	3.5	35
2	1	-1	6.5	35
3	-1	1	3.5	85
4	1	1	6.5	85
5	-1.414	0	3	60
6	1.414	0	7	60
7	0	-1.414	5	25
8	0	1.414	5	95
9	0	0	5	60
10	0	0	5	60
11	0	0	5	60

2.3 Extraction of the pectin from the pulp and pulp with peel of flour of guava

The extraction of pectin was performed in acidic medium with the citric acid. Samples were taken of each flour (4 g) and dissolved in 200 ml of distilled water. The extractions were performed to 97 ºC under different experimental conditions of concentration of citric acid (3.5-7.0%) and time (25-95 min). After extraction, the samples were cooled to 4 ºC for two hours, once filtered. The residue of filtered, containing pectin, was precipitated with ethanol (95%) in the proportion of 1:2 (one part of the residue and two parts of ethanol). After one hour of rest, the pectin precipitated was separated by filtering and dry in stove at 55 °C until weight constant. The yield of pectin was calculated from the initial quantity of raw material (Equation 1):

$$Yield = \frac{pectin_{extracted} \times 100}{mass_{flour\,(dryed)}} \qquad \text{Equation (1)}$$

Where $\text{pectin}_{\text{extracted}}$ is the mass of pectin obtained after extraction and drying in grams and $\text{mass}_{\text{flour (dryed)}}$ is the mass of sample on dry basis in grams.

2.4 Titration characterization of pectin

Samples of pectin obtained in experimental conditions 5 g (100 g $)^{-1}$ and time of 60 min were quantified by titration the content of acid galacturonic and the degree of esterification (Wang; Pagan; Shi, 2002 Apud Fertonani, 2006).

2.5 Analyses of results

The data were statistically assessed by average, standard deviation and coefficient of variation, analysis of variance and Tukey test in the level of 5% probability.

3 Results and discussion

3.1 Pectin extraction

Table 2 shows the average yields of pectin extracted from the pulp and pulp with peel of flour of guava.

Table 2. Yields of extraction of pectin obtained from the flours of pulp and pulp with peel guava by experimental planning.

Experiment	Pulp [g (100 g)$^{-1}$]	Pulp with peel [g (100 g)$^{-1}$]	Independent variables	
			Acid [g (100 g)$^{-1}$]	Time (min)
1	7.83^{c}	7.31^{e}	3.5	35
2	13.64^{a}	10.57^{b}	6.5	35
3	9.38^{b}	8.87^{c,d,e}	3.5	85
4	12.90^{a}	10.64^{b,c,d}	6.5	85
5	9.56^{b}	8.49^{d,e}	3	60
6	13.66^{a}	13.24^{a}	7	60
7	7.91^{c}	5.91^{f}	5	25
8	12.77^{a}	12.85^{a,b}	5	95
9	12.52^{a}	11.41^{a,b}	5	60
10	12.75^{a}	11.81^{a,b}	5	60
11	12.44^{a}	11.36^{a,b,c}	5	60

*Letters equal columns do not differ statistically between them (P>0,05).

The average yields of pectin extracted from pulp of flour of guava *cv* Pedro Sato ranged from 7.83-13.66 g (100 g)$^{-1}$. The yields obtained in the concentrations of citric acid from 5 to 7 g (100 g)$^{-1}$ (experiments 2, 4, 6, 8, 9, 10 and 11) did not differ ($P > 0.05$) between them, but differed ($P \leq 0.05$) than of 3 and 3.5 g (100 g)$^{-1}$. In these experiments were the biggest yields of pectin. The lowest yields were found in experiments 1 and 7. It appears that the increased concentration of the acid gradually affected the yield of extraction.

The analysis of variance of the results of yields from pectin extraction from pulp of flour of guava (Table 3) shows the effects linear, quadratic and the interaction of variables: concentration of acid and time of extraction. The linear and quadratic effects of variable time and the linear effect of variable acid, in the yield of extraction of pectin, were significant, which leads to the conclusion that both the acid as the time of extraction influence the yield of extraction of pectin. However, relatively long time of extraction may degrade the pectin, reducing the amount of waste being precipitated by alcohol due to the formation of a gel weak, during final precipitation (Pagan et al., 2001), and higher concentrations of acid may degrade the pectin. According Fertonani (2006) pectin extracted with high concentrations of citric acid can drag other compounds or may also occur to link of citric at pectic structure precipitate in ethanol. Canteri-Schemin et al. (2005) on the extraction of pectin from apple pomace using tartaric, malic, citric, phosphoric, sulfuric, nitric and hydrochloric acid, had greater yields from the citric acid to 97 ºC in a time ranging from 10 to 210 min and concentration of 0.05 to 9.95 g (100 mL)$^{-1}$.

Tablea 3. Analysis of variance of yield of pectin extraction from pulp and pulp with peel of flour of guava *cv* Pedro Sato depending on the concentration of citric acid cítrico [g (100 g)$^{-1}$] and the time of extraction (min)

In tests, from the planning, it was found that there was better training of the gel (visually observed by its firmness) to the concentration of 5 g (100 g)$^{-}$ de citric acid and time of extraction of 60 min. So, as this condition, there was no significant difference in average yield obtained from the use of higher concentrations of acid and longer time, it was concluded that this condition is the combination better suited for obtaining pectin with good yield.

The yields of pectin extraction obtained from the pulp with peel of flour of guava are also shown in Table 2. The amounts found ranged from 5.91-12.85 g (100 g)$^{-1}$. The experiments 6, 8, 9, 10 and 11 provided the highest yield, whose values are in the range of 11.36 to 13.24 g (100 g)$^{-1}$, with no significant difference ($P > 0.05$) among themselves.

Table 4 presents the analysis of variance of yield of pectin extraction from pulp with peel of flour of guava.

Total	110.80	21			

Coefficients in bold are significant.

The results obtained by analysis of variance show that the linear effects of concentration of citric acid and time of extraction, and the quadratic effect of variable time were significant ($P \leq 0.05$). The other effects were not significant ($P > 0.05$).

The yield on the extraction of pectin from the pulp with peel of flour of guava was higher concentrations of 5 and 7% of citric acid, except for the experiment 7 (Table 2). In experiments with 6.5% of acid the yield was lower, probably the time of 35 min was not enough for extraction of pectin, as also observed in the extraction of acid with 5% and 25 min of extraction. For concentrations greater than 6.5% of the time extraction seems positively influence, as noted for the extraction of pectin the pulp of flour of guava, but depending on the temperature of extracting more time could lead to degradation of pectin (Pagan et al., 2001). From the above, the concentration of 5 g (100 g)$^{-1}$ citric acid and extraction of time of 60 min was also considered the best condition for extraction of pectin.

The use of peel of plants in the extraction of pectin is little studied. Kliemann (2006)), in samples of peel of yellow passion fruit with and without flavedo, won best performance of pectin in conditions for extraction of 90 °C, pH of 1.2 with citric acid for 10 min. Kalapathy and Proctor (2001) studied the acquisition of pectin from the peels of soybeans, the authors assessed the efficiency of extraction using hydrochloric acid in concentrations of 0.06 to 0.18 g. 100 g^{-1} (0.05 e 0.3 N) and found that the higher incomes (17 and 19%) were obtained at concentrations 0.06 e 0.12 g. 100 g^{-1} with no significant difference between both concentrations.

3.2 Characterization of pectin

The characteristics of quality of pectins are presented in Table 5. For galacturonic acids, despite the values make a significant difference ($P \leq 0.05$), they are close to the minimum percentage of galacturonic acid (65%) to commercial pectin established by the FAO (Food and Agriculture Organization of the United Nations).

Table 5. Titration quality of pectin extracted from pulp and pulp with peel of flour of guava with citric acid 5 g (100 g)$^{-1}$, time of extraction of 60 min at 97 ºC and of commercial pectin

Pectin	**Galacturonic acid (%)**	**Degree of esterification (%)**
Pulp	64.88 ^{C} ± *0,11*	38.94 ^{B} ± *1,50*
Pulp with peel	68.84 ^{B} ± *0,77*	40.99 ^{B} ± *1,30*
Commercial	75.38 ^{A} ± *0,54*	72.01 ^{A} ± *1,27*

Averages followed by the superscripted letters in the same column do not differ at the level of 5% probability by Tukey test

Pectins obtained in this study were considered low-esterification (38.94% and 40.99%) and are characterized how pectins of low levels of esterification and can form gels stable in the absence of sugar, but require the presence of bivalent ions. Compared with pectins of high power of esterification, are less sensitive to changes in pH, can form gels in the range of pH 2.6-6.0. It can be stated as a thickener and stabilizer in food emulsions (Sharma; Liptay; Le Marguer, 1998; Yapo et al. 2007). Calliari (2004) obtained similar value (37.50%) for pectin extracted with citric acid from orange pomace, under the conditions of 4% of pomace, 3.5% of citric acid at 75 °C. Kliemann (2006) also extracted pectin low-esterification (45.94%) using citric acid in pH 1.2 to 90 ºC for 10 min in the extraction of peel of passion fruit. Marcon et al. (2005) extracted pectin of low esterification (14.3% to 29.4%) from apple pomace, with citric acid to 5%, times of extraction between 30-80 min and temperatures between 50-100 °C. (2005).

4 Conclusion

The best condition for the pectin extraction from pulp and pulp with peel of flour of guava was: concentration acid 5 g (100 g)$^{-1}$ and time of extraction of 60 min, in that condition the yield around 11 %.

Pectins extracted obtained under the best conditions for extraction, from pulp and pulp with peel of flour of guava showed up low-esterification with degree of esterification of 38.94% and 40.99% respectively. However, the concentration of galacturonic acid was close to the standard commercial.

Topic: Multi-scale and/or multi-disciplinary approach to process-product innovation. Integration of life sciences & engineering.

Abstract

The dehydration of persimmon fruit (*Diospyrus kaki* L.*)* using osmotic process in sugar solutions was studied. Weight reduction, water loss and solid gain were obtained as a function of the temperature (40, 50 e 60ºC) and immersion time (60, 180 e 300 min) in order to choice the best conditions of the osmotic process. Response surface methodology was used to estimate the effects of osmotic dehydration treatments and to optimize those conditions. The best osmotic treatment was at 40ºC during 4 hours of immersion.

1 Introduction

In Brasil, great part of fruits and vegetables produced is lost in the production centers for not using efficient techniques, which assure a longer time of shelf life. The non-processed fruits are sufficiently perishable, their losses postharvest, in the developed countries, not exceed 20% of total production. On persimmon fruit production, specifically, the high perishability of these fruits and the local market, make the demand lower than the offer, causing collapse of prices and diverse losses for the farmer, in the short period of harvest (Brackmann et al., 2006). Thus, the search of alternative methods to minimize these losses is constant. The effect of osmotic dehydration, as pre-treatment, on fruits conservation methodology, is mainly related to the improvement of its nutritional, sensorial and functional properties. The type and degree of alteration in the composition of the osmotic dehydrated fruit depend, specially, on: the intrinsic characteristics of the fruit, the posterior process of conservation and the desired qualitative characteristics (Torreggiani and Bertolo, 2001). The knowledge of mass transfer rates on persimmon osmotic system between the fruit and the dehydrated solution can improve nutritional and sensorial properties to the fruit. The goal of this work was to: construct a system of osmotic dehydration with recirculation of the drying solution; dehydrate slices of persimmon osmotically in the system with recirculation; determine the mass transfer parameters and determine the best condition of osmotic treatment.

2 Material and methods

Persimmon fruits (*Diospyrus Kaki* L.) of variety Fuyu, from the same orchard, were supplied in the local market by the same provider. They were chosen in accordance to size, appearance (healthy fruits), shape and degree of maturation (mature, however firm), in order to get more homogeneous samples. Sugar (sucrose) was commercial provided by Açúcar União (Brasil). Persimmon samples had the rind and seeds

removed, cut into slices of 1 cm of thickness, and then washed with water and dried with absorbent paper, before being submitted to the osmotic process. The samples were weighed, placed on polypropylene trays and put into the osmotic solution (60ºBrix), previously warmed at 40ºC. The flow of the solution was established by a peristaltic bomb with outflow of 0,003 L/h, to guarantee the contact of the sample with the solution. The weight reduction (WR), water loss (WL) and solid gain (SG) at different time of dehydration had been calculated according to equations 1, 2 and 3:

$$PM(\%) = 100 \times \left(\frac{m_i - m_t}{m_i} \right) \quad (1)$$

$$PA(\%) = 100 \times \left(\frac{m_i \cdot X_{bu_i} - m_t \cdot X_{bu_t}}{m_i \cdot X_{bu_i}} \right) \quad (2)$$

$$GS(\%) = 100 \times \left(\frac{ART_t - ART_i}{ART_i} \right) \quad (3)$$

Where: $\mathbf{m_i}$ e $\mathbf{m_t}$ the total mass of sample at the initial time and at time (t), respectively; $\mathbf{X_{bu}}$ e $\mathbf{X_{bu\ t}}$ the humidity at initial humid base and at time (t) of the sample; $\mathbf{ART_i}$ e $\mathbf{ART_t}$ **,** the total reducing sugars at initial time and at time (t).

Analytical methods were determined according to AOAC (1996). Soluble solids content were determined by refractometric index, using refratometer (Zeiss West Germany). The Reynolds number was determined according to Mavroudis, Gekas, and Sjoholm (1998). The experimental data obtained were analyzed through regression and graphical analysis by the software STATISTICA version 5.0 (Statsoft, USA). A full 2^2 factorial design with three replicate at the center point was used to study the effect of the two variables of process: temperature (40, 50 e 60 ºC) and period of immersion time (60, 180 e 300 min) on water loss (WL), weight reduction (WR), solid gain (SG) ratio. The flow type in the system was determined by the Reynolds Number (Re). Where: ρ_{sol}: fluid density, μ_{sol}: fluid viscosity,V_s: fluid velocity, D_L: diameter

$$\mathrm{Re} = \frac{\rho_{sol} \cdot V_s \cdot D_L}{\mu_{sol}}$$

3 Results and conclusion

The selected fruits were analyzed to determine humidity, total sugars, titratable acidity, soluble solids and pH (Table 1). The results obtained were in accordance to the literature for the same variety of fruit (Sato & Assumpção, 2002; Daniele et al., 2002; Vasconcelos, 2000). The differences observed can be attributed to the degree of maturation of the fruit, as well as the climate and soil conditions.

Table 1: Chemical and physical characteristics of persimmon fruits, cultivar *Fuyu.*

Characteristics	Theorical*	Experimental
pH	4.20 a 6.60	5.94 a 6.33
Titratable acidity (g acid malic/100g sample)	0.07 a 0.11	0.06 a 0.13
Soluble solids (^{o}Brix)	9 a 21	16.5
Humidity (%)	82	80.5 a 83.5
Total sugars (%)	17 a 26	16.97 a 19.09

* SATO & ASSUMPÇÃO (2002)

The results determined for the mass transfer coefficients, water loss (WL), weight reduction (WR), solid gain (SG) are shown in Table 2.

Table 2: Experimental results obtained from experimental design: water loss (WL), weight reduction (WR), solid gain (SG).

Independent variables				Dependent variables		
Codified		Decodified		Response		
Temperature (X1)	Time (X2)	T (°C)	t (min)	WL (%)	WR (%)	SG (%)
-1	-1	40	60	31.50	13.08	5.03
-1	1	40	300	55.79	24.74	9.98
1	-1	60	60	39.07	24.17	14.90
1	1	60	300	68.84	46.96	21.88
-1.41	0	36	180	43.32	25.25	18.07
1.41	0	64	180	64.87	48.18	20.69
0	-1.41	50	11	25.60	9.10	16.50
0	1.41	50	350	68.32	48.46	19.86
0	0	50	180	51.64	33.14	18.50
0	0	50	180	55.67	37.41	18.26
R^2	---	---	---	0,99	0,93	0,53

The data of the estimative effect indicate how much each factor influenced in the studied region. Regression coefficients describing the effect of osmotic dehydration variables on the water loss (WL) of persimmon fruit slices are given in Table 3. The determination coefficient (R^2) for water loss and weight reduction was 0.99 and 0.93, respectively, indicating a good adjustment of the experimental data (Table 2). It is observed that the linear effect of temperature (L) and linear term of time (L) had positive effect on the water loss, or either, an increase in any one of these factors caused an increase the water loss, while that the effect of the factors temperature (Q) and time (Q) have negative influence, in the same way, an increase in these factors causes reduction of the loss of water. The interaction between time and temperature presented positive effect, showing that the interaction of both factors contributed to increase water loss. However, among the factors studied, only the immersion time (L) was statistically significant values for the water loss.

Table 3: Effect estimated, pure error, p-value and regression coefficient on water loss

Variables	Effect estimated	Pure error	P-values<0.05	Regression coefficient
Temperature (L)	12.83	2.03	0.099	0.654
Temperature (Q)	-0.44	2.71	0.898	-0.002
Time (L)	28.67*	2.02*	0.045*	0.158*
Time (Q)	-7.62	2.66	0.214	-0.000
Time x Temperature (L)	2.74	2.85	0.512	0.001

*Significant at 95% of level; (L) = linear term; (Q) = quadratic term

In Figures 1 and 2 show the typical response surface diagram of the osmotic treatments,

representing the water loss (WL) and weight reduction (WR) as function of immersion time (min) and temperature (ºC). During the three first hours of immersion treatment, the loss of water was 53-60%, and after 5 hours of immersion, the water loss increased to 60-67%. The high rate of water loss in the beginning of the process can be explained by the driving forces, between the internal solute fruit concentration and the hypertonic solution concentration. Rapid removal of water in early stages of osmotic dehydration has been reported in carrots (Uddin et al. 2004) and in guavas (Sanjinez-Argandoña, 2005). The influence of the temperature on the water loss is barely observed at the beginning of the process, and it can only be verified after 180 min, at 40°C, when losses of water (above of 50%) increases with enhancing time of immersion. However, high temperatures damage the cellular structure (Sanjinez-Argandoña et al., 2004), which increase the solids content in intracellular, besides it makes the fruit soft.

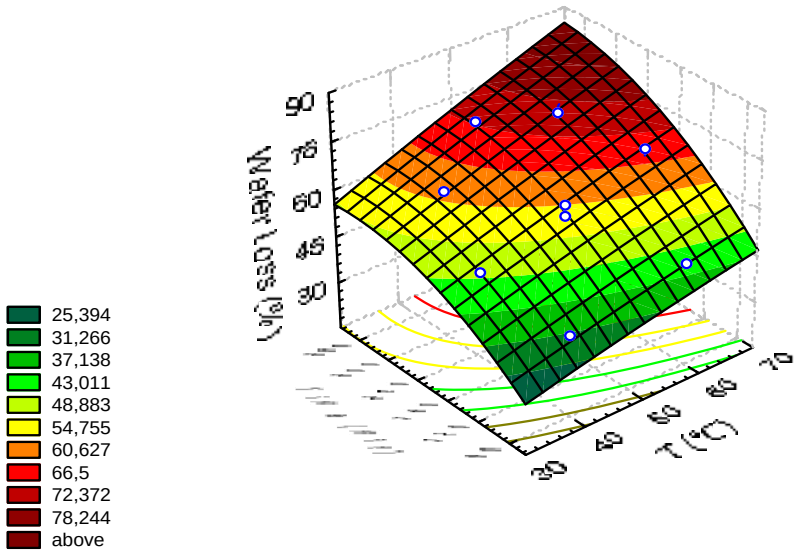

Figure 1: Water loss during osmotic dehydration of persimmon fruit slices as function of immersion time (min) and temperature (°C).

The fluidynamic of the osmotic system was conducted by the laminar flow, and the Reynolds Number determined was 3.33. The water loss was influenced mainly by the period of time of immersion and had less influence by temperature. Sanjinez-Argandoña et al. (2004) had observed, on batch and semi-continuous osmotic treatments of guavas, that the mass transfer is positively affected by the speed of the flow. Consequently, raising outflows (from laminar to turbulent flow) would be more effective to water loss. Although, the solution flow was laminar, the results obtained were similar to the data determined by Azeredo e Jardine (2000) that dehydrated pineapples using osmotic dehydration from 2 to 5 hours, at temperatures of 30 to 50ºC with osmotic solution concentration between 60 and 70ºBrix, they observed that pineapples had 32.3 to 52% of water loss; 17.5 to 32.9% of weight reduction and an increase of solids of 11.4 to 22.3%. Figure 2 shows the weight reduction as function of immersion time and temperature. It can be observed that at three hours of process (180 minutes), at 50 and 60°C, the weight reduction was 43 and 49%, respectively. It is interesting to observe that at temperature of 50°C, the weight reduction for 180 min and 350 min of process was the same (Table 2). These results proved that the reduction of weight was influenced by

temperature and immersion time of osmotic treatment.

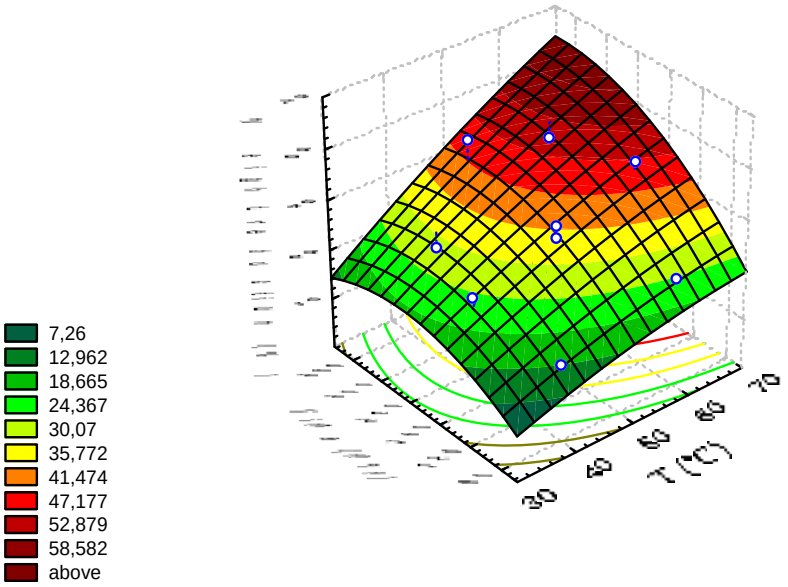

Figure 2: Weight reduction (WR) during osmotic dehydration of persimmon fruit slices as function of immersion time (min) and temperature (°C).

The Pareto chart (Figure 3) shows the influence of immersion time and temperature on the gain of solids. The solid gain is more influenced by temperature than the immersion time. Probably, this fact is due to the temperature that affects directly on the selectivity of the cellular membranes of fruit. The model adjusted for solid gain was statistically significant at the level of 95% for the variables: time, linear (L) and quadratic (Q) term; and temperature, linear (L) term. However, the determination coefficient of predicted values was lower (53%) than the results, determined for water loss and weight reduction (99 and 93%, respectively). This lack of fit can be attributed to the insufficient number of terms, which means that the omission factors had influenced on the response as, for example, different concentrations of osmotic solution.

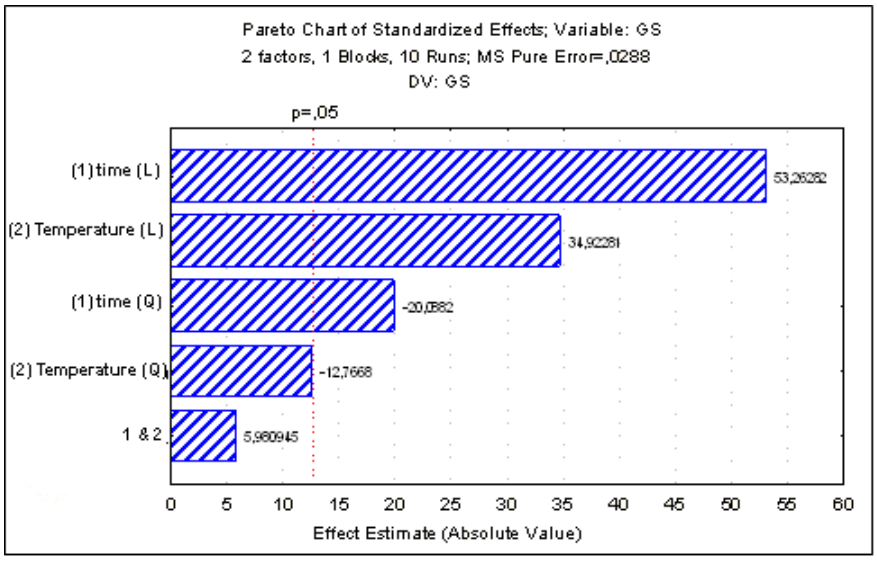

Figure 3: Pareto's chart for solid gain on osmotic treatment of persimmon fruits.

4. Conclusion

The osmotic fluidynamic system was conducted by the laminar flow, and the Reynolds Number determined was 3.33. The water loss was influenced mainly by the time of immersion and had less influence by temperature. The solid gain was significantly influenced by the temperature and time of immersion; however, the analysis of variance demonstrated that the polynomial model did not have good adjustment for the experimental data. The osmotic dehydration of persimmon fruit slices at 40°C, in sucrose solution (60 ºBrix) for 4 hours was chosen as the best condition for water loss (53.5%), weight reduction (38.5%) and solid gain (15%).

Keywords: High pressure treatment, grape seed, extraction yield, supercritical fluid extraction.
Topic: Multi-scale and/or multi-disciplinary approach to process-product innovation.

Abstract

The combination of pre-treatments with natural matrices processing may induce higher extraction yields and/or reduce the treatment times involved. In this essay, the application of a high pressure treatment prior to the supercritical fluid extraction of grape seed (*Vitis vinifera*) oil has been investigated.

Experiments show that, under the operating conditions adopted, the final extraction yield slightly decreases with increasing processing pressure. Up till 3000 bar such effect is negligible, though a variation of 15.5% was measured at 5000 bar.

With respect to the supercritical fluid extraction results, the comparison between cumulative curves achieved with treated and untreated grape seed evidenced faster kinetics in the former case, despite final yields were approximately the same. Therefore, combining a high pressure treatment with supercritical fluid extraction may certainly reduce CO_2 consumption to reach the same extractability under optimized operating conditions.

1. Introduction

Increasing consumer demand for high quality, freshlike, safe foods that are minimally processed, incited the industry to continuously improve the existing technologies and gave birth to many research efforts on novel technologies (Ludikhuyze et al., 2003), such as high-pressure processing. In addition to food preservation, high-pressure treatment (HPT) may result in food products acquiring novel structure and texture, and hence can be used to develop new offers or increase the functionality of certain ingredients (Saraiva et al., 2002; Castro et al., 2006). The application of high pressure leads to rearrangement in the tissue architecture, which may result in increased extractability, even at ambient temperature. The combination of high pressures and lower temperatures could become a viable alternative to some current industrial practice (Rastogi et al., 2007). The inclusion of HPT as a preceding step of other unit operations, such as solid-liquid extraction, is being considered as one of the emerging possibilities in the path leading to novel products and new process development opportunities (Garcia et al., 2001). When applied as a pre-treatment, it may promote higher solute extractability and increase extraction kinetics, which ultimately reduces processing times.

Grape seed (*Vitis vinifera*) is a well known oilseed crop and a major by-product resultant from the wine industry, containing typically between 7-15% (w/w) of oil (Gomez, et al. 1996). It is also an appealing product due to its large availability, as a major by-product resultant from the wine industry. The aim of this study is to investigate and improve the yield of grape seed oil extraction by applying an HPT prior to supercritical fluid extraction (SFE) with CO_2.

2. Experimental Procedure

2.1. Processing of solid plant material

Seeds were collected from grapes (*Vitis vinifera*) of the red variety *Touriga Nacional* harvested at technological maturity, provided by a local wine industry (*Caves* Messias, Anadia, Portugal) during September 2007. Seeds were collected during transfer of the musts in wine fermentation, and separated from pulp and skins by decantation and sieving. A first wash removed immature grains floating at water surface. Subsequently, the seeds were submitted to several washes with water (200 g/L) under gentle stirring with a magnetic bar at 4 ºC during a minimum of three days, with two water exchanges per day, until a minimum constant turbidity was observed. The purified seeds were finally washed with ethanol, air dried at room temperature, and stored at 4 ºC until use. Finally, milling was carried out on a domestic coffee mill, and the particles classified in a standard sifter with several mesh sizes.

In this work, to ensure the biomass used in different runs had the same size distribution, the extractor load was prepared by combining fixed masses of crushed seed from each mesh interval. Specifically, a mean particle diameter $\overline{d}_p = 1.3$ mm was adopted, being calculated by Sauter's equation (Povh et al., 2001) to a set of fractions within [0.71;1.4]:

$$\overline{d}_p = \frac{1}{\sum_{i=1}^{k} \frac{\Delta m_i}{d_{p_i}}} \qquad [1]$$

where d_{p_i} is the size of sieve i, which retains a mass of solid Δm_i.

2.2. High pressure treatment

Prior to both conventional Soxhlet and supercritical fluid extractions of grape seed oil, the HPT was applied. It has been accomplished in a Hydrostatic press (Unipress Equipment, Model U33, Poland). Experiments were conducted at several pressures during 15 min at 22ºC. The milled seed was previously subjected to an overnight water floating (2 mL_{water}/g_{seed}) and only then subjected to the HPT. After the samples were freeze dried.

2.3. Soxhlet extraction

The yield of grape seed oil extraction was assessed by conventional Soxhlet carried out with 150 mL of *n*-hexane in a Soxhlet apparatus (50 mL capacity; 23×100 mm cartridge) during 4 h. The mass oil was determined gravimetrically after solvent evaporation. Furthermore, to ensure that the resultant oil carries no water, the

extracted samples were passed over sodium sulfate anhydrous under vacuum in a G1 sintered glass filter, and evaporated in a rotary evaporator at 30 ºC. The oil was then transferred to speed-vacuum tubes and dried by centrifugal evaporation. The yield of the process is expressed as the mass of oil extracted from 100 g of dried grape seed. The results thus obtained were assumed as reference values, being used for comparison with those achieved by SFE. The yield of the process $(\eta,\%)$ was expressed as the mass of oil extracted from 100 g of dried grape seed.

2.4. Supercritical fluid extraction

The experiments of SFE of grape seed oil were carried out in a semi-batch extraction apparatus built/assembled at the University of Aveiro. It has been operated with nearly 65 g of crushed grape seed, a CO_2 flow rate of 0.6 kg h^{-1}, at 180 bar and 40ºC. Two sets of experiments were carried out, using treated and untreated samples for comparison.

3. Results and discussion

The results obtained by conventional Soxhlet confirmed that the average particle diameter has a strong effect on the yield of the grape seed oil extraction. Figure 1 shows an increase in the oil recovery of 128% when d_p is reduced from range 1-1.4 mm $(\eta = 6.7\%)$ to $d_p < 0.5$ mm $(\eta = 15.3\%)$. These determinations evidenced it is fundamental to ensure that the same size distribution is being processed to allow comparisons between them. Therefore, the procedure based on Eq.1 and described in section 2.1 was always carried out in this essay, and the average value $\overline{d}_p = 1.3$ mm has been adopted and fixed since then.

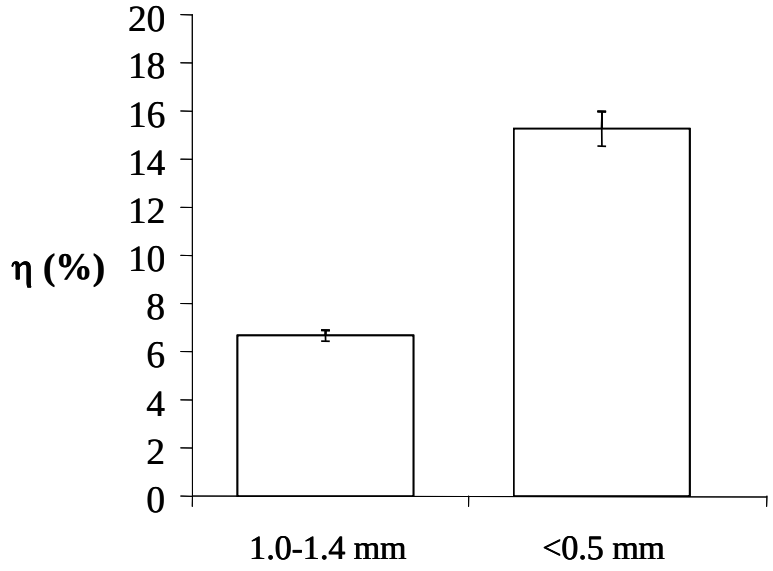

Figure 1. Extraction yield (%) against granulometry of crushed seed particles.

Introducing HPTs prior to conventional Soxhlet extractions, slightly lower recoveries were obtained by increasing the operating pressure, P, (Figure 2). The lowest pressures applied (1000 and 3000 bar) produced nearly the same yields, $\eta = 6.5\%$ and 6.4%, respectively, while $P = 5000$ bar decreases oil removal to 5.8%. These observations correspond to a global variation of 15.5%, and suggesting that pressure treatment change the oil availability, givin rise to lower yields.

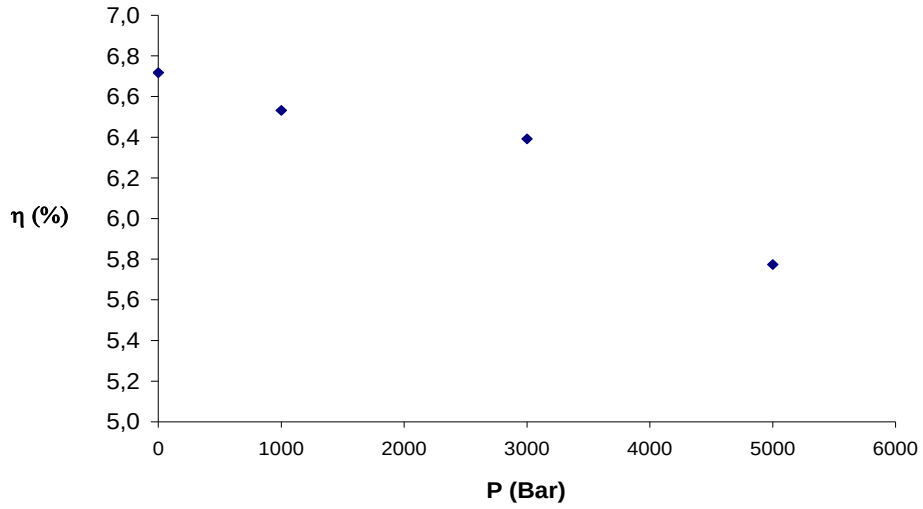

Figure 2. Extraction yield (%) as function of the operating pressure of several high pressure treatments, for $\overline{d}_p = 1.3$ mm and $t = 15$ min.

In Figure 3 cumulative curves for grape seed oil extraction with supercritical CO_2 are plotted, for the operating conditions of 180 bar and 40ºC, and $\overline{d}_p = 1.3$ mm. In abscissas the ratio of solvent consumption to seed charge $\left(m_{CO_2} / m_{seed}\right)$ is presented. The two cumulative curves correspond to measurements achieved with untreated samples and with high pressure pre-treated biomass at $P = 1000$ bar during 15 min. These results exhibit the characteristic behaviour associated to seed oils (e.g., Sovova et al., 1994): a first equilibrium and film controlled period approximately linear, followed by a second diffusional controlled period with more asymptotic behaviour.

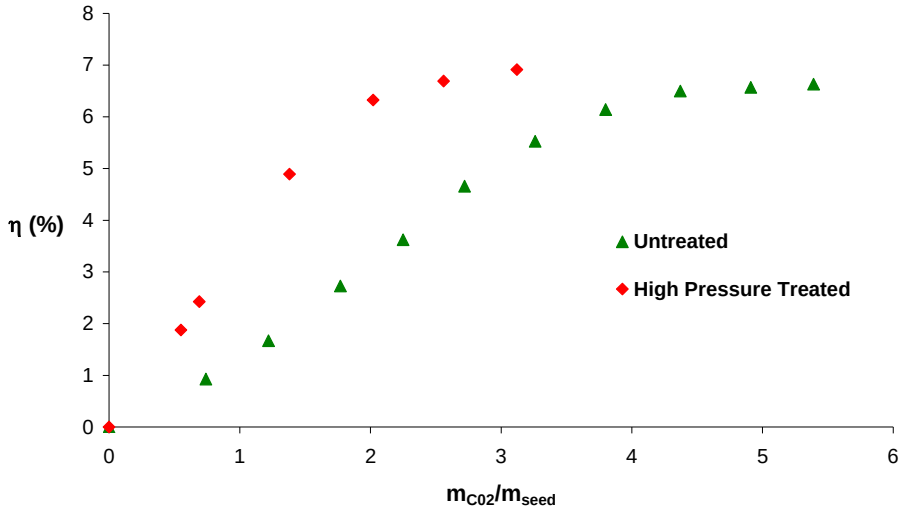

Figure 3 – Effect of HPT ($P = 1000$ bar; $t = 15$ min) upon the cumulative extraction curves obtained by SFE of grape seed oil at 40ºC and 180 bar, for $\overline{d}_p = 1.3$ mm.

Figure 3 corroborates previous finding by Soxhlet experiments, *i.e.* HPT does not increase the final yield, as both curves tend nearly for the same plateau. Nonetheless, a distinct behaviour was observed during extraction, since the curves are different for the intermediate conditions. Such fact shows that the extraction kinetic is faster for the treated samples. It is worth noting that the CO_2 consumption necessary to achieve complete oil removal almost doubles from pre-treated $\left(m_{CO_2}/m_{seed} \cong 3\right)$ to untreated $\left(m_{CO_2}/m_{seed} \cong 5.5\right)$ samples. In terms of processing time, it additionally implies that only half extraction time is need to accomplish total oil removal.

4. Concluding remarks

In this work, the effect of a high pressure pre-treatment upon the yield and efficiency of grape seed oil extraction has been evaluated.

Experiments show a slight impact of HPT on the final yield up till 3000 bar performed during 15 min. Nonetheless a weak yet consistent decrease has been observed with increasing operating pressure, which may suggest possible changes on the oil availability from the biomass.

The comparison between cumulative curves of the SFE of treated and untreated grape seed evidenced faster kinetics in the former case, despite final yields are approximately the same. Therefore, combining HPT and SFE we may reduce CO_2 consumption to reach the same extractability under optimized operating conditions.

Keywords: Antioxidant activity, Rancimat Method, vegetable oil, antioxidant extract
Topic: Multi-scale and/or multidisciplinary approach to process-product innovation

Abstract

In vegetable oils, particularly virgin olive oil and sunflower oil and in lard, the effects of temperature and antioxidant extracts concentration on the induction time were investigated using a sequence of simple factorial designs.

The antioxidant extracts were obtained from aromatic plants by hydrodistillation followed by liquid-liquid extraction using diisopropyl ether as a solvent. Vegetable oils and lard were spiked with those extracts in a range of concentrations from 250 to 2500 ppm and then subjected to oxidation in a 679 Rancimat apparatus.

In the sequence of factorial designs, two blocks of 2^3 design were run. In the first block only peppermint extract was used in two different matrices (virgin olive oil and sunflower oil). In the second block the antioxidant extract was introduced as a new variable but keeping the same matrix (sunflower oil). A simple equation was derived trying to relate the induction time (T_I) with the extract concentration (C_{Ext}): $T_I / T_{I_0} = 1 + k^{\alpha} C_{Ext}$. The model was validated with data obtained from rosemary (Rosmarinus officinalis), peppermint (Mentha piperita), lemon balm (Melissa officinalis) and marjoram (Origanum majorana) in virgin olive oil and sunflower oil at temperatures of 100, 110, 120, 130, 140 and 150 ºC. To confirm the results, supplementary experiments were done with peppermint in lard at 120 and 130 ºC.

1 Introduction

One of the great challenges in food and cosmetic industries is to find new ways to control the degradation in food and in biological systems. Since the lipids are one of the major bulk constituents in food, the antioxidants susceptible of delaying the oxidation process have attracted a lot of attention as food additives. Lipid oxidation causes the development of off-flavor compounds, reduces the shelf life and nutritive value of food products and can be related with some health problems like arteriosclerosis, cancer, coronary diseases and the aging process (1).

The compounds widely used to delay the lipid oxidation in foods are synthetic (phenolic type) like butylated hydroxyanisole, butylated hydroxytoluene, tert – butylhydroquinone and propyl gallate commonly named BHA, BHT, TBHQ and PG, respectively. The effectiveness of those compounds depends on several factors which include the concentration used, the chemical nature of the food and the storage or processing conditions. However, the information about the possible carcinogenic effect of the synthetic antioxidants restricts their use (2) and instigates the research in the development and utilisation of antioxidants from natural sources, such as plants.

* Corresponding author. Tel + 351-218417312. E-mail: mercedes.esquivel@ist.utl.pt

Antioxidant activity, of herbs and spices extracts, have created widespread interest. Several authors have reported data about the utilisation of natural substances to stabilise edible oils against oxidation. These natural substances include rosemary (3), oregano, thyme, marjoram, dittany (4,5) and clove (6).

Methods for the determination of the oxidative stability of oils and fats have been reviewed by Rajalakshmi and Narasimhan (7). Rancimat method used in the present work allows the stability evaluation at high temperatures (up to 220 ºC with 679 Metrohm Rancimat) which is important in the use of the antioxidants in food products as French fries, potato chips, margarine uses, etc. However, there have been no reports about general predictive correlations for the antioxidant activity of natural products in oils.

This study reports the antioxidant effect of natural extracts in vegetable oils during accelerated oxidation in order to establish an empirical equation between protection factor and extract concentration.

2 Materials and Methods

Raw material

Two commercial oils, extra virgin olive oil – Azeite de Moura (ATOM, nº190369) and refined sunflower oil – 3a's Girassol – SOVENA (lote nº 093AG2) were purchased from local market. Lard without additives was supplied by local shop.

Rosmarinus officinalis was collected in the central region of Portugal, Lisbon, Mentha piperita and Origanum majorana were collected in the north of Portugal– Mirandela, and Melissa officinalis was obtained from Dietoforma (Lisboa). The air-dried materials were grounded using an Armfield mill to give the particle size of $3X10^{-3}$ m.

Organic solvents and all the other chemicals used of the highest available purity were purchased from Merck.

Apparatus

Antioxidant activity evaluation was conducted in a model 679 Rancimat apparatus Metrohm, Switzerland (8). For the preparation of the samples (vegetable oil or lard with the extract dissolved), the calculated quantities of each extract were first solubilized in a few drops of methanol, then added to the vegetable oil. The mixture was homogenised in an ultrasound bath for 5 minutes and finally the methanol traces were evaporated using nitrogen gas. The air flow was set to 20 L/h. Induction time was determined automatically by the inflection point of the conductivity vs. time curve.

The temperature calibration was done monthly. The reproducibility of the results was calculated from three to five repetitions using the same kind of sample at the same temperature.

Extraction

Ground vegetable material (100 g) was extracted with boiling distilled water (2 L), at normal pressure for 90 minutes with stirring. The aqueous extract was filtered (filter paper Whatman 4) and the pH was rendered to a value of 2.0 (pH Meter E603, Metrohm, Switzerland) by the addition of 25% hydrochloric acid.

The precipitated by-products were separated by filtration (filter paper Whatman 1) and the resulting solution was extracted four times with diisopropyl ether (Vibromatic, Selecta, Spain), using 30 mL of ether for 100 mL of solution each time.

The combined organic phases were dried over anhydrous magnesium sulfate, filtered (filter paper Whatman 1) and evaporated to dryness using a vacuum rotary evaporator VV2000. The extracts were kept under inert atmosphere in the dark until subsequent analyses. The

yield of dried water extracts from the rosemary, peppermint, marjoram and lemon balm were 0.5%, 0.4%, 0.6% and 0.8% respectively.

3 Results and Discussion

In the first part of the work a factorial design was applied on two levels to determine the main effects and the interaction of the following items:

A: Type of vegetable oil.

B: Oxidation temperature.

C: Extract concentration in vegetable oil.

D: Vegetable material used wyle obtaining the extract.

Because it was impossible to do the complete randomization of all the trials of a factorial design of 2^4 we chose to do two blocks of 2^3 each. This impossibility is due both to dry plants validity limits (if results are to be reproducible, plants should be harvested at the same time of the year and in the same place) and also due to the antioxidant extracts which only keeps its properties during approximately one week.

In the first block only peppermint extract was used in two different matrices (sunflower and virgin olive oil). In the second block the antioxidant extract was introduced as a new variable but keeping the same matrix (sunflower oil). Two variable answers were considered: the induction time *TI* (h) and the protection factor *PF* calculated by the ratio of the induction time of the sample (mixture of oil and antioxidant extract) to the induction time of oil without additives (TI_0). The variables and levels are summarized in table 1.

Table 1: Variables and levels of factorial designs

Variables	Level	
Block 1: Peppermint extract	-	+
A: Vegetable Oil	Sunflower	Virgin Olive Oil
B: Temperature, ºC	110	130
C: Extract Concentration, ppm	250	2500
Block 2: sunflower oil		
A: Extract	peppermint	rosemary
B: Temperature, ºC	110	130
C: Extract Concentration, ppm	250	2500

The results obtained in the trials are shown in Figures 1a) and 1b).

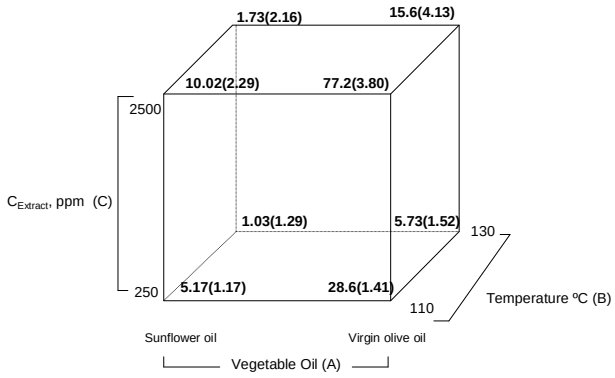

Figure 1a) first block of 2^3 factorial design. Protection factors in parenthesis.

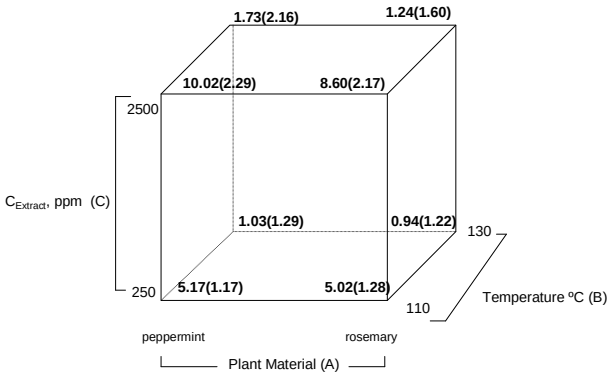

Figure 1b) second block of 2^3 factorial design. Protection factors in parenthesis.

The factor effects were calculated by measuring the difference between the average of the trials, were the factor is in the + level, and the average of the trials, were the factor is in the level – (eq.1).

$$Effect_{Factor} = \bar{y}_{Factor^+} - \bar{y}_{Factor^-} \qquad \text{eq. 1}$$

The error of each effect was estimated by the equation:

$$Error_{Efeito} = \sqrt{\frac{4}{8} s_n^2} \qquad \text{eq. 2}$$

being s_n^2 the variance obtained from four trials done in intermediate conditions (central points). In table 2 the factor effect and its respective confidence intervals are shown. The most significant effect shown is the matrix type used followed by the concentration effect. It seams that the plant used in the extracts doesn't have a noticeable relevance.

Table 2: Factor effects

		TI	*PF*
Block 1: Peppermint extract	Effect A (Vegetable Oil)	27.30±0.07	0.99±0.08
	Effect B: (Temperature, ºC)	-24.23±0.07	0.10±0.08
	Effect C: ($C_{Extract,\ ppm}$)	16.00±0.07	1.75±0.08
Block 2: sunflower oil	Effect A: (Extract)	0.54±0.07	-0.16±0.08
	Effect B: (Temperature, ºC)	-5.96±0.07	-0.16±0.08
	Effect C: ($C_{Extract,\ ppm}$)	2.35±0.07	0.82±0.08

A simple equation was derived trying to relate the induction time with extract concentration:

$$T_I / T_{I_0} = 1 + kC_{Ext}{}^{\alpha} \qquad \text{eq. 3}$$

being the linear form:

$$\ln(T_I / T_{I_0} - 1) = \ln k + \alpha \ln C_{Ext} \qquad \text{eq. 4}$$

where T_I and T_{I_0} are the induction time of the mixture and of the control sample respectively (h), C_{Ext} is the concentration of the extract in the mixture (ppm), and k and α are constants that should depend on the matrix type. The figures 2 and 3 show a graphic representation of the results.

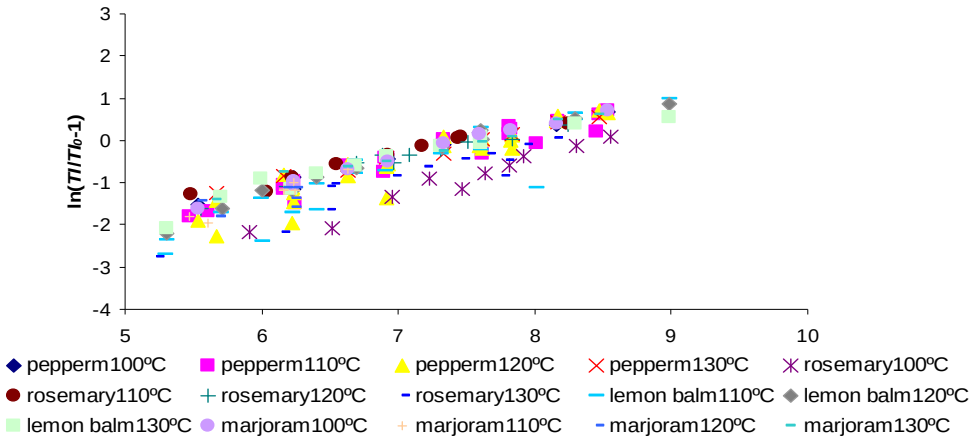

Figure 2: Experimental results from different extracts in sunflower

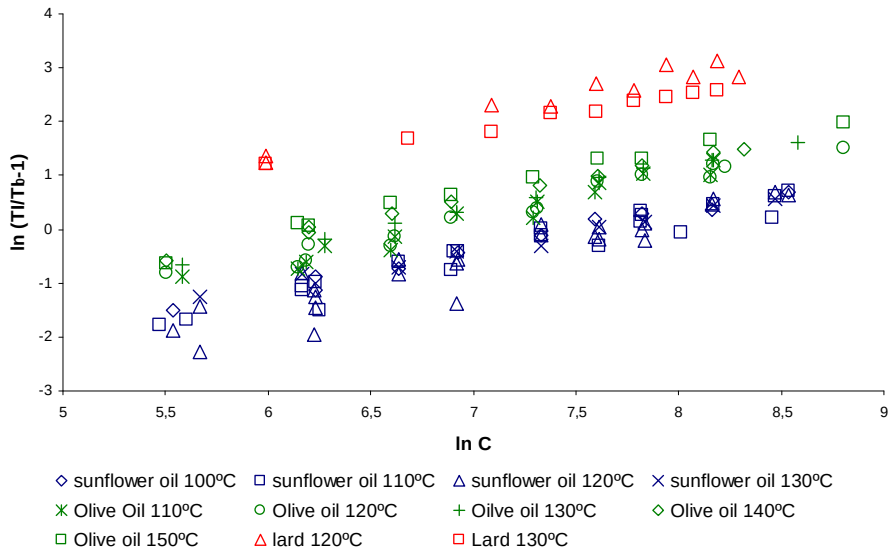

Figure 3: Experimental results from peppermint extracts on sunflower oil, olive oil and on lard

The equations obtained were:

Table 3: Model parameters

System	Equation 4b	Observations	F
Vegetal extract on sunflower oil	$\ln(T_I / T_{I_0} - 1) = (-6.3 \pm 0.3) + (0.82 \pm 0.05) \ln C_{Ext}$	208	1165.6
Peppermint on sunflower oil	$\ln(T_I / T_{I_0} - 1) = (-6.2 \pm 0.6) + (0.80 \pm 0.04) \ln C_{Ext}$	55	417.9
Peppermint on olive oil	$\ln(T_I / T_{I_0} - 1) = (-5.2 \pm 0.5) + (0.79 \pm 0.07) \ln C_{Ext}$	58	490.0
Peppermint on lard	$\ln(T_I / T_{I_0} - 1) = (-3.01 \pm 0.05) + (0.7 \pm 0.1) \ln C_{Ext}$	19	126.7

Conclusions

The proposed equation adjusts itself to the experimental points obtained in the different conditions. As previewed by the factorial design, the ratio TI/T0 (protection factor) only depends on the type of oil and the extract concentration used and not of the temperature.

By the analysis of the parameters used, it can be said that the parameter α is constant and equal to 0.8 while the parameter K depends on the type of matrix used. The equation does not depend of the type of plant extracts, which could be explained because the extraction process is selective towards a type of antioxidants – phenols, being the extract components expected to be similar.

The range of temperatures selected in this work is limited and took into consideration that, for lower then 100 ºC temperatures the induction times are extremely high and for values greater then 140 ºC the degradation of the chemical components takes place.

Keywords: Water activity, Gravimetric method, Equilibrium moisture content, Isosteric heat.
Topic: Food Engineering.

Abstract

Sorption isotherms of loquat (pulp and seeds) and quince fruits were determined by a static gravimetric method at different temperatures (20 to 65ºC). Curves obtained can be considered as type II at 20ºC and type III at higher temperatures according to the Brunauer–Emmett–Teller (BET) classification. Equilibrium moisture content data were correlated by different mathematical models applied to foodstuffs (GAB, Oswin, Henderson, Peleg and Halsey). Most of these models showed high coefficients of determination (R^2>0.943), acceptable standard error (E<18 %) and low root mean square error (E_{RMS}<0.147). These results indicate that all models can be considered as acceptable for predicting the equilibrium moisture content of these fruits. Peleg and GAB models (four and three parameters, respectively) were found to have the highest coefficient of determination.

1 Introduction

Loquat is an edible fruit (*Eriobotrya japonica Lindl.*) belonging to the Rosaceae family, originated in China and is widely cultivated in the subtropical regions of Southern China, Japan, Mediterranean area, United States, Brazil and Australia (Badenes *et. al*, 2000). Loquats have a thin but tough skin. Each fruit contains 3 to 5 dark-brown seeds (1-2 cm long). The harvest is short (around two months) and is susceptible to decay, with moisture and nutritional losses during postharvest life. Loquat composition reported (wet basis) refers water 78.0%, carbohydrates 10.6%, fibre 10.2%, fat 0.5%, protein 0.40% and other components (Mataix *et al.*, 1998). It is high in vitamin A and potassium, but low in vitamin C and sodium. Loquat has been used as a pharmaceutical plant, particularly; is used in a traditional herbal medicine for skin diseases, inflammation and expectoration (Koba *et al.*, 2007). Loquat fruit can be eaten fresh or lightly cooked for use in gelatine desserts and jams and is also employed by its high pectin content to make jelly.

The world production of loquat in 2006 is estimated at 550,000 t, being the main commercial producer China (453,600 t). Spain (43,300 t) is the leader in loquat production in the Mediterranean area. Other producers are Turkey (12,000 t) and Japan (10,200 t) (Lin, 2007).

The quince (*Cydonia Oblonga Mill*) belongs to the pome fruit family. Quince is one of the earliest known fruits. For over 4,000 years, quince trees have grown in Asia and the Mediterranean countries. Today, quince is also found in South America and United States. In the raw form, the rind is rough and woolly, and the flesh is hard and unpalatable and acidulous taste. It is rarely used in its raw form, the hard and dry flesh of the quince becomes softer and sweeter and its colour turns from light pink to purple when it is cooked. The main constituents of quince are water 84% and carbohydrates 15% (wet basis). Other small constituents include proteins 0.4% and fats 0.6%. It is also considered a good source of fibre, potassium and vitamin C. High dietary fibre content 12% (dry basis), makes dried quinces an excellent ingredient for cereals, cakes and desserts.

* Corresponding author. Tel + 34-981-563100 ext. (16759). E-mail:eqmoncho@usc.es

The world production of quince in 2006 is estimated at 490,000 t, being the main commercial producers, Turkey (106,000 t), China (85,000 t), Uzbekistan (49,000 t), Iran (39,300 t), Marocco (28,000 t), Argentina (25,700 t) and Spain (20,000 t) (FAO, 2007).

The expense of hand harvesting, together with the fact that the fruit does not travel or keep well, limit its commercial expansion, so the study of these edible fruits has become of recent interest. Data on moisture content and water activity is important to predict the physical, chemical and biological changes occurring during storage and processing of food materials. The water sorption isotherm represents the equilibrium relationship between moisture content of food sample and water activity at constant temperature and pressure. Food systems typically exhibit Type II and III according to the BET classification (Brunauer *et al.*, 1940). As theoretical prediction is not possible, experimental studies are necessary. Knowledge of the sorption isotherm of food materials is very important for prediction of quality and optimisation of the drying, storage and other processes. Moisture sorption isotherm models, therefore, constitute an essential component of the overall drying theory. In the literature there is a long list of available isotherms models, which can be classified into several categories: kinetic models based on an absorbed mono-layer of water, e.g. BET model, kinetic models based on a multi-layer and condensed film, e.g. Guggenheim-Anderson-de Boer (GAB) model (Van den Berg and Bruin, 1981), semi-empirical models, e.g. Halsey and Peleg models (Halsey, 1948; Peleg, 1993), and purely empirical models, e.g. Oswin and Henderson models (Oswin, 1946; Henderson, 1952). GAB equation is recognised as the most widely utilised and versatile. This work was developed due to absence of experimental data on sorption isotherms of loquat and quince fruits.

2 Materials and methods

2.1. Preparation of samples

Loquat and quince were purchased from a local market; pieces were selected according to its size and ripeness. The fruits were peeled and cut into thin slabs of about 3 mm. Loquat seeds were separated and their peel was also removed, seeds were cut into thin slabs.

2.2. Determination of sorption isotherms

The equilibrium moisture contents of loquat and quince were determined by static gravimetric technique, which is based on the use of saturated salt solutions to maintain constant water activity at determined values of the samples when equilibrium is reached between atmosphere and sample food. The salt solutions used to obtain constant relative humidity of surrounding air were KOH, LiCl, $MgCl_2$, K_2CO_3, $Mg(NO_3)_2$, NH_4NO_3, NaCl, KCl and $BaCl_2$ which were prepared according to recommendations (Greenspan *et al.*, 1977); this group of salts allows to obtain a wide range of relative hymidity of air (7 to 91 %RH) in equilibrium. The determination of sorption isotherms for loquat pulp and seeds and quince pulp was carried out in the same range of temperatures from 20 to 65ºC. The temperatures studied for loquat samples were 20, 35, 50 and 65ºC while for the quince fruits were 20, 45, and 65ºC.

In order to inhibit microbial growth a small quantity of thymol was also placed in the flasks in which water activity was greater than 0.5. Triplicate samples of 2 g were placed on Petri dishes inside the jars. Samples were weighted at regular intervals until constant weight (±0.0005 g) in an analytical balance (Mettler AJ150). The equilibrium period was about 8 weeks. The moisture content was determined using a vacuum oven (Heraeus Vacutherm VT 6025) at 70ºC and 13 kPa, achieving constant weight after three days (A.O.A.C., 1995).

2.3. Data analysis

Sorption isotherm represents the equilibrium moisture content (X) variation with water activity (a_w), which is defined as the ratio between vapor pressure of water in the food surface and vapor pressure of pure water at the same temperature. Sorption isotherm models used to fit experimental data are showed in Table 1 (Eq. (1- 5)).

Table 1. Sorption isotherm models applied to the fitting of experimental data

Model	Mathematical equation	
GAB	$X = \frac{X_M C K a_w}{(1 - K a_w)(1 - K a_w + C K a_w)}$	(1)
Oswin	$X = A\left[\frac{a_w}{(1 - a_w)}\right]^B$	(2)
Henderson	$X = \left[\frac{-\ln(1 - a_w)}{A}\right]^{\frac{1}{B}}$	(3)
Halsey	$X = \left[\frac{-a}{\ln a_w}\right]^{\frac{1}{r}}$	(4)
Peleg	$X = m_1 a_w^{n_1} + m_2 a_w^{n_2}$	(5)

The parameters of the models were estimated by non-linear regression procedure employing Table Curve software (Jandel Scientific), in order to select the best correlation and to improve the analysis of the experimental data. The goodness of the fitting of each sorption model was evaluated based on statistical parameters like coefficient of determination (R^2), mean relative percentage deviation modulus (E) and root mean square error (E_{RMS}).

$$E = \frac{100}{N} \sum_{i=1}^{N} \frac{|X_{exp} - X_{cal}|}{X_{exp}} \quad (6)$$

$$E_{RMS} = \left[\frac{1}{N} \sum_{i=1}^{N} (X_{exp} - X_{cal})^2\right]^{1/2} \quad (7)$$

where N is the number of samples, X_{exp} and X_{cal} are experimental and model calculated moisture content, respectively.

In the GAB model there are three parameters (C, K, and X_M), which are functions of temperature. These parameters can be associated to some physical meanings, X_M is the monolayer moisture content, C is a constant related to heat of sorption of the first layer and K is related to the heat of sorption of the multilayer. The influence of temperature on GAB parameters can be calculated by Arrhenius equations:

$$X_M = X_{MO} \exp(\Delta H / RT) \quad (8)$$

$$C = C_O \exp[(H_M - H_N)/RT] \quad (9)$$

$$K = K_O \exp[(H_L - H_N)/RT] \quad (10)$$

where R is the ideal gas constant, T is the absolute temperature (K), H_M, the monolayer enthalphy, H_N is the multilayer enthalpy and H_L is the average heat of condensation of water vapor (43.14 kJ/mol in the investigated range of temperature from 20 to 65ºC). The heats ΔH, H_M, and H_N and were determined by fitting of the equations (8), (9) and (10) after fit of the experimental data values to the GAB model to obtain the three-parameters (C, K, and X_M).

3 Results and discussion

Figure 1 show the experimental data of equilibrium sorption isotherm for quince, loquat pulp and loquat seed at different temperatures.

According to BET classification (Brunauer et al., 1940) curves obtained are type II at 20ºC and type III at higher temperatures.

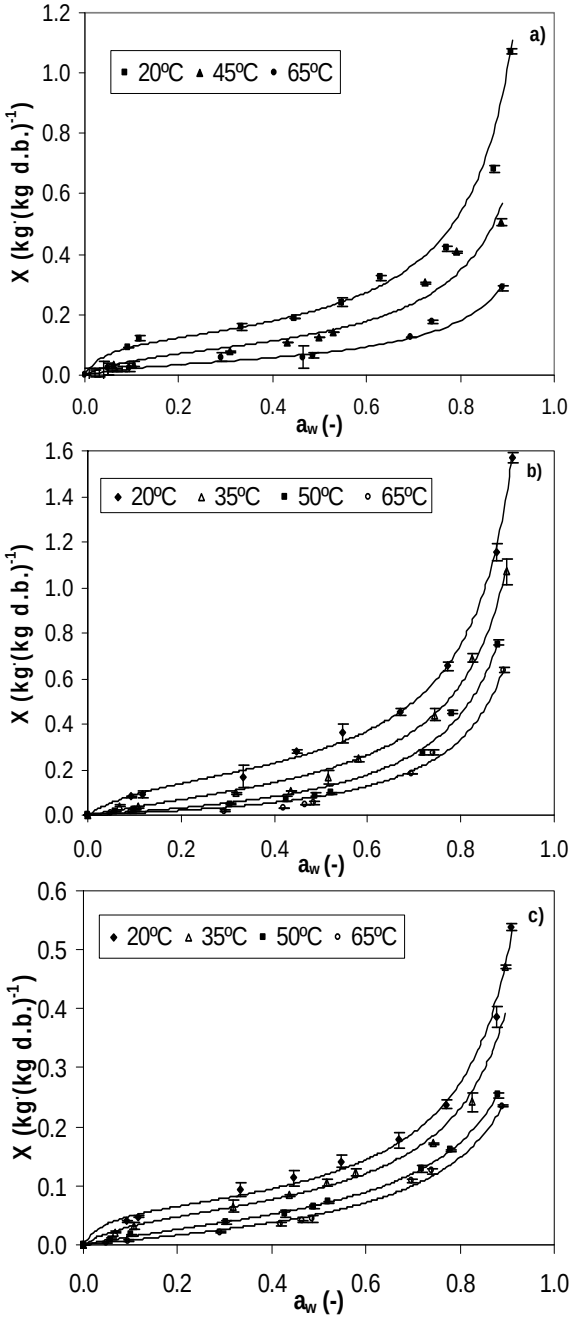

Fig.1. Experimental data of equilibrium moisture content of (a) quince, (b) loquat pulp and (c) loquat seed. Lines correspond to GAB model (Eq. 1).

As expected, the equilibrium moisture content increased with water activity at constant temperature. These changes in are due to the tendency of the food material to lower vapour pressure when decreasing the relative humidity of air. A more detailed analysis lead to identify two regions in the sorption isotherm, at low water activities, the so-called multilayer sorption region, moisture content increases linearly with water activity, whereas at high water activity, the so-called capillary condensation region, water content rapidly increases with water activity. Falade and Aworh (2004) explain this behaviour based on sugar state.

There is also an increase in moisture content with decreasing temperatures, at constant water activity. This can be explained because at higher temperatures, the activation of the water molecules changes to higher energy levels and the links become less stable and break away from the water-binding sites of food material, consequently the equilibrium moisture content decreases (Palipane and Driscoll, 1992). The increase of temperature has also an important effect on chemical and microbiological reactions relative to the spoilage. The temperature influences the physicochemical properties of fruits, which in turn reduces the number of active sites for water binding.

An interesting phenomenon was observed when Figs.1a and 1b are analysed. Sorption isotherms of quince are lower than those of loquat fruit in the range of temperatures. This means that quince presents lower strength in holding water in comparison with loquat. This behaviour is observed when comparing experimental data of pulp fruits with seeds too, Figs.1b and 1c. In this case, the sorption isotherm of seeds is the lowest by its composition, as expected.

Most of these models showed high coefficients of determination (R^2 0.943), acceptable standard error (E<18 %) and low root mean square error (E_{RMS}<0.147). These results indicate that all models can be considered as acceptable for predicting the equilibrium moisture content of these fruits. However, Peleg (Eq. 5) and GAB (Eq. 1) models (four and three parameters, respectively) were found to have the lowest standard error and the highest coefficient of determination (R^2). It is expected that models with more parameters give best results; comparing only two-parameter models, Oswin model (Eq. 2) gives the best adjustment; Henderson (Eq. 3) was the model that worst fitting of the experimental results. Coefficients of the five sorption models tested at different temperatures are shown in Table 2.

The sorption equilibrium isotherms of quince and loquat (pulp and seeds) using the GAB model, are plotted in Fig.1. It can be observed a good quality of fitting. A correlation of the GAB model parameters with temperature was established. The monolayer moisture content (X_M) is the minimum moisture content covering hydrophilic sites on the material surface at a given temperature, the safest water activity level is that corresponding to X_M or lower. Estimated values for X_M are within the reported values for fruits, which vary between 4% and 15% (dry basis) (Moraga et. al., 2006). Rizvi (1986) noted that X_M decreases with temperature increases, which has been ascribed to a reduction in the number of active sites induced by temperature. The values of C and K parameters are also within the reported limits for fruits. A more detailed analysis of the GAB parameters can provide further valuable information. Value of (H_M-H_N) represents the difference in enthalpy between monolayer and multilayer sorption and (H_L-H_N) represents the difference between the heat of condensation of water and heat of sorption of the multilayer (Van den Berg and Bruin, 1981). Values of C_O, K_O, X_{MO}, (H_M-H_N), (H_L-H_N) and ΔH evaluated with Eqs. (8), (9) and (10) are showed in Table 3. They agree with literature data for other fruits (Goula et al. 2008).

Table 3. Values of the parameters of the Eqs. (8), (9) and (10).

	C_0	K_0	X_{M0}	ΔH	(H_M-H_N)	(H_L-H_N)
			kg water/kg d.b.	kJ/mol	kJ/mol	kJ/mol
Ouince	$2.14.10^{-3}$	0.815	$1.00.10^{-4}$	17.31	110	0.461
Loquat pulp	$8.15.10^{-8}$	0.912	$4.34.10^{-2}$	8.84	44.6	0.189
Loquat seed	$1.08.10^{-7}$	0.675	$5.28.10^{-3}$	5.99	46.7	0.892

The values of (H_M-H_N) and (H_L-H_N) indicate how strong water molecules are bound in the respective layers. The estimated (H_M-H_N) values have positive values as expected, due to the strong exothermic interaction of water vapour with primary sorption sites of the material. The (H_L-H_N) values are in agreement with the literature (Samaniego-Esguerra et. al, 1991).

4 Conclusions

The results obtained for both fruits are analogous, but different. This was expected since each food is a complex combination of various constituents, which not only can sorb water independently but can also interact among themselves. Sorption isotherms of quince and loquat can be described as belonging to type II at 20ºC and type III at higher temperatures according to BET classification. An increase in temperature caused a decrease in the amount of adsorbed water for a water activity. After testing five equations describing moisture sorption isotherm in the temperature range investigated (20-65ºC), the kinetic three-parameters GAB model and the empirical four-parameters Peleg equation were found the best correlations for the quince and loquat data in the range of water activity studied (0-0.9).

Keywords: Dehydration, Water sorption, Rehydration indexes, Peleg's model
Topic: Food engineering.

Abstract

Rectangular prisms of chestnuts (10 x 10 x 15 mm) previously dried at 65 ºC without and with sucrose treatment (60 % (p/p) at 25 ºC during 8 hours) until different moisture content (0.33 and 0.15 kg water/kg d.b.) were rehydrated by inmersion in water at 25 ºC during different periods of time (10, 30, 60, 120 and 180 min). Rehydration kinetics were obtained by measuring their weigths at several intervals of time. At the same time, the swelling was experimentally determined.

Peleg's model was succesfully applied to describe the water uptake in all experiments. The parameters K_1 and K_2 were obtanined and it was observed that both Peleg's constants decrease when osmotic treatment was carried out. Rehydration indexes, such as dry basis holding capacity (DHC), water absorption capacity (WAC) and rehydration ability (RA) were determinated. The results indicated that rehydration capacity of sample with sucrose treatment was greater than chestnuts dried at same moisture content without osmotic treatment. The chestnuts volume recovery can be considered as ideal swelling.

1. Introduction

Chestnut (*Castanea sativa* Mill.) is a traditional seasonal fruit (autumn) from Mediterranean countries. It presents high water content (50 % wet basis, approximately) and also is an important carbohydrate source (46 % dry basis; mainly starch and several sugars like sucrose and, glucose and fructose in less proportion) and (Scharz, 1990; De la Montaña et al., 2004). The main chestnut countries producers (10^3 t/year) in the European Community are Italy (50), Portugal (31), Greece (19), France (12) and Spain (10), (FAOSTAT, 2007). Owing to chestnut high moisture content and it seasonal characteristics, drying can be considered as a useful method to improve product availability. Air drying is the method frequently used in the drying of food materials. Some process variables during drying as temperature, velocity of air, relative humidity could have a highly negative effect on the quality of the product. Furthermore, most of dehydrated products need to be rehydrated before consumption or further processing. So many reconstitution properties can be obtained through control of the dehydration and rehydration processes conditions (Marabi et al., 2006) to achieve a product with characteristics similar to the fresh.

The study of the rehydration kinetics is very important to improve the global food processing. In this way, it is necessary the knowledge on the food product composition, pre-drying treatment, drying techniques and conditions, composition and temperature of rehydration media (Funebo and Ohlsson, 1998; Lewicki, 1998a). The determination of rehydration indexes is useful to quantify the degree of cellular and structural disruption caused during processes previous to rehydration so as to establish the market acceptability (Lewicki, 1998b). The water absorption capacity (WAC) index

* Corresponding author. Tel + 34-981-563-100. E-mail:eqmoncho@usc.es

provides information on the ability of the material to absorb water and increases with water absorption. WAC value can be calculated according to equation:

$$WAC = \frac{M_r X_r - M_d X_d}{M_0 X_0 - M_d X_d} \quad (1)$$

where M is the dry mass (kg d.b.), X is the moisture content (kg water/kg d.b.), and subscripts d, o and r refer to after drying (or before rehydration), before drying and after rehydration, respectively.

The dry matter holding capacity (DHC) index is a measure of the ability of the material to hold soluble compounds and represents the extent of tissue damage and its permeability to soluble compounds. The DHC was calculated according to equation:

$$DHC = \frac{M_r s_r}{M_d s_d} \quad (2)$$

where s is the solid content and subscript r and d are refer to after and before rehydration.

Finally, rehydration ability (RA) index is a measure of ability of the product to rehydrate and shows the damage of the tissue by drying and rehydration processes. The RA was calculated according to equation:

$$RA = (WAC)\,(DHC) \quad (3)$$

The rehydration kinetics of dehydrated chestnut was obtained and the resulting data were fitted to the Peleg's model (Peleg, 1988) defined by:

$$X = X_0 + \frac{t}{K_1 + K_2 t} \quad (4)$$

where K_1 (s·kg d.b./kg water) is a kinetic parameter and K_2 (kg d.b./kg water) is other parameter related to equilibrium moisture content, X_e. When $t \rightarrow \infty$, equilibrium moisture content can be calculed by:

$$X_e = X_0 + \frac{1}{K_2} \quad (5)$$

Equation (4) can be linearized:

$$\frac{t}{X - X_0} = K_1 + K_2 t \quad (6)$$

allowing for the determination of K_1 and K_2 values by linear regression of experimental data.

The effect of the previous dehydration steps (osmotic treatment and convective air drying) on rehydration kinetics of chestnuts was evaluated.

2. Materials and Methods

Raw Material. Chestnut samples (*Castanea sativa* Mill), variety Famosa, with similar initial moisture content (0.55 ± 0.02 kg water/kg wet product) were carefully prepared with rectangular prismatic geometry (10x10x15 mm) from the parenchymatic tissue with a cuter mechanized in longitudinal direction to the basis of the chestnut. The moisture content was determined using a vaccum oven (< 15 kPa) and 70 ºC (Heraeus

Vacutherm VT650) up to constant weight of samples, following standard procedure (AOAC, 1995).

Dehydration Experiments and Conditions. Prisms were previously dehydrated by osmosis in aqueous sucrose solutions (60 % w/w) at 25 ºC during 8 h (optimal conditions (Chenlo *et al*., 2007)). The relation of weights solution sample was around 10 in order to maintain constant sucrose concentration of solution during the osmotic process. After, convective air-drying was carried out in a chamber at pilot-plant scale, with a hot air closed circuit and assisted by a heat pump (Vázquez *et al*., 1997), at 65 ºC, 30 % of relative humidity and speed of air at 2.4 m/s, (Moreira *et al*., 2005). Different drying times (0.5, 1.5, 3 and 6 hours) were assayed (obtaining samples with different moisture content).

Rehydration Experiments and Conditions. After drying, samples of chestnuts were immersed into distilled water at 25 ºC during different periods of time (10, 30, 60, 120, and 180 min). Rehydrated samples were carefully blotted with absorbent paper in order to remove external water and after they weighted and introduced into the vaccum oven to obtain the dry solid.

Determination of swelling. Four samples, for each experimental condition tested, were used at the specified rehydration times to evaluate swelling of samples during rehydration and after determination of dry solids contents. Swelling was determined by displacement technique and samples were weighed at 20 ºC in air and in n-heptane liquid (ρ_{hep} = 710 kg/m^3), consecutively. On the basis of Archimedes' principle, volume of sample, V, was calculed by:

$$V = \frac{m - m_{hep}}{\rho_{hep}} \quad (7)$$

where m (kg) is the weight of chestnut in air and m_{hep} (kg) is the weight of the same sample immersed in n-heptane.

3. Results

Figure 1a,b shows, as examples, rehydration kinetics of chestnuts, with or without osmotic pre-treatment with sucrose, partially air-dried at 65 ºC up to 0.33 and 0.15 kg of water/kg d.b. Rehydration kinetics showed initially high water absorption rates that decrease as samples achieve to equilibrium. Initial moisture content is also a significant variable in rehydration kinetics. Samples previously dried for longer periods (lower initial moisture contents) showed less rehydration capacity, indicating the presence of modified structures (Moreira et al., 2008). In this manner, the amount of water imbibed during rehydration depends on the extension of the drying step. After long drying periods (chestnut dried until 0.15 kg water/kg d.b.) samples showed a diminution of rehydration rate regard as samples dried for shorter periods (chestnut dried until 0.33 kg water kg d.b.). Similar behaviour in rehydration of chestnuts (without pre-treatment) at several temperatures and initial moisture contents (after dried) has been found by Moreira et al., 2008. It could be explained due the occurrence of shrunken and closed structures that avoid the passage of water. The osmotic pre-treatment increased the rate and the amount of water gained during rehydration process regarding to chestnuts without pre-treatment. Basically, the explanation of these results is based on the fact of the dry solid of samples increases during osmotic treatment due to the osmotic solute acquisition that contributes to retain greater water amount.

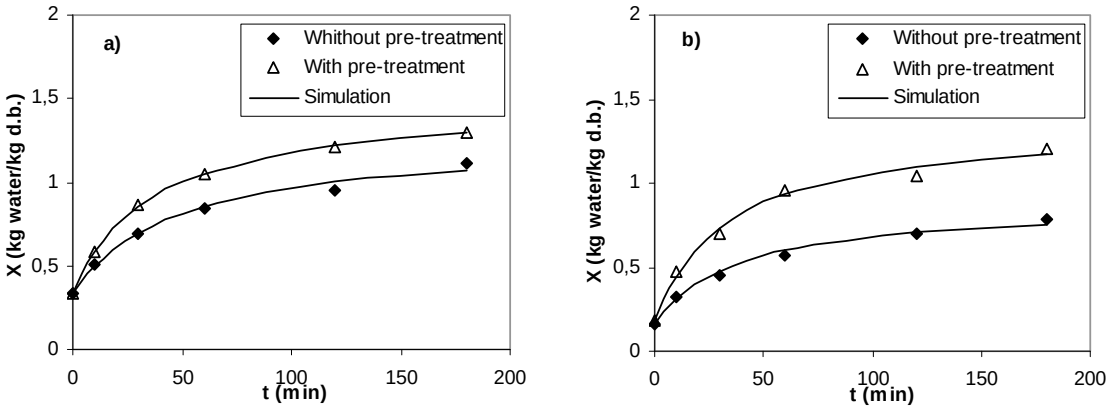

Figure 1. Rehydration kinetics at 25 ºC of chestnuts, with and without sucrose pre-treatment, and dried at 65 ºC up to a) 0.33 and b) 0.15 kg water/kg d.b.

Table 1 shows values of K_1 and K_2 parameters and equilibrium moisture content obtained from equations (5) and (6) at 25 ºC and to the initial moisture content tested at 0.33 and 0.15 kg water/kg d.b., respectively. All values of coefficients of determination (R^2) were equal or higher than 0.98 indicating that Peleg's model was satisfactorily applied (lines in Figure 1a,b) to describe rehydration kinetics of chestnuts at the experimental conditions tested. Values of K_1 and K_2 decrease with osmotic treatment at each initial moisture content. This behaviour indicates that water transfer and water absorption capacity (related to the inverse of K_1 and with K_2, respectively) are promoted by osmotic treatment. The water capacity absorption depends on the type of material, structure of tissue, and chemical composition and can be modified by application of treatments. This behaviour is in accordance with other authors who considered that parameter K_2 can change if structure or other properties are modified during rehidration (García-Pascual et al., 2005; Lopez et al., 1995). Otherwise, values of equilibrium moisture increase when the osmotic treatment was carried out.

Table 1 Parameters and coefficients of determination of equation (6) and values equilibrium moisture content, equation (5), for rehydration at 25 ºC of chestnuts dried with and without sucrose treatment until 0.33 and 0.15 kg water/kg d.b.

Treatment	K_1 s.(kg water/kg d.b.)$^{-1}$	K_2 (kg water/kg d.b.)$^{-1}$	R^2	X_e (kg water/kg d.b.)
X_0 (kg water/kg d.b.) = 0.33 ± 0.05				
Without	2990.9	1.07	0.98	1.26
With	1861.0	0.86	0.99	1.49
X_0 (kg water/kg d.b.) = 0.15 ± 0.03				
Without	3264.3	1.39	0.99	0.88
With	1747.4	0.85	0.99	1.36

Table 2 shows values of DHC, WAC and RA rehydration indexes, as function of the applied osmotic treatment, rehydration times and initial moisture content (chestnuts pre-dried until 0.33 and 0.15 kg water/kg d.b.). These results confirm that the rehydration ability is reduced due to the drying modifies the structure of the chestnut. This behaviour is more emphasize in samples pre-dried at low moisture contents. According to expectations, DHC index decreases and WAC and RA indexes increase with rehydration time for samples with and without pretreatment. Chestnuts previously dried with osmotic treatment show WAC and RA indexes higher than chestnut dried without pre-treatment. This result indicates a largest rehydration capacity without additional loss of soluble compounds acquired during osmotic treatment.

Table 2 Values of DHC, WAC and RA indexes at different times of rehydration (and moisture content) for chestnuts dried at 65 ºC without and with sucrose (60%, 25 ºC, 8 h) treatment at 0.33 and 0.15 kg water/kg d.b.

Figure 2 shows the variations of the volume of samples with and without osmotic pretreatment at different initial moisture content obtained experimentally with n-heptane by displacement techinique (calculed by Equation (7)) versus the volume of samples imbibed water, which is calculed from the mass of water obtained from rehydration kinetics. Experimental data are appromixately on the diagonal (random differences). In this way, the volume recovery can be considered ideal swelling. These results are different regarding to volumetric shrinkage of chestnut during drying. In that case, it was observed the presence of collapsed structure due to volumetric shrinkage was higher than equivalent volume occupied by water that was removed (Moreira et al., 2005). Ideal volumetric swelling can mean that water firstly fills the open void spaces of chestnut and after tissue structure. So, the chestnut is partially rehydrated in the more external areas.

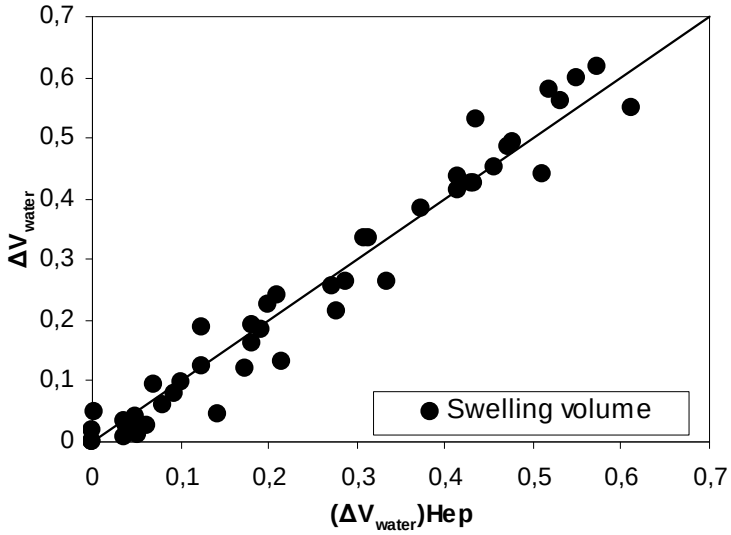

Figure 2 Volumetric swelling during rehydration of chestnuts samples

4. Conclusions

Rehydration kinetics show high initial water absorption rates that decreases during rehydration time. Samples previously dried during longer period showed a minor rehydration, indicating the existence of modified structure. Osmotic treatment increases water absortion rates and the amounts of absorbed water. Peleg's model was successfully applied to the experimental data of rehydration of chestnuts. Equilibrium moisture content increases and K_1 and K_2 decrease when osmotic treatment was carried out. With regard to rehydration indexes, DHC index decreases and WAC and RA indexes increase with time. The osmotic treatment increases the values of WAC and RA indexes regard as samples was rehydrated without pre-treatment. Analisys of indexex rehydration confirms that drying modifies the structure of chestnuts, reducing the rehydration ability. By other hand, the pre-treatment increase the rehydration capacity without additional loss of soluble compounds that was acquired during osmotic treatment. No effect of pre-treatment and initial moisture content was observed on the swelling and the volume recovery can be considered as ideal swelling.

Topic: Multi-scale and/or multi-disciplinary approach to process-product innovation

Abstract

Tomato pomace and pectin were used as the sole carbon sources for production of polygalacturonase from a strain of *Coriolus versicolor* in submerged culture. The culture of *C. versicolor* grown on tomato pomace exhibited a peak of polygalacturonase activity (1427 U/L) on the 3rd day of culture with a specific activity of 14.5U/mg protein. The production of polygalacturonase by *C. versicolor* grown on pectin as sole carbon source, increased with the time of cultivation, reaching a maximum activity of 3207 U/L of fermentation broth with a specific activity of 248 U/mg protein. Differential chromatographic behaviour of lignocellulosic enzymes produced by *C. versicolor* (i.e polygalacturonase, xylanase and laccase) was studied on immobilized metal chelates. The effect of ligand concentration, pH, the length of spacer arm and the nature of metal ion were studied for enzyme adsorption on immobilized metal affinity chromatography (IMAC). The adsorption of polygalacturonase as well as other enzymes to immobilized metal chelates was due to coordination of histidine residues which are available at the protein surface since the presence of imidazole in the equilibration buffer abolished the adsorption of the enzyme to immobilized metal chelates. A one-step purification of polygalacturonase from C*. versicolor* was devised by using a column of Sepharose 6B-EPI 30-IDA-Cu(II) and purified enzyme exhibited a specific activity of about 150 U/mg protein, final recovery of enzyme activity of 100% and a purification factor of about 10. The use of short spacer arm and the presence of imidazole in equilibration buffer exhibited a higher selectivity for purification of polygalacturonase on this column with a high purification factor. The purified enzyme preparation was analysed by SDS-PAGE as well as by “in situ” detection of enzyme activity.

1 Introduction

A major issue faced by the food processing industries involves the accumulation, handling and disposal of wastes which arise both economical and environmental problems. Tomato (*Lycopersicon esculentum* Mill.) is a widely cultivated vegetable crop in Mediterranean countries. During tomato processing, a huge amount of a by-product is produced known as tomato pomace which consists of tomato peel, seeds as well as some pulp. The chemical composition of tomato pomace consists of proteins, lipids, carbohydrates including pectins, amino acids, carotenoids and minerals (Alvarado, Pacheco-Delahaye, Hevia, 2001; Knoblich, Anderson, Latshaw, 2005; Valle, Cámara, Torija, 2006). Several pectin-rich substrates such as wheat, deseeded sunflower head, apple pomace and citrus peel have been used for the production of microbial pectinases in both submerged and solid-state fermentation. However, to our knowledge tomato pomace has not been used for production of pectinases.

Pectins are a family of polysaccharides with a backbone of 1,4-linked α-D-galacturonic acid residues, partially present as their methyl esters. Pectinases are widely used in biotechnological applications [19], namely in food industry (i.e fruit juice extraction, coffee and tea fermentation, oil extraction, improvement of chromaticity and stability of red wines), textile, paper and pulp industries and in waste water treatment. However, industrial production of pectinases makes use almost exclusively of *Aspergillus niger* strains [31].
Polygalacturonases (EC 3.2.1.15 and EC 3.2.1.67) catalyse the hydrolysis of α-1,4-linkages between α-D- galacturonic acid units in pectin, by endo and exo action. There is only one report in the literature about the production of endo and exo-polygalacturonases from a white rot fungi, *Coriolus trogii* (Levin, Forchiassin, 1998). Polygalacturonases are of industrial interest since they are used in specific applications, such as in baby and functional foods (Jayani, Saxena, Gupta, 2005; Gummadi, Panda, 2003).
Since this enzyme is secreted extracelularly by white-rot fungi as well as other lignocellulosic enzymes, it is of great interest to devise a simple and cheap separation method for these enzymes so as to be used in different industrial applications.
Immobilized metal affinity chromatography (IMAC) has been used for purification of wild-type and recombinant proteins. The interactions between accessible coordination sites of metal ions and electron-donating groups present on the protein surface are responsible for retention of proteins in IMAC. Several factors affect the adsorption process, such as the nature of metal ion involved in coordination, the matrix, the length of spacer arm, the ligand concentration, the pH and buffer used (Porath, 1992; Gutiérrez, Valle, Galán, 2007).
To our knowledge, IMAC has not been reported in the literature for fractionation and purification of polygalacturonase as well as xylanase and laccase from microbial sources.
The present work is concerned with the production of polygalacturonase from *Coriolus versicolor* by using either tomato pomace or pectin as sole carbon source in culture media. Subsequently, the chromatographic behavior of this enzyme as well as other lignocellulosic enzymes (i.e xylanase and laccase) on immobilized metal chelates will be investigated as a function of ligand concentration, pH, length of spacer arm and nature of metal ion. The selective adsorption of polygalacturonase on immobilized metal chelates will be carried out for purification of this enzyme with high yield and activity.

2 Methods

2.1 Fungal growth conditions
Fungal growth conditions were previously described (Freixo, Karmali, Arteiro, 2008).

2.2 Enzyme assays
Enzymatic assays were performed as described in the literature (Freixo, Karmali, Arteiro, 2008).

2.3 Preparation of chromatographic matrices
Chromatographic matrices were prepared as described in the literature (Freixo, Karmali, Arteiro, 2008).

2.4 Adsorption tests of polygalacturonase, xylanase and laccase on metal chelates
As previously described (Martins, Andrade, Karmali, Serralheiro, 2006), a rapid batch method carried out in ELISA microtiter plates was used to study the adsorption of polygalacturonase, xylanase and laccase on the following Cu(II), Ni(II), Zn(II) and Co(II) metal chelate supports: Sepharose 6B- BDGE-30-IDA- M(II), Sepharose 6B- EPI-30-IDA- M(II) and Sepharose 6B- EPI-10-IDA- M(II).

2.5 Purification of polygalacturonase from *Coriolus versicolor*

Based on the results of the batch mode on ELISA microtiter plates, a set of experimental conditions were selected to purify polygalacturonase from this fungal strain, as described in the literature (Freixo, Karmali, Arteiro, 2008).

3. Results and Discussion

3.1 Production of polygalacturonase and protein content in culture supernatants

The cultivation of *Coriolus versicolor* on tomato pomace and pectin media was followed for 14 days (Fig.1) and the content of soluble reducing sugars, protein and polygalacturonase activity were measured throughout the cultivation process. Polygalacturonase activity in culture medium containing tomato pomace displayed a "two peaks" time-course curve for this strain of basidiomycete, as shown in Fig. 1A. Such feature was observed by other authors which suggested that it was due to catabolic repression of polygalacturonases in the presence of glucose and other sugars which were released to the medium during fermentation of other polysaccharides. The culture of *Coriolus versicolor* exhibited a peak of polygalacturonase activity (1427 U/L of fermentation broth) on the 3rd day of culture with a specific activity of 14.5 U/mg protein (Fig. 1A). The data presented in the literature revealed that C*oriolus trogii* secreted polygalacturonase with a lower activity (1000 U/L of fermentation broth) on the 15th day of culture [22]. On the other hand, several strains of *Aspergillus sp.* have been used for production of polygalacturonase in submerged culture which exhibited the highest levels in the range of 1000 – 6500 U/L of fermentation broth containing either citrus pectin, dried orange peel or sugar beet as carbon sources.

A- Tomato pomace as carbon source and B- Pectin as carbon source (Polygalacturonase activity - ●; Specific activity - ○ and Soluble reducing sugars - □).

3.2 Chromatographic behaviour of polygalacturonase, xylanase and laccase on immobilized metal chelates

The chromatographic behaviour of these lignocellulosic enzymes is summarized in Table 1, for different stationary phases (Sepharose 6B-BDGE 30 – IDA, Sepharose 6B EPI 30–IDA, Sepharose 6B–EPI 10–IDA) as well as for different immobilized metal ions. The results from adsorption assays did not vary with either different ligand concentration or length of spacer arm, suggesting that protein adsorption takes place through the immobilized metal ion at different pH (Table 1). Xylanase exhibited partial adsorption to immobilized Cu(II)-IDA chelates at pH 7.0 and 8.0 whereas it did not adsorb at pH 6.0. Polygalacturonase and laccase revealed full adsorption to immobilized Cu(II)-IDA chelates at pH 6.0, 7.0 and 8.0 (Table 1).

Table 1 – Differential chromatographic behaviour of lignocellulosic enzymes from *Coriolus versicolor* on immobilized metal chelates

	pH	Stationary phase	Cu(II)	Ni(II)	Zn(II)	Co(II)
Xylanase	6	BDGE-30, EPI-30, EPI-10	–	–	–	–
	7	BDGE-30, EPI-30, EPI-10	±	–	–	–
	8	BDGE-30, EPI-30, EPI-10	±	–	–	–
Polygalacturonase	6	BDGE-30, EPI-30, EPI-10	+	–	–	–
	7	BDGE-30, EPI-30, EPI-10	+	–	–	–
	8	BDGE-30, EPI-30, EPI-10	+	–	–	–
Laccase	6	BDGE-30, EPI-30, EPI-10	+	–	–	–
	7	BDGE-30, EPI-30, EPI-10	+	–	–	–
	8	BDGE-30, EPI-30, EPI-10	+	-	-	-

3.3 Purification of polygalacturonase by using imidazole in equilibration buffer

The combination of tailor-made stationary phases for IMAC and a correct choice of the adsorption conditions permitted to design a one-step purification procedure for polygalacturonase from *Coriolus versicolor*. The chromatographic behaviour of polygalacturonase on Sepharose 6B – EPI 30 – IDA- Cu(II) column at pH 6.0 (Fig.2B) resulted in partially purified enzyme according to the electrophoretic analysis (data not shown). However, the presence of 2mM imidazole in the equilibration buffer abolished the adsorption of several protein contaminants to Sepharose 6B – EPI 30 – IDA- Cu(II) column including laccase and xylanase (data not shown). Hence, polygalacturonase was desorbed from the column with a linear gradient of imidazole (Fig. 2C) with a specific activity of about 150 U/mg protein, a final recovery of enzyme activity of about 100% and a purification factor of about 10 (Table 2). The degree of purification of this polygalacturonase activity peak was high and exhibited no contamination (data not shown) with either laccase or xylanase activities (Table 3). However, the final recovery of enzyme activity was only about 50% with a specific activity of about 180 U/mg protein in the presence of 4mM imidazole in the equilibration buffer (Table 3).

The purity of chromatographic fractions from Sepharose 6B – EPI 30 – IDA- Cu(II) was analysed by SDS-PAGE which revealed that the purified fractions exhibited three protein bands and three activity bands of polygalacturonase with Mr of 63.3, 43 and 30 kDa. The presence of two additional activity bands of polygalacturonase may be due to other forms of this enzyme in white-rot fungi. However, the Mr value of 41.7 kDa was also reported in the literature for purified preparations of endopolygalacturonases from *Phanerochaete chrysosporium*. On the other hand, an extracellular polygalacturonase from *Trichoderma harzianum* exhibited a Mr of 31 kDa on SDS-PAGE.

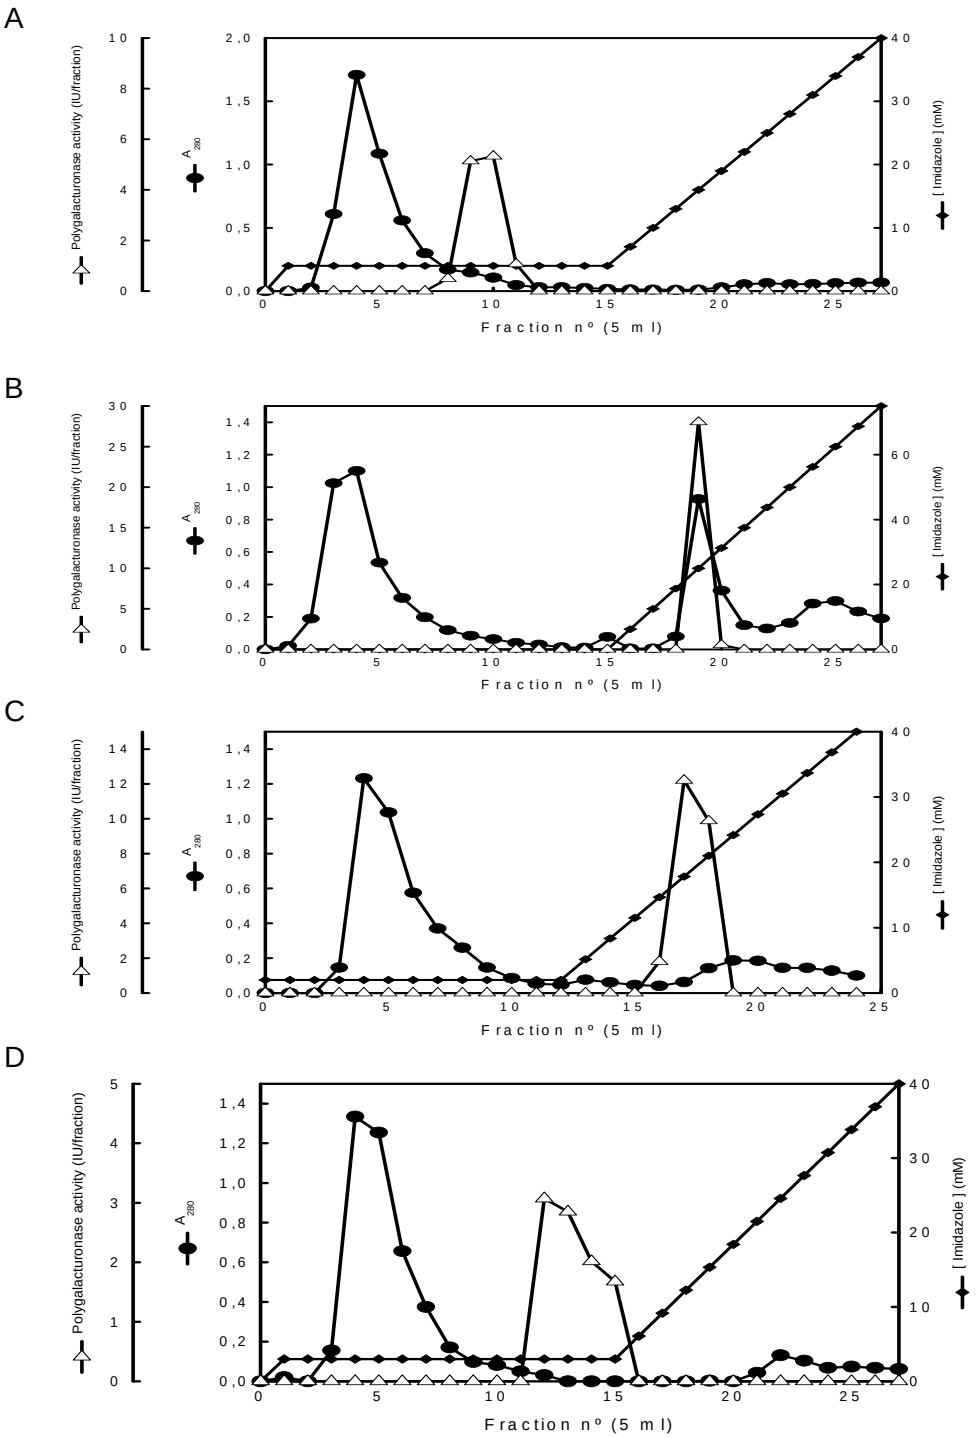

Figure 4 - Chromatographic behaviour of polygalacturonase from *Coriolus versicolor* on a Sepharose 6B–EPI-30–IDA-Cu(II) column at pH 6.0. Elution was carried out with a linear gradient of imidazole, as described in Materials and Methods. A- 4mM imidazole in the equilibration buffer (increments of 3 mM imidazole per fraction); B- No imidazole in the equilibration buffer (increments of 3.33 mM imidazole per fraction); C- 2mM imidazole in the equilibration buffer (increments of 3.17 mM imidazole per fraction); D- 3 mM imidazole in the equilibration buffer (increments of 3.08 mM imidazole per fraction).

Table 2 - Purification of polygalacturonase from *Coriolus versicolor* by Immobilized Metal Affinity Chromatography on Sepharose 6B – EPI 30 – IDA - Cu(II) at pH 6.0 in the mobile phase containing 2mM imidazole.

	Purification Steps	Total protein (mg)	Total activity (U)	Specific activity (U/mg protein)	Recovery (%)	Purification factor
1.	Culture supernatant	1.4	20.62	14.73	100	1

Keywords: Maloalcoholic fermentation, *Schizosaccharomyces pombe*, immobilized yeast, wine deacidification
Topic: Integration of life sciences & engineering

Abstract
Maloalcoholic fermentation of wine-must by *Schizosaccharomyces pombe* immobilized in alginate double-layer beads was studied in batch mode in Erlenmeyers and in a total recycle fixed-bed reactor. The influence of some parameters on must deacidification was discussed: the concentration of sulphur dioxide didn't affect the reaction rate significantly; the reaction is 1st order in relation to L-malic acid concentration with k=0,00174 h^{-1} at 15ºC and Ea= 16 ± 2 kcal/mol; the presence of ethanol slows the reaction by a factor of 2-3. Under similar conditions conversion of L-malic acid is faster in the recycle reactor than in the closed flaks. The recycle reactor handles larger volumes of must and this enables its implementation in wineries. The reaction can be stopped by adding *Saccaromyces cerevisiae* to inhibit the activity of *Schiz. pombe.*

1 Introduction

Total acidity is a key parameter for the organoleptic equilibrium and the stability of wines during ageing. It depends essentially on the relative amounts of tartaric and malic acids. It can be reduced by biological, chemical or mechanical methods but biological deacidification is usually preferred (Garcia *et al,* 2006). Traditional biological deacidification involves the growth of lactic acid bacteria, either spontaneously or induced by inoculation methods depending on the wine's microflora.

Malolactic fermentation (MLF) is a naturally occurring biological process where lactic acid bacteria transform malic acid (a dicarboxylic acid) into lactic acid (a monocarboxylic acid) and CO_2. This transformation reduces the wine's total acidity but it also changes wine's aromatic characteristics. Furthermore, MLF is often difficult to occur because during wine fermentation the pH, the temperature and the concentration of SO_2, ethanol and micronutrients can reduce the activity of lactic acid bacteria (Silva *et al*, 2003).

Maloalcoholic fermentation (MAF) is an alternative to MLF that uses yeast species such as *Schizosaccharomyces pombe* to transform malic acid into pyruvic acid which is further metabolised to ethanol and CO_2 (Fig. 1). The transformation of a dicarboxylic acid (malic acid) into an alcohol has the double effect of reducing acidity and increasing ethanol yield. Another advantage of MAF is the fact that *Schiz. pombe* yeasts are more tolerant to the above mentioned factors that inhibit lactic acid bacteria (Silva *et al,* 2003; Delpech, 2002).

* Corresponding author. Tel + 351-234 370 708… . E-mail:inesport@ua.pt

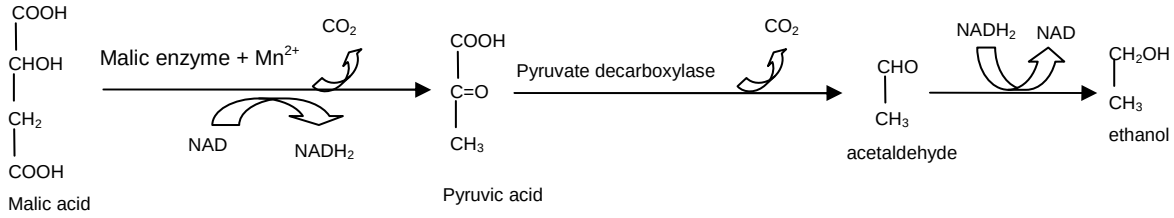

Figure 1 – Schematical representation of maloalcoholic fermentation (Garcia *et al,* 2006).

The consumption of L-malic acid by *Schiz. pombe* occurs without consumption of sugars and with similar activity when used either as free cells or immobilized cells (Silva *et al,* 2003). After total breakdown of L-malic acid *Schiz. pombe* yeast must be removed from the fermentative medium because prolonged contact with the deacidified must causes an unpleasant taste associated with the sugars' metabolism and thus the wine's organoleptic qualities are reduced (García *et a*l, 2006; Lepe, 1997). Yeast removal is easier to accomplish when using immobilized cells.

The purpose of this work was to study the activity of *Schiz. pombe* yeast encapsulated in double-layer alginate beads (diameter ~2 mm) for the biological deacidification of wine-must in a batch recycle fixed-bed reactor.

2 Materials and Methods

The yeast used for MAF was *Schizosaccharomyces pombe* immobilized in alginate double layer, commercially known by ProMalic®. Fermentative media (must) contained aprox. 200 g/L of sugar, the concentration of L-malic acid was adjusted to 2, 4 or 8 g/L , the initial pH was aprox. 3 and ProMalic® load was aprox. 1 g/L.

Total and free sulphur dioxide, total acidity and pH were evaluated at the beginning and at the end; sugars and L-malic acid concentrations were evaluated along time using enzymatic methods (ABX Pentra 400). The occurrence of MAF was confirmed by HPLC (Eurokat® 10 µm, refractive index detector, 0,4 mL/min H_2SO_4 0,01N, 25ºC).

Batch experiments in Erlenmeyers

Sterile must (430 mL, sterilized by ultrafiltration) was placed in 500 mL sterile Erlenmeyers closed with a cotton stopper. The concentration of L-malic acid was adjusted to the desired initial value (2, 5 or 8 g/L) and the pH was adjusted with 85% orthophosphoric acid to aprox. 3. This medium was inoculated with 1 g/L re-hydrated ProMalic® (re-hydration in a 40 g/L sugar solution during 4 to 5 hours) and reaction proceed at controlled temperature (± 1ºC). In some experiments must was replaced by wine to evaluate the influence of ethanol.

Experiments in a total recycle fixed bed reactor

The reactor scheme and photo are shown in Fig. 2. The glass reactor (h=20 cm, ϕ= 4cm) contained glass beads (Dp=3 mm) and re-hydrated ProMalic® beads (Dp=2 mm). Sterile must was placed in the feed-deposit (5 L) and pumped with an Ismatec MCP-Z peristaltic pump. Before each experiment all parts of the experimental set-up were sterilized by chemical methods using a 2-5 oxonium solution or by autoclaving during 15 minutes at 121ºC. The experimental assembly was placed in a controlled temperature chamber (±1ºC).

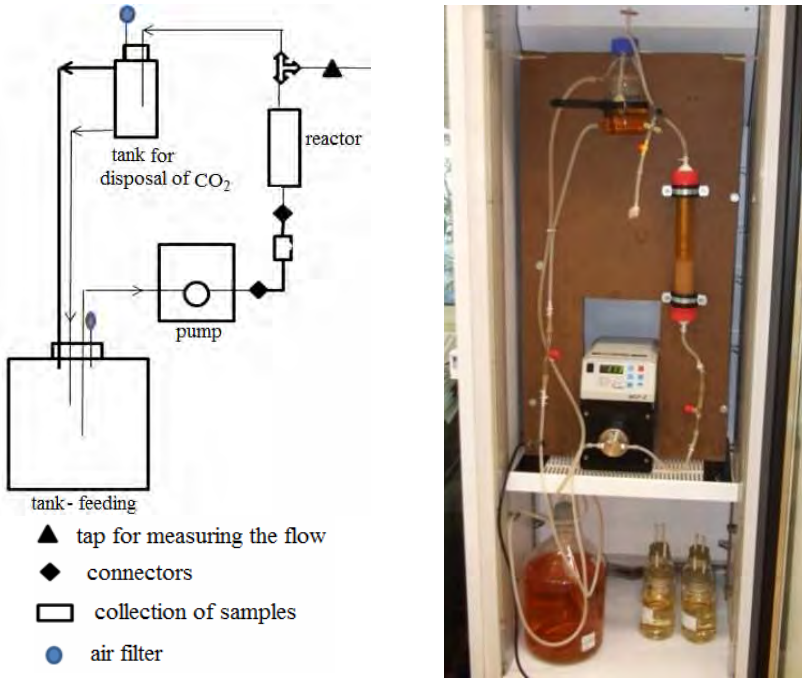

Figure 2 - Scheme and photo of the experimental assembly.

3. Experimental Results and Discussion:

The influence of L-malic acid initial concentration, ethanol and temperature on MAF rate was evaluated performing batch experiments in Erlenmeyers.

Experimental results for MAF at 15ºC using different initial concentrations of L-malic acid are presented in Fig. 3 and Table 1. L-malic concentration curves present a 1st order characteristic behaviour represented by equations (1) and (2)

$$\frac{d[L-malic]}{dt} = -k[L-malic] \quad (1)$$

$$[L-malic] = [L-malic]_0 . e^{-kt} \quad (2)$$

with k=0,00174 h^{-1} at 15ºC.

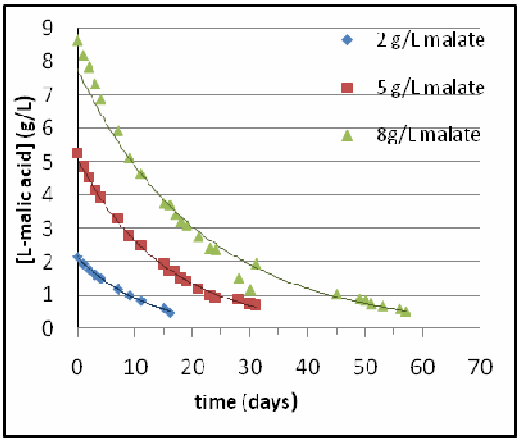

Table 1- Initial reaction rates (r_0) for different initial substrate concentrations (1 g/L ProMalic ® , 15ºC).

$[L\text{-malic acid}]_0$ (g/L)	r_0 (g/L day)
2	0,14
5	0,27
8	0,39

Figure 3 – MAF of L-malic acid in must using immobilized *Schiz. pombe* (1g/L ProMalic ®, 15ºC): experimental data and 1st order model curves.

Experimental results for MAF at different temperatures in the range 10 – 22 ºC are presented in Fig. 4 and Table 2. The results obtained with free yeast are also presented in Fig. 4 to discuss the effect of immobilization on deacidification rate.

Temperature increases the rate of MAF with an apparent energy of activation (Arrhenius type equation) of 16±2 kcal/mol and 31±8 kcal/mol for immobilized and free *Schiz. pombe* yeast, respectively. This difference is attributed to the existence of mass transfer limitations in the case of immobilized yeast due to the alginate's double layer. (Gòdia and López-Santín, Eds – 2005).

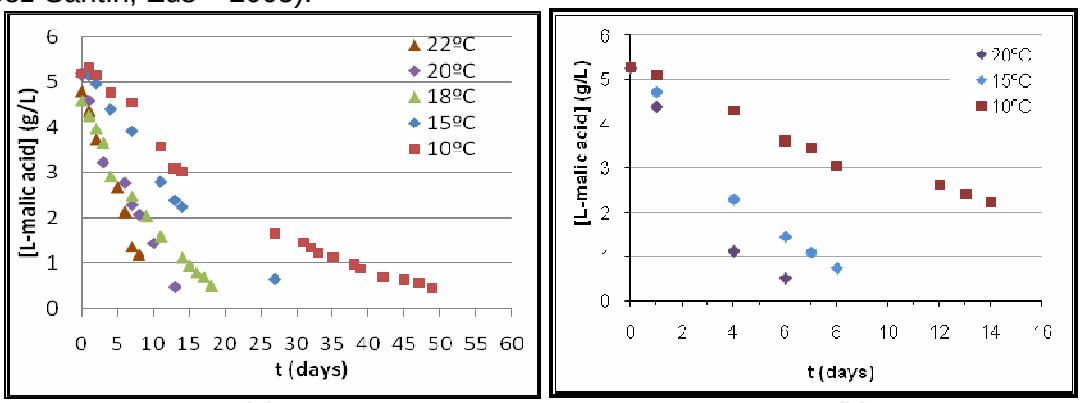

Figure 4 –Evolution of L-malic acid concentration with time during MAF of must by immobilized (a) and free (b) *Schiz. pombe* (1 g/L ProMalic ®) at different temperatures.

Table 2 – Initial rate of MAF at different temperatures by immobilized and free *Schiz. Pombe.*

	immobilized	free
T (ºC)	r_0 (g/L day)	r_0 (g/L day)
22	0,42	----
20	0,39	1,05
18	0,32	----
15	0,20	0,67
10	0,17	0,28

The inhibition of yeast's activity by ethanol is well known. To ascertain the effect of ethanol on the activity of immobilized *Schiz. pombe* the results for MAF of must were compared with the results for MAF of wine (11,3 º) (Fig. 5 and Table 3). Ethanol lowers the initial reaction rate by a factor of 1,5 to 3,5 and inhibition is stronger for higher concentrations of L-malic acid.

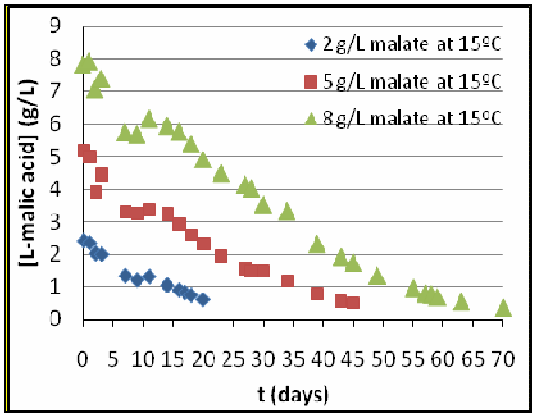

Table 3- Initial reaction rates (r_0) for MAF of wine and must with different initial substrate concentrations (1 g/L ProMalic ®, 15ºC).

$[L\text{-malic acid}]_0$ (g/L)	r_0 (g/L day)	
	must	wine
2	0,14	0,085
5	0,27	0,097
8	0,39	0,11

Figure 5 –Evolution of L-malic acid concentration in wine during MAF (1 g/L ProMalic ®, 15ºC).

Further experiments were performed in a recycle fixed-bed reactor operating in batch mode (i.e. closed circuit). Fermentation media flows at constant flow rate (~100 mL/min) through a fixed-bed of ProMalic® (~1 g/L) connected to a 5-L deposit. Samples were collected at the reactor's inlet and outlet and analyzed for sugar and L-malic content. These results are identical and thus the reactor may be considered a differential type of reactor. Since the fermentative media is not withdrawn during the experiment the reactor operates in batch mode and the substrate concentration changes with time.

The evolution of L-malic acid concentration with time during MAF of must with *Schiz. pombe*, in the recycle reactor and in Erlenmeyers, is presented in Fig. 6. The rate of deacidification is higher in the recycle reactor. This may be related to the fact that in the Erlenmeyers the reactions were performed without agitation and this causes mass transfer limitations of substrate diffusion into the yeast beads. In the recycle reactor mass transfer limitations are lower because the flow rate used causes some "agitation" around the yeast beads.

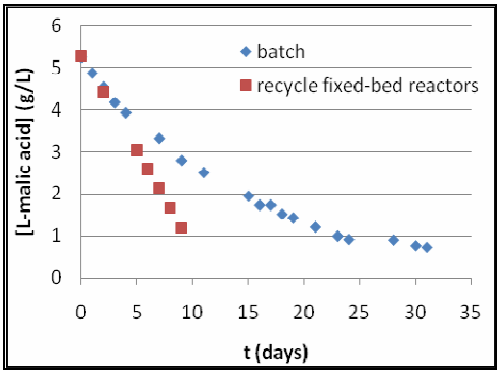

Figure 6 –Evolution of L-malic acid concentration in wine during MAF in Erlenmeyers (batch) and in the recycle reactor (1 g/L ProMalic ®, 15ºC).

The influence of mass transfer limitations was further discussed by performing experiments in similar conditions with higher yeast loads (Fig. 7 and Table 4). Higher loads of ProMalic® increased MAF rates, as expected, for this corresponds to longer contact times. With this type of reactor it is possible to obtain a residual value of L-malic acid (0.5 g/L) in 3 days. This represents a great process improvement. Presently, in wineries that are using ProMalic® the reduction of must acidity by MAF requires 2 to 3 weeks to reach 0,5 g/L of L-malic acid.

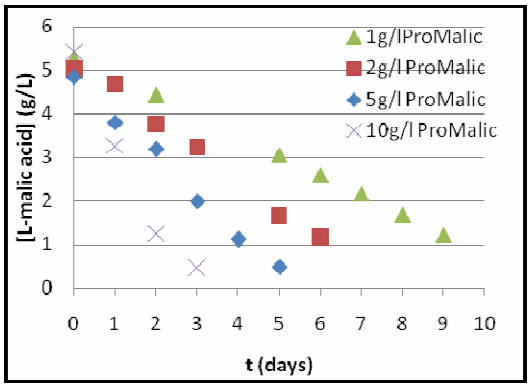

Table 4- Initial reaction rates (r_0) for MAF of must in the recycle reactor with different ProMalic® loads at 15ºC.

ProMalic® (g/L)	r_0 (g/L day)
1	0,47
2	0,71
5	0,89
10	1,70

Figure 7 –Influence of the recycle reactor's yeast load (ProMalic ®) on the evolution of L-malic acid concentration during MAF of must at 15 ºC.

The process of wine making from must requires inoculation with other yeasts such as *Saccharomyces cerevisiae* for example. Since *S. cerevisiae* is known to inhibit the activity of *Schiz. pombe* (Strehaiano and Taillandier, 2001) it is important to know exactly when to

inoculate. A reaction was performed in the recycle reactor as describe before and after two days *S. cerevisiae* was inoculated (Fig 8). During a period of aprox. 2 days MAF proceeded as usual: sugar concentration remained constant and the concentration of L-malic acid was reduced. After this period a drop of sugar concentration was observed and the concentration of L-malic acid remained aprox. constant, i.e. MAF was halted. Inhibition of *Schiz. pombe's* activity was not immediate after inoculation probably due to a lag-phase of *S. cerevisiae*.

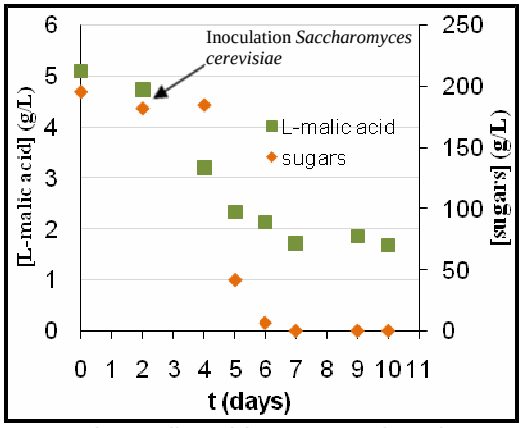

Figure 8 – Evolution of sugars and L-malic acid concentrations in must during MAF in the recycle reactor (1 g/L ProMalic ®, 15ºC): influence of inoculation with *S. cerevisiae*.

4. Conclusions:

Grapes and musts may present different values of L-malic acid concentration. This parameter was found to influence the MAF rate of must deacidification by immobilized *Schizosaccharomyces pombe*. The reaction is 1st order in relation to L-malic acid with k=0,00174 h^{-1} at 15ºC and Ea = 16±2 kcal/mol. Although immobilization reduces the rate of deacidification the advantages associated with yeast removal after reaction and the use of a total recycle fixed-bed reactor are favourable. In this type of reactor a residual value of L-malic acid (0.5 g/L) is obtained in 3 days while in a conventional batch process it takes 2 to 3 weeks to reach the same value.

Topic: Multi-scale and/or multi-disciplinary approach to process-product innovation: Food Engineering

Keywords: Madeira wine, GC-MS, principal component analysis, maximum likelihood principal component analysis

Abstract:

The results presented here outline the preliminary developments of a study which aims to find out and characterize the ageing phenomenon of Madeira wine, understanding the evolution of its aroma profile over ageing time, in such a way that it will be possible to develop a tool for assessing Madeira wine authenticity. For this purpose, a preliminary screening of volatile compounds by gas chromatography, coupled with mass spectrometry detection (GC–MS) was carried out, in order to perform the necessary wine flavour fingerprinting.

The amount of information obtained was simplified in order to support an easier analysis. In this work, two different methods for dimensional reduction of the original data set were applied: principal component analysis (PCA) and maximum likelihood principal component analysis (MLPCA). Two models were obtained, and the performance of each one was evaluated regarding the possibility of finding patterns of ageing in different samples of Madeira wine. PCA was also applied to differentiate varieties used in wine production, given that ageing time is known.

I. Introduction

Our image as a country which produces distinctive wines implies the responsibility and the need for conducting research aimed at supporting wine production, and the optimization of the procedures involved, such as ageing. Madeira wine, despite being one of the world's most famous dessert and aperitif wines, does not have yet many studies carried out in order to keep up with the increasing demand for higher quality in the current global markets. Moreover, its peculiar characteristics, namely regarding its exceptional longevity, makes of it a product with high economic value, attractive for possible fraudulent copies. For these reasons, a reproducible method, able to provide a credible evaluation of the authenticity and identity of Madeira Wines, is opportune and of the utmost relevance.

Understanding the chemical nature of wine aroma demands quantitative determination

of a quite large number of different odour-active compounds. The use of mass spectrometry as an on-line GC-detector for the identification of flavour compounds is perhaps the most widely used analytical technique for wine flavour chemical analysis due to the good results that have been reported on the literature (Ferreira, Jarauta et al. 2006; Ortega-Heras, González-Sanjosé et al. 2007).

Such an analytical measurement procedure generates large amounts of experimental data, with strong correlations among them. Therefore, such data are well suited to be analysed through multivariate statistical techniques, in order to efficiently extract useful information from the data sets available. The usefulness of multivariate techniques is reported in different areas: in process analysis, monitoring and control (Kourti and MacGregor 1995; Hu and Yuan 2008), in pharmaceutical applications (Gabrielsson, Lindberg et al. 2002), in the field of metabolomics (Jansen, Hoefsloot et al. 2004) and in the food industry, to characterize and authenticate products either for quality control or marketing purposes (Preys, Vigneau et al. 2007). The latter applications usually fall under the heading of “Chemometrics” a discipline described by Wold, in 1998, as able to solve the following problems in chemistry: to get chemical relevant information out of measured chemical data, to represent and display this information and to get such information into data.

The focus of this study is to conduct an exploratory data analysis related to the changes in the aroma profiles that take place during maturation of Madeira wine in oak casks.

Most multivariate statistical methods require more samples (wines) than variables (volatiles/flavour compounds), in order to perform the data analysis. This is frequently a problem, since instrumental techniques are sensitive enough to identify and quantify a large number of compounds. Therefore, statistical pre-processing is usually required to reduce the number of variables. In flavour chemistry the work involved in analyzing 5 or 10 wines is enormous. Therefore, most studies do not use many samples to model the relationships between chemical data and flavour compounds.

In this context, principal components analysis (PCA) has been used to look for patterns in a data set with a large number of variables, including the cases where there are more variables than samples. PCA is a very useful methodology for looking at patterns or trends and simplify large data sets, by finding linear combinations (principal components, PC) of variables (the compounds identified) that still describe the major trends present in the original data set. The relationships between the original variables can be seen by looking at the loading coefficients, which represent the most important linear correlations present in the original data. The first principal component (PC) explains the largest amount of variation among the samples. The second PC and subsequent PCs are then derived in such a way that they maximize the amount of unexplained variation under the constraint of being orthogonal to the previous components (Johnson and Wichern 2007).

In this work, another method for the dimensional reduction of the original data set was also applied: maximum likelihood principal component analysis (MLPCA). This is also a PCA method that estimates subspaces explaining the maximum variability present in the original data sets, differing from the first one mentioned due to the information that it uses, while solving its related objective functions. While in conventional PCA only the (scaled) data are used, in MLPCA (Wentzell, Andrews et al. 1997; Jansen, Hoefsloot et al. 2004) one further considers their associated uncertainties, which are used to weight the relative impact of each data point in the estimation of the PCA subspace (compounds containing smaller experimental errors are more influential in the MLPCA

estimation process). In our study the weights used are the uncertainties of each measurement, given by the standard deviation of the GC-MS replicates.

The application of these techniques results in two different models. An analysis of each one is performed separately, to identify how well each one best describes trends in our data set. It is useful to have a quantitative measure of similarity between them in order to have an idea of how different the subspace estimates obtained from both methodologies are. Some geometric concepts are pointed out as useful criteria to evaluate similarity between PCA models (Krzanowski 1979; Raich and Çinar 1995).

II. Materials and Methods

Samples

Two groups of samples were considered in this study: one group collected after 5 years of ageing in casks (five year old wines), and another group collected after 10 years of ageing in casks (10 year old wines). All samples, within each group, were submitted to the same ageing conditions, and submitted to the same vinification process. In each group, samples were collected for the four most important and recommended white wine varieties used in Madeira Wine production, namely: “Malvasia”, “Boal”, “Verdelho” and “Sercial”.

Experimental procedures and data analysis

Volatiles compounds were extracted from samples according to the following procedure: 3 mL of distilled water were added to 5 mL of sample and mixed with 1 mL of ethyl acetate and 10 µL of 3-octanol (internal standard). After mechanical agitation, during 30 min at 2500 rpm, the organic phase was dried with anhydrous sodium sulphate. The extract was analysed in an Agilent 6890N gas chromatograph coupled to an Agilent 5975 quadrupole inert mass selective detector. The identification of compounds was carried out by comparison of the mass spectra obtained for the analysis and those included in the NIST MS Library Database. Afterwards, the results obtained were analyzed using multivariate statistical techniques.

Data for the mean values of the two injections, corresponding to the relative response area for each wine volatile compound to an internal standard, were organized in a matrix with 24 rows (samples analysed) by 37 columns (compounds identified). In this format, it is very difficult to identify any significant trend in the behaviour of samples. Therefore, we proceeded by reducing the number of relevant dimensions present in this data set, in order to highlight the underlying analytical information that is really relevant for characterizing the wine flavours. All data analysis tasks were performed with the computational platform Matlab (version 7.6, The Mathworks Inc.).

Results

Using both approaches, two PCA models were estimated. The scores and loading coefficients obtained confirm that there are indeed differences between the MLPCA and PCA models. Analysing the scores plot shown in Figure 1, for the first and second principal components (explaining 61% of the overall data variability), one can see that samples from each wine variety, with different ageing times in casks, appear quite well separated under the conventional Principal Components Analysis representation (Figure 1a). Results regarding the “Malvasia, (M5)” variety seem rather distinct in this analysis from the remaining varieties with same ageing time, but its trend in the projection space is similar, namely regarding the second principal component (PC2). All samples (of the same variety) have one underlying similarity, concerning their evolution in the ageing process: the value of the second principal component (PC2) decreases with wine ageing. In Figure 1a) arrows highlight the direction of varieties ageing over time. Another result worth mentioning is the similarity of trends found in wine samples that are similar from the organoleptic point of view: “Malvasia” and “Boal”, the sweetest wines, follow one direction, and the remaining two, “Sercial” and “Verdelho”, wines with lower values of residual sugar, follow another one. The coupled analysis of the score and loading values does allow one to identify which set of volatile compounds are responsible for this trend, namely the furanic lactones and the ethyl and diethyl ester amounts.

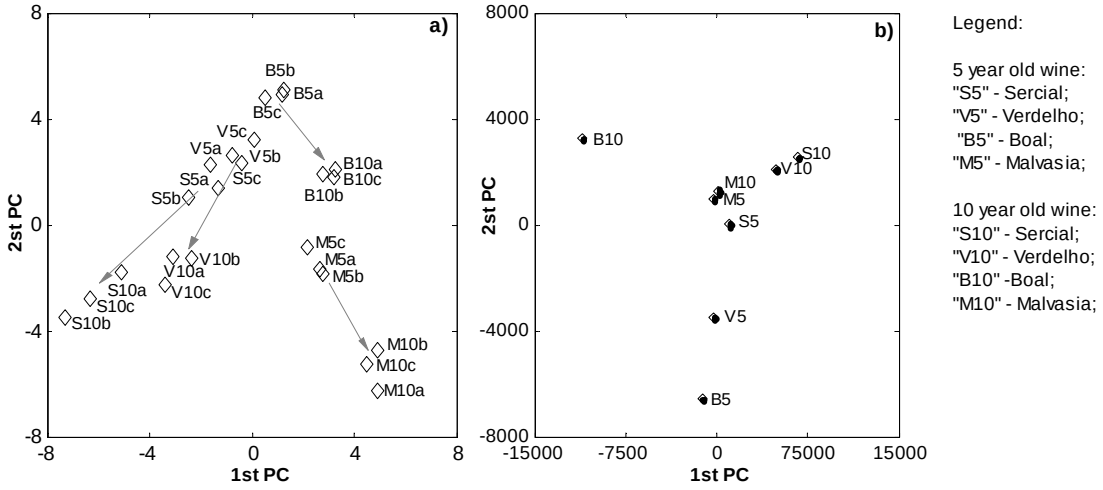

Figure 1 – Scores plots for the 1st and 2nd principal components, with ageing signature for samples from different wine varieties: a) Principal Components of Analysis; b) Maximum Likelihood Principal Components of Analysis.

As can been seen from Figure 1b), using MLPCA the separation obtained is not so clear. This may be due to the fact that the uncertainty estimates, based on three replicates only, may not be reliable enough, and thus contributes to deteriorate the analysis, rather than improving it. In future work, more samples should be considered, in order to verify if this approach can indeed improve performance over conventional PCA in capturing the natural underlying data variation.

In this study, the evaluation of the similarity between the two estimate subspaces was done by considering the angle between their coordinate axes. Using PCA decomposition, the angle β, between PCA coordinate direction sets P_{PCA} (loading values of conventional PCA) and P_{MLPCA} (loadings values of MLPCA), corresponds to eigenvalues $\left(s_k^{1/2}\right)$ of the following matrix:

$$P_{PCA}^{T} P_{MLPCA} P_{MLPCA}^{T} P_{PCA} = L^{'} S L \quad (1)$$

$$\beta = \cos^{-1}\left(s_k^{1/2}\right) \quad (2)$$

where L gives a set of coordinates and s_k corresponds to the k^{th} largest values in S (Raich and Çinar 1995), corresponding to the smallest angle β between *2*-dimensional subspaces. In our case, the angle from the two subspaces was equal to 52,11º, a value that expresses a highly significant difference between them.

Each group of aged samples was also analysed separately (i.e., the 5 year old group and the 10 year old group), as shown in Figure 2. In this case, the first two components do show good separation capabilities for all of the four varieties, each one of them explaining approximately 80% of the overall original data variance (Johnson and Wichern 2007). Therefore, using PCA, one is indeed able to identify: 1) the period that wines were in casks – ageing time (using the PCA model estimated considering all the groups); and 2) the wine variety (using the PCA models for each group).

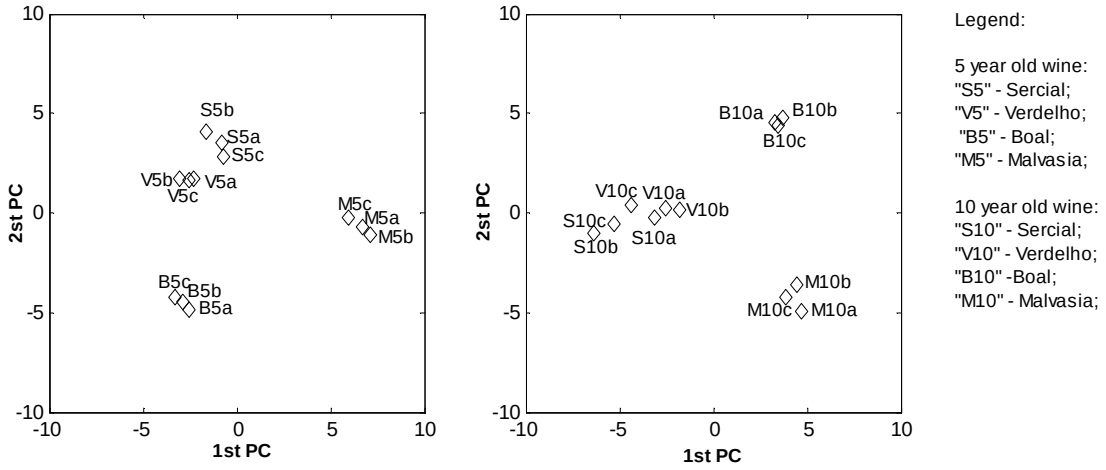

Figure 2 – Scores plots for the 1st and 2nd principal components for different varieties of wine with the same ageing period: a) 5 year old wines; b) 10 year old wines.

Conclusions

A global strategy to analyse the characteristic bouquet of Madeira Wine was presented.

The data set, with many variables obtained by GC/MS analysis, was simplified, through the use of multivariate projection methods. The application of such multivariate statistical methods revealed patterns of the original measurement variables, increasing the diagnostic value of laboratory assays.

These preliminary results reveal that the different varieties employed in Madeira Wine production have one similarity, concerning their evolution in the ageing process. Nevertheless, each one follows a particular trend in the proposed model, whereas new studies have been conducted considering one variety individually but in more detail across ageing time. We are also planning in the future to consider a more representative set of samples, in order to validate the ability of our methodology. In the end, we hope to come up with a credible evaluation procedure, able to safeguard Madeira Wine identity and assure its quality of ageing over time.

Keywords: Beer, Adjunct, Banana, Brewing, Fermentation
Topic: Multi-scale and/or multi-disciplinary approach to process-product innovation

Abstract

Beer is a traditionally fermented beverage made from malted grains of barley, hops, yeast, and water, while banana is an important food crop cultivated widely in tropical and subtropical areas and is one of the major fruits in Brazil. Besides, the banana is also very favorable to food industry (*e.g.* fermented beverages) due to its rich content on soluble solids, presence of minerals, and providing low acidity. In this context, the objective of this work was to evaluate a new strategy for using banana as adjunct to increase the fermentable sugars and to supply a specific aroma in pilot-plant brewing experiments. For this, static fermentations were conducted in a 180 L cylindrical-conical reactor using 140 L as working volume. Addition of banana was evaluated when changing the concentration of the wort from 10 to 12 ºP and from 10 to 13.5 ºP (ºP is the weight of the extract or the sugar equivalent in 100 g solution, at 20 ºC) and fermented under a constant temperature of 10 and 12.5 ºC, respectively. The results showed that the increment in the initial sugar concentration (12 to 13.5 ºP, due to the use of banana juice as adjunct), and in the temperature (10 to 12.5 ºC), increased approximately 17% the ethanol productivity. Thus, it was concluded that by using of simple preparation techniques of banana juice, banana can be used as adjunct in brewing processes, helping in the development of new products as well as in the elaboration of more concentrated worts when compared the traditional brewing worts.

1 Introduction

Produced in large quantities in tropical and subtropical areas, due to the special climatic conditions needed to its growth, banana is one of the most extensively consumed fruits and one of the most significant foodstuffs in the world, while being a good source of mineral salts and vitamins. Sensorial attributes of this fruit, as flavor, taste, texture and color are significantly influenced by its chemical composition, especially by acids, sugars and phenolic compounds. Studies have revealed physicochemical, nutritional and sensorial differences according to the region of origin of the bananas (Cano *et al.*, 1997; Hardisson *et al.*, 2001).

According to Food and Agriculture Organization of the United Nations (FAO, 2008), among the major producers of the banana worldwide in 2006, India was the first with 11.7×10^6 tonnes, which corresponded to 16.5% of the worldwide production, and Brazil was the second with 7.1×10^6 tonnes (approximately 10% of the worldwide production). Thus, banana can be regarded as a important staple food that is critical to the nutritional and economic well being of millions of people throughout the developing world and are grown in about 120 countries (Olorunda, 2000).

* Corresponding author. Tel +55-12-3159-5044. E-mail: joaobatista@debiq.eel.usp.br

On the other hand, biotechnology includes a wide range of diverse technologies that may be applied in each of the different food and agriculture sectors. In this context, several studies to obtain foods or beverages from fruits, such as orange, grape or apple, have been carried out. In brewing process, the conventional beer fermentation technology is initially based in the wort preparation and on its batch fermentation. With no mechanical stirring and with a temperature profile along appropriate fermentation time, fermentable sugars present in the wort are transformed to ethanol and in several taste and aroma compounds in order to obtain the desired characteristics on the final product (Linko, 1998; Almeida e Silva, 2005).

Nowadays, the brewing industry has applied a whole spectrum of technical, biochemical, microbiological and genetic innovations. Furthermore, in today's competitive beer-market it is very important to develop different types of beers, *e.g.* obtained by the use of new ingredients or new adjuncts. Thus, in previous works we have evaluated the feasibility of new technologies, *e.g*. for selectively producing beers from more concentrated wort (using high maltose syrup), aiming at obtaining good quality beer in a shorter time and in the least expensive way, or using different processing ways (Almeida *et al*., 2001; Almeida e Silva *et al*., 2004; Dragone *et al*., 2004; Brányik *et al*., 2006; Silva *et al*., 2008). By increasing wort concentration, after preparation, the beer is adjusted to the desired ethanol concentration with oxygen-free water, which makes of this process of considerable interest as higher levels of ethanol per given plant capacity and labor costs are obtained.

In this work, the objective was to describe and evaluate the performance of the use of banana juice as adjunct to increase the fermentable sugars and to supply a specific aroma, in pilot-plant brewing experiments. Special attention was paid to fermentation performance in terms of fermentation parameters as volumetric productivity, ethanol yield, and sugars consumption. For this, the addition of banana was evaluated when changing the concentration of the wort from 10 to 12 ºP and from 10 to 13.5 ºP (ºP is the weight of sugar extract equivalent to the weight of sucrose in a 100 g solution/20 ºC), fermented under a constant temperature of 10 and 12.5 ºC, respectively.

2 Materials and methods

The yeast strain used in this work was a commercial lager brewing strain (*Saccharomyces cerevisiae*). The yeast biomass for initial inoculation in the fermentation reactor was cultivated using all malt wort (12.5 ºP) firstly on a rotary shaker (200 mL / 30 ºC / 200 rpm, 18 h), followed by a 4 L Erlenmeyer flask under static and aerobic conditions (2 L / 15 ºC / 0.1 vvm of aeration, 30 h), then in a 40 L stainless steel vessel under static and aerobic conditions (20 L / 15 ºC / 0.01 vvm of aeration, 54-60 h) until the cell concentration was sufficient to provide a cell concentration of 10-20×10^6 cellsmL^{-1} in the beginning of the fermentation in the pilot tank (140 L).

All-malt worts and worts with banana as adjunct were produced according to conventional brewing techniques in the pilot installation used for the experiments, as shown in Figure 1. Banana juice, prepared with fruits of the variety *Prata* (*Musa spp*) and provided by EMATER (Empresa de Assistência Técnica e Extensão Rural do Estado de Minas Gerais, Cristina-MG/Brazil), was used to change the concentration of the all malt wort from 10 to 12 ºP and and from 10 to 13.5 ºP. This banana variety was chosen considering the great production and availability in Brazil which results in accessible price at markets. They were sanitized with running potable water, manually peeled, cut in the form of discs (thickness: 0.5 cm) and triturated in a blender before use. The typical carbohydrate profile of the banana used in this work, classified by the peel color as ripening stage 8 - yellow with more brown specks, according to Loeseck (1950), was: sugars as glucose and fructose (12.4 %ww^{-1}), sugars as sucrose (3.2 %ww^{-1}) and starch (0.5 %ww^{-1}). The banana juice was produced in a concentration of 0.29 gL^{-1} by enzymatic treatment (43.2 ºC during 1.3 h, with agitation at 32 rpm, pH 5 and 8.4x10^{-7} L of Ultra Pectinex SP-L enzymatic pectinolytic solution by gram of medium) followed by a thermal treatment (84 ºC during 0.67 h).

After wort preparation, the initial pH value was adjusted at 5 (by the addition of lactic acid) and the initial dissolved oxygen concentration was set at approximately 8 mgL^{-1}; static fermentations were performed in a 180 L cylindrical-conical tank (brewing fermenter) with 140 L working volume at constant temperature of 10 ºC to wort of 12 ºP and 12.5 ºC to wort of 13.5 ºP. The fermentation runs were carried out until the apparent attenuation was about 70-75% (1.0 ºP above the final value of fermentable sugars).

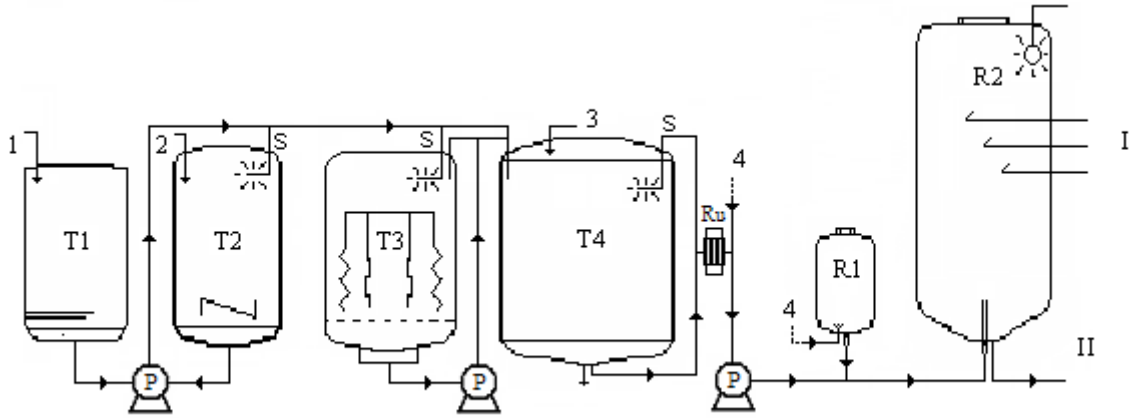

Figure 1. Pilot brewery for wort preparation and beer fermentation (Biotechnology Department at the Engineering School of Lorena, University of São Paulo EEL-USP/Brazil): T1 hot water tank, T2 wort treatment tank, T3 filtration tank, T4 boiling tank, P pumps, S spray-balls (in-line cleaning system), Ru refrigeration unit, R1 inoculation/propagation tank, R2 fermentation/maturation reactor, I and II sampling points or final product, 1 water supply, 2 malt supply, 3 hops supply, 4 air/O_2 supply.

During fermentations, samples were taken in triplicate at specified intervals and the yeast was removed by centrifugation at 4000 g for 20 min. The apparent extract and ethanol concentrations in the supernatant were measured at 20 ºC using an automatic beer analyzer (Beer Analyzer 2, Anton Paar, Graz, Austria). Part of the supernatant was also filtered through a syringe filter (Sep-Pak C18 cartridge, Waters, Milford, MA), and 20 µL were injected into an HPLC system which consisted of an Aminex HPX-87H column (300 × 7.8 mm^2, Bio-Rad Laboratories Ltd, Hercules, CA) at 45 °C using a Shimadzu chromatograph LC-10AD (Shimadzu Co., Tokyo, Japan) with refractive-index detector. The mobile phase was 0.005 $molL^{-1}$ H_2SO_4 at 0.6 $mLmin^{-1}$ flow rate. Sugar concentrations, reported as glucose, fructose, maltose and maltotriose, were determined from calibration curves obtained with pure compounds. The yeast cell number was determined using a Neubauer counting chamber and the viability was determined by methylene blue staining. All analyses were based on the techniques described in ASBC (1996). The ethanol productivity (ratio between ethanol produced and total fermentation time, $gL^{-1}h^{-1}$) and the ethanol yield coefficient (ratio between produced ethanol and consumed extract, gg^{-1}) were determined after conversion of the apparent extract (ºP) to grams of extract per liter of wort (gL^{-1}).

3 Results and discussion

According with the Figures 2 and 3, in both experiments, the final fermentation time was achieved at 120 h. These Figures show the performance of *S. cerevisiae* (yeast in suspension, lager strain), extract consumption and ethanol production as a function of the time of fermentation. As can be observed, during the first 24 and 36 h of fermentation, using banana as adjunct on 12.0 ºP/10.0 ºC and 13.5 ºP/12.5 ºC, respectively, the substrate consumption (measured in terms of apparent extract) was closely related to the increase of yeast biomass in suspension.

However, and after this time, the concentration of yeast in suspension decreased until the final time due to flocculation effect. This profile is in agreement with conventional profiles for brewing processes (Silva *et al*., 2008; Dragone *et al*., 2004). Besides, several factors are known to affect the cell viability in fermentative process, however, in both experiments obtained in this work the cell viability showed few variations (100-95%).

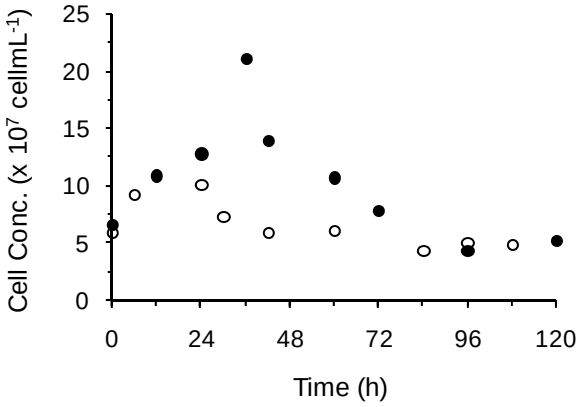

Figure 2. Performance of *S. cerevisiae* (yeast in suspension, lager strain) during fermentation of wort with banana as adjunct under the following conditions of concentration and temperature: (●) 13.5 ºP/12.5 ºC and (○) 12.0 ºP/10.0 ºC.

For the fermentation conditions of this work, the increment in the initial sugar concentration (12 to 13.5 ºP), due to the use of the banana as adjunct, and in the temperature (10 to 12.5 ºC), increased approximately 17% the ethanol productivity. The final productivity of the 12 ºP/10 ºC process was 0.29 $gL^{-1}h^{-1}$, while in the 13.5 ºP/12.5 ºC process was 0.34 $gL^{-1}h^{-1}$. Ethanol yield values were close at the end of each experiment (approximately 0.45 gg^{-1}).

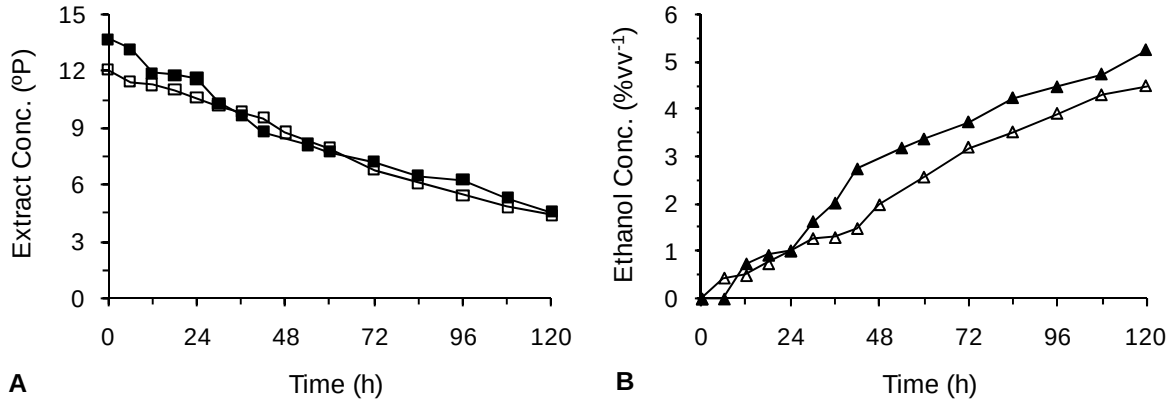

Figure 3. Extract consumption (A) and ethanol production (B) during fermentation of wort with banana as adjunct under the following conditions of concentration and temperature: (■, ▲) 13.5 ºP/12.5 ºC and (□, Δ) 12.0 ºP/10.0 ºC.

Figure 4 shows the profile of the glucose, fructose, maltose and maltotriose concentrations as a function of the time of fermentation. According to Navarro *et al.* (2007), the sugars in wort are not all fermented equally well. Since the yeast has to hydrolyze sugar polymers before it can use them, it always attacks hexoses first. In our work, as shown in Figure 4, comparing the consumption rate for each fermentable sugar found in concentrated wort with banana juice as adjunct, in general the following order of assimilation was observed: part of the glucose was consumed firstly, followed by fructose, maltose and finally maltotriose.

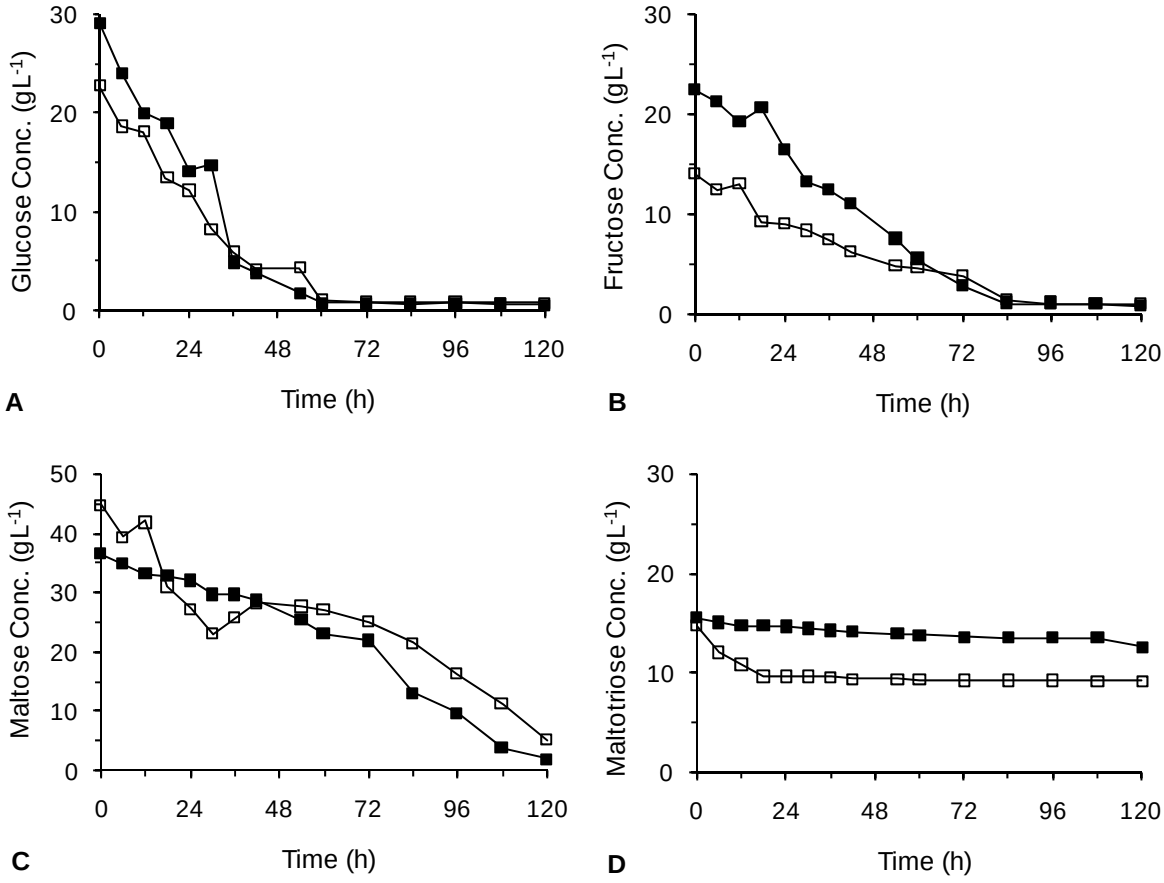

Figure 4. Fermentation performance of glucose (A), fructose (B), maltose (C) and maltotriose (D) at wort with banana as adjunct under the following conditions of concentration and temperature: (■) 13.5 ºP/12.5 ºC and (□) 12.0 ºP/10.0 ºC.

4 Conclusion

From this work it can be concluded that, by using simple preparation techniques of banana juice, banana can be used as adjunct in brewing processes, helping in the development of new products as well as in the elaboration of more concentrated worts when compared the traditional brewing worts (11-12 ºP). As a complement, the authors suggest the use of statistical designs to evaluate the optimization conditions of the variables simultaneously considered in this work (temperature and concentration). Besides, an increased productivity in brewing processes cannot be achieved at the expense of an unbalanced flavor profile of the final product and therefore future works are needed, especially to provide an understanding of the organoleptic profile obtained during the process of beer production using banana juice as adjunct.

Abstract

β-Galactosidase from *Aspergillus oryzae* is an enzyme with a wide industrial application, mostly in the hydrolysis of lactose and, more recently, in the synthesis of oligosaccharides. Several advantages are associated with the application of immobilized enzymes on magnetic supports. In this work, β-galactosidase was covalently immobilised onto a Polysiloxane-Polyvinyl Alcohol Magnetic Composite (mPOS-PVA), Magnetic Polysiloxane with Polyaniline (mPOS-PANI), Magnetized Dacron (DACRON) and Magnetite with Polyaniline (MAG-PANI) using glutaraldehyde as activating agent being the synthesis of GOS evaluated and compared at different temperatures (30, 40, 50 and 60 ^{o}C) and various initial lactose concentration (50, 100, 200, 300, 400 and 500 g/L). The kinetic parameters obtained by fitting the experimental data were compared in order to determine the effect of the immobilization process with different supports on the synthesis of oligosaccharides. These results clearly demonstrate that all supports may be used for β-galactosidase immobilization as, besides improving the enzyme hydrolytic and GOS synthesis properties, its separation from the obtained reaction products is easy to accomplish.

1 Introduction

During the lactose hydrolysis catalyzed by β-galactosidase GOS are produced by transgalactosylation activity and the production increases by increasing the initial concentrations of lactose in the reaction mixture (Albayrak and Yang, 2002). GOS are nondigestible oligosaccharides, which are prebiotics acting as growth-promoting substrates for bifidobacteria in the human intestine. Enzymes have been utilized in a large number of practical applications, particularly in biomedical and biotechnological fields, through immobilization on a variety of supports (Bayramoglu *et al*., 2008). The applications of immobilized enzymes may be challenged by difficulties that arise in enzyme recovery and recycling, which are the most important processes that can decrease the overall cost of the enzyme immobilization process (Lee *et al*., 2007). The use of magnetic micro-beads as supports for enzyme immobilization is mainly based on the magnetic feature of the solid-phase that enables to achieve a rapid separation in a magnetic field, as well as decrease of operation cost. In addition, the nano-scaled immobilized enzyme can greatly alleviate the transfer barrier, and thus improve the catalytic efficiency (Hong *et al*., 2008). Immobilization of enzyme or biomolecules to the magnetic microbeads is usually accomplished through reactive groups existing on their surface. Nowadays, these functional composites cold be produced in many ways, i.e. emulsion polymerization (Csetneki *et al*., 2004), in situ formation (Li *et al*., 2006) and sol-gel (Luo *et al*., 2006), but usually involve the coating of magnetically susceptible particles with synthetic polymers or biomacromolecules (Hong *et al*., 2008). Actually, the use of magnetic particles in enzyme technology is constantly increasing.

Permanent magnetization could cause the particles to aggregate even if the supports are removed from the magnetic field (Neri *et al*., 2008 and Bayramoglu *et al*., 2008). In this study, β-galactosidase from *Aspergillus oryzae* was covalently immobilized onto different magnetic supports (mPOS-PANI, DACRON, mPOS-PVA and MAG-PANI) for GOS production. The effects of the temperature, initial lactose concentration and reutilization were investigated. In addition, the kinetic parameters were determined and compared between the four supports using experimental data (10-50% initial lactose concentration).

2 Materials and methods

Supports synthesis: mPOS-PVA – beads were synthesized according to the procedure described by Barros *et al.* (2002) and the magnetized particles were obtained by Carneiro-Leão *et al*. (1991); MAG-PANI – magnetite (MAG) was obtained by co-precipitation (Carneiro-Leão *et al*., 1991) and after coated with polyaniline (PANI) as was done by Oliveira *et al*. (2008); mPOS-PANI – POS was prepared polymerizing the tetraethylorthosilicate and after was coated with polyaniline as described in Oliveira *et al*. (2008); DACRON – was converted to magnetic DACRON according to Pinheiro *et al*. (1999). The immobilization of β-galactosidase was done using glutaraldehyde as activating agent. The supports activated (100 mg) were incubated with 10 mL β-galactosidase solution (4 mg solid/mL) in 20 mM citrate-phosphate buffer, pH 4.5, for 18 h at 4 °C and 20 rpm. Production of GOSs from lactose was studied with immobilized enzyme on various supports in different conditions. The reaction kinetics was studied at six different initial lactose concentrations (5, 10, 20, 30, 40, and 50 %, w/v and four different temperatures (30, 40, 50, and 60ºC). GOSs, lactose, glucose and galactose concentration were determined using HPLC. As the concentration (w/v) of these sugars is proportional to their peak areas, normalized sugar concentrations as weight percentages of total sugars or initial lactose were determined from peak areas and are reported in this work.

Trisaccharides synthesis and lactose hydrolysis mechanisms including glucose and galactose competitive inhibition was mathematically modelled following four ordinary differential equations:

The lactose hydrolysis (*L*) is given by,

$$\frac{dL}{dt}=\frac{n_{1L}[L][H_2O]+n_{2L}[Tri][H_2O]+n_{3L}[L]^2}{d_1} \quad \text{where,} \quad n_{1L}=\frac{-k_1k_2}{k_4};n_{2L}=k_2;n_{3L}=\frac{-2k_1k_3}{k_4} \qquad \text{Equation 1}$$

the glucose (*G*) formation by,

$$\frac{dG}{dt}=\frac{n_{1G}[L]^2+n_{2G}[L][H_2O]}{d_1} \quad \text{where,} \quad n_{1G}=\frac{k_1k_3}{k_4};n_{2G}=\frac{k_1k_2}{k_4} \qquad \text{Equation 2}$$

and the galactose (*Gal*) by,

$$\frac{dGal}{dt}=\frac{n_{1Gal}[H_2O][L]+n_{2Gal}[Tri][H_2O]}{d_1} \quad \text{where,} \quad n_{1Gal}=\frac{k_1k_2}{k_4};n_{2Gal}=k_2 \qquad \text{Equation 3}$$

Finally, the trisaccharides production (*Tri*) is described by the equation 4

$$\frac{dTri}{dt}=\frac{n_{1Tri}[Tri][H_2O]+n_{2Tri}[L]^2}{d_1} \quad \text{with,} \quad n_{1Tri}=-k_2;n_{2Tri}=\frac{k_1k_3}{k_4} \qquad \text{Equation 4}$$

and $$d_1=\frac{k_2}{k_4}[H_2O]+\left(\frac{k_3}{k_4}+\frac{k_1}{k_4}\right)[L]+[Tri]+\frac{k_2k_5}{k_4k_6}[G][H_2O]+\frac{k_3k_7}{k_4k_8}[Gal][L]+\frac{k_2k_7}{k_4k_8}[Gal][H_2O]+\frac{k_3k_5}{k_4k_6}[G][L]$$

The kinetic model was adapted from the work of Boon *et al.* (1999) and the rate expressions were derived with the King-Altman method (King and Altman, 1956; BioKin, Lda). The model used only lactose as substrate and temperature effect was not included. The parameters were grouped into five parameters (k_1,is the overall reaction rate constant; k_4, describes the reaction of water with the galactosyl-enzyme complex; k_3/k_4, ratio between rate constants oligosaccharides synthesis and hydrolysis of the formed oligosaccharides; k_5/k_6 and k_7/k_8 ,account for glucose and galactose inhibition, respectively) that were estimated and one fixed

parameter (k_2, describes the reaction of water with the galactosyl-enzyme complex), which was assumed constant. The estimation of the model parameters was performed by the simulated annealing algorithm of the Systems Biology toolbox for *Matlab* (Mathworks) software (Schmidt and Jirstrand, 2006) using the results of the independent batch experiments, with the sets of experimental data from different initial lactose concentration (10%-50%; w/v) as substrate. All experimental data points were fitted simultaneously for each concentration and support.

3 Results and Discursion

Effects of lactose concentration on GOS production by free and immobilized enzyme on different magnetic supports

The percent of total GOS plotted against the percent of lactose conversion at 5% and 50% of initial lactose concentration, 40 ºC and pH 4.5 by different supports and free enzym, is shown in Figure 1A. Similar experiments were performed for different initial lactose concentrations (10 to 40%, w/v) and the tri- and the tetra-saccharides were quantified (data not show). GOS (tri- and tetra-saccharides) production increased with increasing lactose concentration. However, for each lactose concentration the GOS production decreased after a certain degree of lactose conversion. This can be attributed to a preferential hydrolysis (formation of glucose and galactose) rather than GOS synthesis. Furthermore, there was no marked difference between the free and immbilized enzyme performances. As the initial lactose concentration increased from 5% to 50%, the maximum GOS content in the product increased from 11.2% (at 35% conversion) to 26.1% (at 56% conversion) for the free enzyme, from 10.3% (at 38% conversion) to 25.7% (at 49% conversion) for the immobilized enzyme on mPOS-PANI, from 10.1% (at 34% conversion) to 26.2% (at 54% conversion) for the immobilized enzyme on DACRON, from 10.4% (at 30% conversion) to 26.0% (at 55% conversion) for the immobilized enzyme on mPOS-PVA, and from 10.8% (at 33% conversion) to 26.0% (at 52% conversion) for the immobilized enzyme on MAG-PANI. The maximum amount of tri-, tetra-saccharides and total GOS obtained for the free enzyme were 104.5 g L^{-1}, 33.2 g L^{-1} and 130.3 g L^{-1} for a lactose conversion of about 48%, 61% and 56%, respectively, in 500 g L^{-1} of lactose. For the immobilized enzyme, the corresponding values of 103.7 g L^{-1} on DACRON, 31.9 g L^{-1} on MAG-PANI and 131.0 g L^{-1} on DACRON were obtained for about 46%, 59%, and 54% lactose conversion, respectively in 500 g L^{-1} of lactose. These results suggest that enzyme immobilization on different supports does not impose any limitation or changes on GOS formation from lactose. Similar results were obtained with β-galactosidase from *A. oryzae* immobilized on cotton cloth (Albayrak and Yang, 2002). Thus, the GOS formation ability of the enzyme was not affected by the immobilization of the enzyme onto different supports, what is a clear demontration of the absence of mass transfer limitations using mPOS-PANI, DACRON, mPOS-PVA and MAG-PANI as supports.

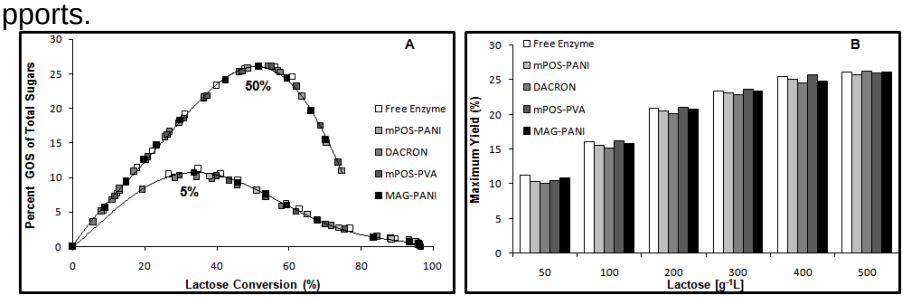

Figure 1. Total GOS (A) formation by free and immobilized (closed symbols) *A. oryzae* β-galactosidase on different supports at pH 4.5 and 40° C catalysing the hydrolysis of initial lactose concentrations (5 and 50%, w/v). GOS Yield (B) *versus* lactose concentration by free and immobilized *Aspergillus oryzae* β-galactosidase on different suports.

GOS yields during lactose hydrolysis catalyzed by the free and the immobilized β-galactosidase on different supports are shown in Figure 1B. The maximum GOS yield

increased with the initial lactose concentration for both enzyme preparations. It was observed that the hydrolysis and transgalactosylation reactions occurred simultaneously and that the product profile of the reaction is largely dependent on lactose concentration. The hydrolysis reaction dominates at low lactose concentration while GOS formation dominates at high lactose concentrations. β-Galactosyl groups should have a higher probability of attaching to lactose than water at increasing lactose concentrations (Iwasaki et al., 1996).An increase was observed up to 300 g L^{-1} of initial lactose concentarion, while for higher lactose concentrations the GOS yield was almost constant at 22.8–26.2% for free and immobilized enzyme on different suports. Park et al (2007) observed the same behavior for high lactose concentration with a thermostable β-galactosidase from *Sulfolobus solfataricus*. It is possible that some disaccharides such as allolactose and galactobiose are formed by the enzymatic transfer of galactose to glucose and galactose, respectively. The absence of this side reactions, was confirmed by checking the molar balances on glucose and galactose over the course of the reaction, assuming that all GOS only contained one unit of glucose with galactose as the remaining sugar. It is also possible that different trisaccharides were also formed, but were not detected by HPLC.

Higher operational and thermal stability, making possible its reuse, has been demonstrated to be one of the advantages of this system for enzyme immobilization (Neri *et al*, 2008). An immobilized β-galactosidase on different supports preparation acting on 20% (w/v) lactose was successively reutilized for 10 cycles at 25 ºC and at the end the enzymatic derivative retained approximately 87% for mPOS-PANI, 90% for DACRON, 84% for mPOS-PVA, and 85% for MAG-PANI of its initial activity (see Figure 2), confirming the advantages of the magnetic supports β-galactosidase derivative.

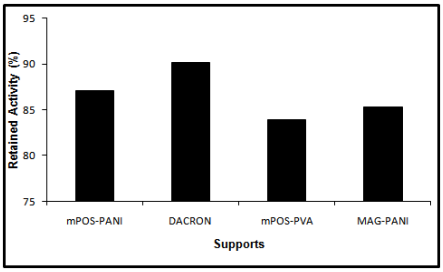

Figure 2. Effect on the activity of β-galactosidase immobilized on different supports after 10 reutilization.

Effects of temperature

Temperature normally has a pronounced effect on the enzyme reaction rates but showed to have a minimal effect, if any, on GOS production (Iwasaki et al., 1996; Monsan and Paul, 1995; Albayrak and Yang, 2002). As shown in Figure 3A and B, GOS production was almost unchanged despite temperatures varying from 30° C to 60° C (Figure 3B) for the conversion of 40% (w/v) lactose, for both the free and immobilized enzyme preparations. Albayrak and Yang (2002) reported similar results for β-galactosidase from *Aspergillus oryzae* immobilized on cotton cloth. It is well known that enzymes do not affect equilibrium constant of the reactions.

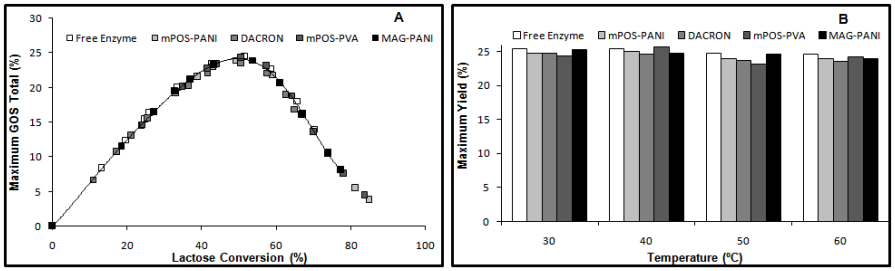

Figure 3. Effects of temperature on the GOS production from the hydrolysis of 40% (w/v) lactose catalyzed by the free and immobilized *A .oryzae* β-galactosidase on different supports at 60 ºC (A). GOS Yield (B) on different supports at various temperature.

Kinetic analysis β-galactosidase free and immobilized on different supports

To verify the precondition that the model parameters are independent of the initial lactose concentrations and in this way to use the parameters by taking the average values, the 95% confidence interval of the slope of the linear dependence of the kinetic parameters on initial lactose concentration was estimated (data not shown). For all the simulations runs the average parameters from each initial lactose concentration were used (Table 1).
To determine the effect of the different supports on the kinetic parameters, experiments were carried out at various initial lactose concentrations ranging from 10-50% (w/v). Figure 4 shows a comparison of the experimental and calculated concentrations profiles with the averaged parameters obtained for the supports at 20% initial lactose concentration. As can be seen, the good quality of the model is remarkable. The model describes well the time course of lactose conversion, glucose and galactose formation and overpredicts slightly the trisaccharides concentration for all the runs.

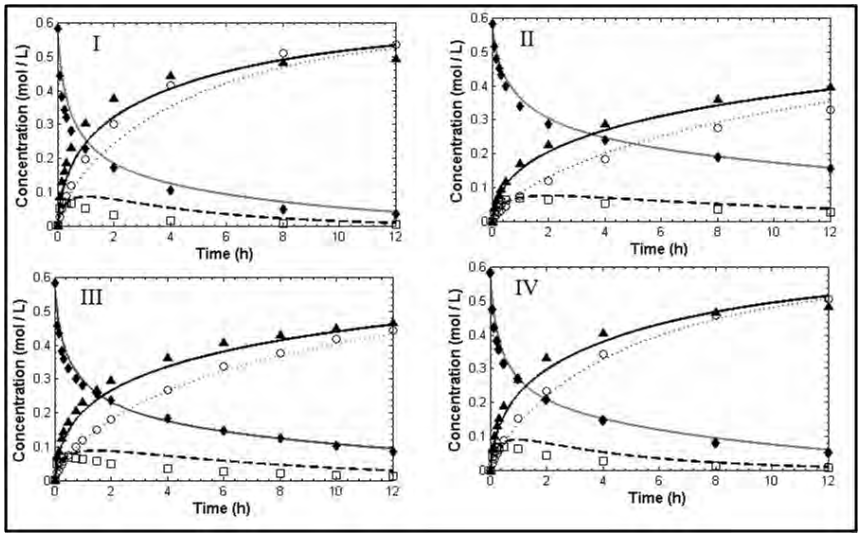

Figure 4. Comparison between experimental (symbols) and simulated data (descending gray solid line: lactose; ascending black solid line: glucose; depicted line; galactose and dashed line: trisaccharide) of (♦) lactose, (▲) glucose, (○) galactose and (□) trisaccharides concentration by immobilized β-galactosidase on Support I (mPOS-PANI), II (DACRON), III (mPOS-PVA) and IV (MAG-PANI) at pH 4.5, 40ºC for 20% initial lactose concentration. Lines represent the simulation using the fitted parameters.

The parameter k_3, that regulates the oligosaccharides synthesis and k_4, which regulates the hydrolysis of the formed oligosaccharides are assumed to be key parameters in the overall process. Not surpringly, as can be observed in Table I, the ratio between k_3 and k_4 is of the same order of magnitude for free and immobilized enzyme on different supports, indicating that the relative extent of the synthesis and hydrolysis reactions is not affected by the immobilization procedure. This is in accordance with the obtained experimental data (see Figure 1).

Table I. Estimated average values and 95% confidence intervals of parameters for the immobilized at different supports and free β-galactosidase obtained by fitting the experimental data for *A. oryzae* at different initial lactose concentration, pH 4.5 and 40ºC.

Parameter (units)	mPOS-PANI	DACRON	mPOS-PVA	MAG-PANI	Free
k_1 (h^{-1})	1.93 ± 0.93	1.09 ± 0.78	1.87 ± 0.70	1.59 ± 0.76	3.06 ± 2.90
Log(k_3/k_4) (-)	1.50 ± 0.043	1.52 ± 0.029	1.49 ± 0.013	1.50 ± 0.017	1.55 ± 0.22
k_4 (h^{-1})	3.69 ± 2.82	4.83 ± 1.613	4.59 ± 1.37	6.15 ± 2.50	3.45 ± 5.06
Log(k_5/k_6) (-)	1.023 ± 0.22	1.12 ± 0.24	1.015 ± 0.17	1.012 ± 0.46	1.50 ± 0.33
Log(k_7/k_8) (-)	0.75 ± 0.35	1.480 ± 0.13	1.45 ± 0.026	0.85 ± 0.41	1.51 ± 0.21

4 Conclusions

All supports proved to be an adequate support for *Aspergillus oryzae* **β**-galactosidase immobilization and its use on GOS production using lactose as substrate. The galacto-oligosaccharides formation ability of the enzyme was not affected by its immobilization onto the magnetic supports that can be easily recovered by applying a magnetic field. The galacto-oligosaccharides production was almost unchanged despite temperatures varying from 30° C to 60° C for the free and immobilized enzyme preparations on different supports. The model describes the experimental data well in the range of the initial lactose concentration used. Such kinetic model may be used bio-process engineering studies to increase knowledge of catalytic studies and the most appropriate support for immobilization process can be selected.

Topic: Systems Biology

Abstract

cDNA microarrays and oligonucleotide chips have the capability of performing genome-wide gene expression analysis, that potentially bring insights and relevant information on how cell and microorganisms are organized or behave at the transcriptome level. Even though this is only a part of the big picture that Systems Biology tries to describe and elucidate, it is certainly an important piece in the puzzle of life, to be properly integrated with the subsequent analysis levels (proteome, metabolome, microbiome, etc.). However, the specific nature of data generated in these experiments does raise relevant difficulties in their analysis which may hinder the full exploitation of their information content. In this paper, an integrated multivariate approach is proposed for analysing gene expression data for classification purposes, incorporating intermediates steps of gene screening, data projection, transformation and classification, in a coherent way. A VIP measure for the combined mapping PLS-DA/FDA is proposed in order to rank genes according to their relevance for achieving a given level of class separation, as well as a "non-classification" option is included in the method, with the purpose of informing the user about the uncertainty in class predictions.

1 Introduction

The analysis of processes going on at the cell scale plays a central role in bioengineering activities. In this field, fundamental knowledge about the complex behaviour of such systems is continuously increasing through the application of the scientific method to well defined biologic problems, through iteration between data analysis stages and hypothesis testing stages, until a mechanistic explanation is found that is consistent with all known results. Between the wide range of currently available data gathering methodologies from biologic systems operation, cDNA microarrays and oligonucleotide chips have become standard techniques, since all cellular processes originate at the transcription stage of cell operation (Stephanopoulos et al., 2002), enabling the simultaneous monitoring of the gene expression levels at a genome-wide scale. Therefore, this class of techniques is able to provide fundamental data-driven information over which explanations about system operation can be elaborated, or through which one is capable to characterize a variety of physiologic states (classification) or discover new ones (discovery).

DNA microarrays result from the hybridization of target samples of labelled mRNA representative of different cells states, with genomic DNA sequences immobilized in a solid matrix (probes). The magnitude of signal intensity at each probe location is then interpreted as a measure of the expression level of that particular gene, at the state corresponding to the label being analyzed.

Data from cDNA microarrays and oligonucleotide chips have been analyzed through univariate techniques, where genes that most differentiate between the states under analysis are identified through F and t statistics, or through other techniques, such as the signal to

* Corresponding author. Tel + 351-239-798700. E-mail:marco@eq.uc.pt

noise ratio (Golub et al., 1999) and the SAM method (Tusher et al., 2001). The simplicity of these methodologies enables the adequate control of classification error rates, such has the False Positive Rate (FPR), Family-Wise Error Rate (FWER) and the False Discovery Rate (FDR). However, they do disregard the cooperative behaviour of gene expression, a widely recognized feature of biologic systems.

Multivariate approaches, on the other hand, are more suitable for taking into account gene co-expression, but still present some methodological limitations. For instance, Fisher Discriminant Analysis (FDA) requires the number of variables (genes, in microarray data) to be less than the number of observations, a condition not met in practice in microarrays studies, where the number of genes whose expression levels are assessed is much larger than the number of analyzed samples. Therefore, such multivariate techniques do require a preliminary stage of variable selection, usually based on the simpler univariate approaches, a clear manifestation that some coherency and integration is lacking in the way the problem is being addressed.

In this work, an intrinsic multivariate approach is presented where such preliminary univariate variable reduction stage is not needed, but where genes screening can still be conducted after a first run of the proposed methodology, on the basis of multivariate information thus generated (genes VIP's). The proposed classification approach, to be described in the second section of this paper, combines PLS-DA (Barker and Rayens, 2003) and FDA (Johnson and Wichern, 2002), and has incorporated a "non-classification" option, that results from the analysis of the uncertainty associated with each class prediction, according to two distance measures of the expression profile in new samples, when compared to those in the training dataset.

2 Methods

In this section, the main steps of the proposed classification methodology are briefly described. In the first stage (training stage), a model is preliminarily estimated using all genes in the training data set, after selecting the number of PLS-DA dimensions (an adjustable parameter of the method). The X-scores thus obtained, are then transformed again, now using Fisher's Discriminant Analysis, in order to maximize the separation of class clusters in the resulting transformed space. If such separation is acceptable, it is then possible to estimate the importance of each gene in this process, after such a PLS-DA / FDA combination, using the following Variable Importance in Projection (VIP) metric:

$$VIP_{PLS-DA/FDA}(i) = n_{genes} \sum_{j=1}^{LV_{FDA}} \sum_{l=1}^{LV_{PLS}} \left\{ W(i,l)^2 \cdot L_N(l,j)^2 \cdot d(j) \right\} \tag{1.1}$$

where, $VIP_{PLS-DA/FDA}(i)$ is the VIP metric for observation i, n_{genes} stand for the original number of genes present in the data set, W is weighting matrix of PLS-DA, L_N the normalized eigenvector matrix of FDA (Johnson and Wichern, 2002; Stephanopoulos et al., 2002) and d is the vector with the inter/intra distances for each FDA component ($LV_{FDA} \leq LV_{PLS}$), a separability metric of classes, given by the ratio of the interclass to the intraclass variability. In Figure 1, it can be seen that the order suggested by the proposed VIP scores does correlate well with the ordering obtained with the Wilks's lambda statistic (a univariate measure of the classification ability of an isolated gene), but, being multivariate in nature, it necessarily leads to differences between the two methodologies.

Selecting the genes with the highest VIP values, it is possible to estimate a more parsimonious classification model, without the deleterious influence of genes not correlated with the cell states, which are the objects of classification. Such number of selected genes

can be put forward by estimating the classification performance using cross-validation, while the number of genes is successively reduced by removing the ones with the lower VIP scores. The maximum of the curve *cross-validated classification performance* versus *number of genes retained*, provides the desired number of retained genes. Using only such set of genes with highest VIP scores, result in a reduced training data set, for which a new combined PLS-DA/FDA model is estimated. Finally, for the scores in the FDA space, a suitable classifier is estimated, according to the topology of the data clusters for each class in this domain.

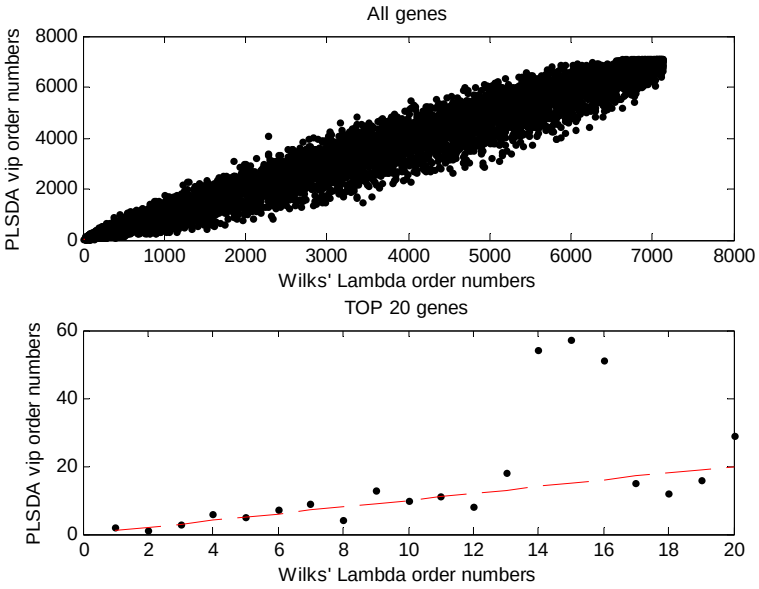

Figure 1. Correlation study of the order numbers proposed by the VIP metric and by the Wilks' Lambda statistic, for all genes in the data set.

Using some results of the estimated models, namely the classification probabilities for the attributed classes, computed using the Bayesian formalism for all samples in the training data set, and their distances to the PLS-DA's X-scores subspace, it is possible to put forward two metrics that characterize: (i) the "normal" distance of each sample (gene expression profile) to the subspace fitted with the training data, and the (ii) "normal" probabilities with which classes were assigned in the training samples. After analysing the variability of these metrics in the training data set, thresholds can be set for each one of them. Then, for a gene expression profile relative to a new sample, metric (i) will allow the user to verify whether it falls in the region where the model was estimated, and therefore it can be applied for assigning a class label to it, or not, in which case the model is no longer valid; metric (ii), on the other hand, addresses the problem of how confident are we in a given proposed classification (assuming that the sample is close enough to the PLS-DA subspace, which can be verified by analysing metric (i)), relatively to what was done in the training stage: classes that are predicted with probabilities significant lower than those for the training stage, should be taken with caution, or even rejected, if such probability is really low. In the next section we provide an illustrative example of this methodology.

3 Results and Discussion

In order to illustrate the proposed methodology, a well known data set was used (Golub et al., 1999), where different expression phenotypes were measured in samples from patients with different types of leukaemia: acute lymphoblastic leukaemia (ALL), subdivided according

to their lineage (ALL-B and ALL-T) and acute myeloid leukaemia (AML). The combined multivariate approach was applied to the training set containing 38 samples (19 ALL-B, 8 ALL-T and 11 AML) with 7129 genes, using LV_{PLS}=5 and LV_{FDA}=2. We would like to point out that, in this work, these parameters were not optimized for achieving the best classification performance, but are set to these values only for the sake of illustrating the approach. Analysing the curve of *cross-validated classification performance* versus *number of genes retained*, it was decided to select only the TOP-30 genes in the VIP ranking. Figure 2 provides de VIP scores in a decreasing order of magnitude, where we can see that the few TOP genes do indeed present magnitudes significantly higher than most of the others.

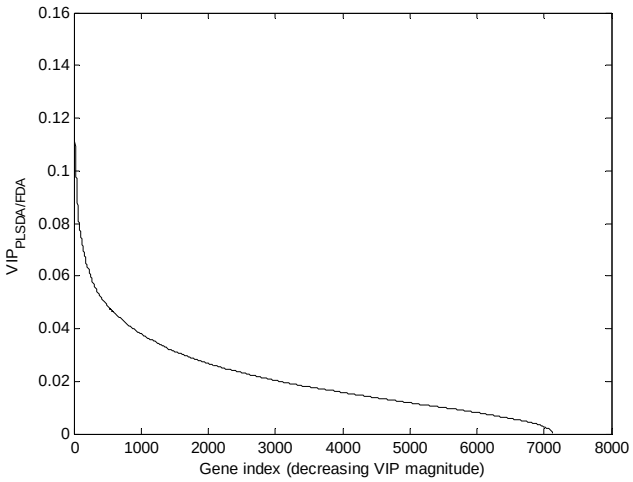

Figure 2. Profile of gene VIPs, by decreasing order of magnitude, in the leukaemia case study (Golub et al., 1999).

Even though the results obtained by using only PLS-DA over the entire training data set (Figure 3-a), do provide already an interesting class separation, it can be significantly improved by selecting the most important genes, according to the proposed VIP criteria, as a large number of them do not carry relevant information for classification purposes (Figure 3-b).

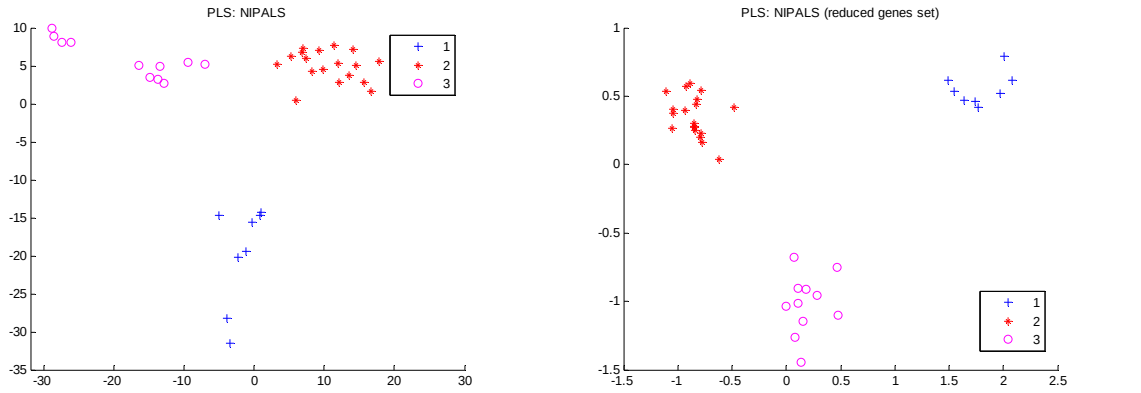

Figure 3. Scatter plots for the several leukaemia classes in the reduced dimensional space after a first run analysis (a) and after gene selection using the VIP criteria (b). (1:ALL-T; 2:ALL-B; 3:AML)

Applying the estimated classification model to the test data set containing 34 samples (19 ALL-B, 1 ALL-T and 14 AML), an average classification rate (per class) of ~9% was achieved (which can be significantly improved through a better choice of the adjustable parameters,

LV_{PLS} and LV_{FDA}). What is interesting to analyse here, being something that is generally overlooked in the literature, is the strong dissimilarity of the test set, when compared to the training samples. This can be confirmed by looking at the combined plot for the squared distance to the PLS-DA subspace versus the log-probability of classification, for each sample in the training data set (Figure 4), where most of the samples are in the “safety classification region”, located in the lower-right corner, whereas for the test set, most of them are outside such region. Therefore, even though in this example the classification rate achieved for the test set was reasonably good, it should be looked quite carefully, since the new samples are now arranged differently in the classification subspace, most of the falling outside the “safety classification region”.

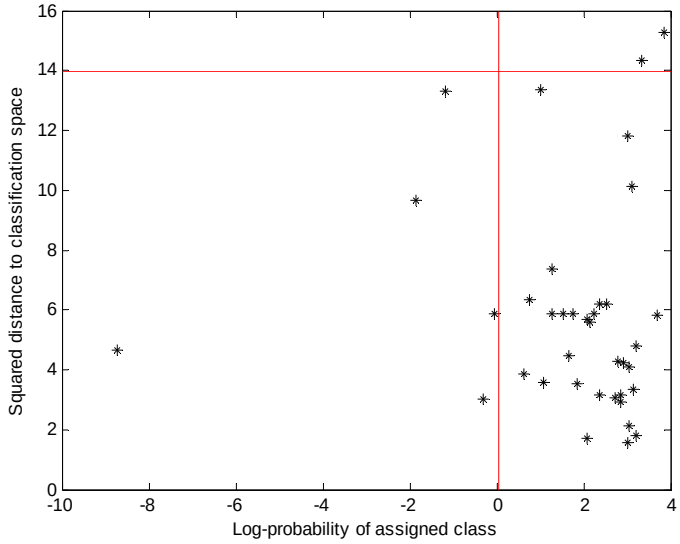

Figure 4. Combined plot for the squared distance to the PLS-DA subspace versus the log-probability of classification, for each sample in the training data set.

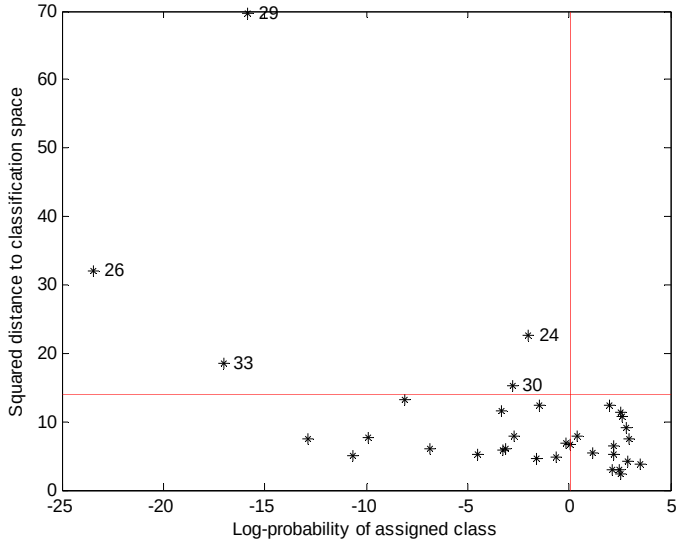

Figure 5. Combined plot for the squared distance to the PLS-DA subspace versus the log-probability of classification, for each sample in the test data set.

4 Conclusions

In this paper an integrated multivariate approach was presented for addressing classification tasks using gene expression data. The proposed approach has the capability of performing genes screening on the basis of multivariate information thus generated (genes VIP's), and it combines PLS-DA and FDA. Furthermore, it has incorporated a "non-classification" option that results from the analysis of the uncertainty associated with each class prediction, according to two distance measures of the expression profile: the squared distance to the PLS-DA subspace and the probability of classification. The proposed approach was illustrated with a classic gene expression data set (Golub et al., 1999), where its potentialities were explored, leading to the conclusion that, in spite of the reasonable accuracy of the classifier, the test samples were significantly different from those in training data set, which may prevent, in real world situations, the possibility of making class predictions.

Topic: Integration of life sciences & engineering

Abstract

The aging mechanisms of olive oil-lemon juice emulsion were investigated using image analysis. The emulsions were prepared with different ratios of modified starch (or maltodextrin) and xanthan gum. After preparation, emulsions stability was followed through analysis of the evolution of mean droplet size. The results indicate that stability of this salad dressing may take place for two aging mechanisms, coalescence or molecular diffusion. Analysis of the evaluation of the mean droplet size during 63 days indicated that coalescence is more common amongst the samples, the mean diameter droplets were greater in the samples with maltodextrin and with only xanthan gum and although this, during the storage time studied, any samples presented separation of phases.

1 Introduction

Emulsions are thermodynamically unstable systems because of the positive free energy needed to increase the surface area between oil and water phases and because oil and water have different densities. To form emulsions kinetically stable for a reasonable period of time, chemical substances known as emulsifiers must be added prior to homogenization (McClementes and Decker, 2000).

The Mediterranean diet has been associated with greater longevity and quality of life in epidemiological studies (Majem-Serra, Roman and Estruch, 2006). “Greek salad dressing” is, by definition, mixtures of virgin olive oil and lemon juice instantly prepared before use. Due to their compositions, they are a good source of biophenols as well as lipid-soluble and water-soluble vitamins. Besides, it has highly appreciated nutritional characteristics (Paraskevopoulou, Boskou and Paraskevopoulou, 2007).

Several kinds of physicochemical mechanisms contribute to the instability of an emulsion, including gravitation separation (creaming), coalescence, and flocculation. Polysaccharides are usually added to the aqueous phase of oil-in-water food emulsions to improve creaming stability of emulsions (Quintana et al, 2002).They are generally odorless, colorless and tasteless, have low energy and digestibility. The majority of such polysaccharides show little surface activity and their incorporation into oil-in-water emulsions is aimed inhibiting droplet creaming by increasing the viscosity of the aqueous phase thus preserving the desired textural properties of the emulsion (Paraskevopoulou, Boskou and Kiosseoglou, 2005). Starch, similar to other major polysaccharides, has low surface activity and is often used as a thickening agent or stabilizer in food emulsions. However, it has been found recently that starch causes a decrease in the creaming stability of beverage emulsions via depletion flocculation, similar to other major polysaccharides (Ye, Hemar and Singh, 2004).

* Corresponding author. Tel + 55 21 2562-7572. E-mail: alice@eq.ufrj.br

Emulsions containing maltodextrin as stabilizers therefore require an additional emulsifying agent for the production of a stable emulsion. In an emulsion system containing surfactant and polysaccharide, the nature and strength of emulsion stability will depend on surfactant–polysaccharide interactions at the surface of the emulsion droplets as well as in the aqueous medium between the droplets (Klinkesorn, 2004). Xanthan gum is a heteropolysaccharide aquosoluble produced industrially by fermentation of sucrose by *Xanthomonas campestris*. Excellent gum rheological properties contribute to its use in a wide range of applications in the food industry (Druzian, 2007). Hydrophobically modified starch, such as octenyl succinate anhydride starch, is an amphiphilic macromolecule. It offers properties that have many applications within the formation and stabilization of dispersed food systems such as emulsions.

Emulsion stability can be studied through the evolution of the droplet size and size distribution. The increase in droplet diameter is an indicator of the loss of stability of the emulsion and the growth rate of the droplets reveals the mechanism responsible for their aging. Two main mechanisms have been proposed for the loss of stability of these emulsions: coalescence and molecular diffusion (Sjoblom, 1996).

The objective of the present work was to develop oil-in-water emulsions containing two basic ingredients, olive oil and lemon juice, added by different combinations of xanthan gum with modified starch or maltodextrin that would exhibit reasonable stability over prolonged storage. Digital image processing was used to evaluate the stabilization of the emulsion by distribution of the droplet sizes along storage time at room temperature (± 27 ^{o}C).

2. Aging Mechanisms

The physical degradation of emulsions is due to the spontaneous trend toward a reduction in the Gibbs free energy *(∆G)*, achieved by reducing the size of the oil/water interface, *A*, and/or of the interfacial tension between the continuous and the dispersed phases, *γ* :

$$\Delta G = \gamma \Delta A - T \Delta S \quad (1)$$

The reduction of the interfacial area is achieved mainly by two mechanisms: coagulation, followed by coalescence, and molecular diffusion. Coalescence is the formation of a larger droplet from the merging of smaller ones. This requires that the small droplets come into contact, with thinning and disruption of the film that covers them. Emulsion degradation by coalescence is characterized by a broadening in particle size distribution, with an exponential increase in the mean droplet size with time, according to the Van den Tempel Theory,

$$a^{-3} = a_0^{-3} \exp(Kt) \quad (2)$$

where $\bar{a}_o$ is the initial average particle radius, $\bar{a}$ is the average particle radius at time t , and K is the coalescence constant. The coarsening of emulsions through molecular diffusion, also known as Ostwald ripening, is due to the gradual growth of the larger droplets of the emulsion at the expenses of smaller ones. This is a direct consequence of the Kelvin effect, which states that the solubility of a particle is inversely proportional to its radius, meaning that individual molecules tend to leave smaller particles and to diffuse through the continuous phase to join larger ones. There is essentially one theoretical treatment known as the Lifshitz–Slyozov–Wagner (LSW) theory and its modifications, where the molecular diffusion mechanism is characterized by linear growth of the droplet volume with time,

$$d(\bar{a})^3/dt = 8CD\gamma V m^2/9RT \quad (3)$$

where C and D are respectively the solubility and the diffusion coefficient of the dispersed phase in the continuous medium, V_m is the molar volume of the dispersed substance, R is the usual gas constant, and T is the absolute temperature. (Freire et al, 2005; Trindade et al, 2008). According to Eq. (3), an increase in the particle's volume is proportional to the solubility, the diffusion coefficient, and the interfacial tension of the dispersed phase (olive oil) in the continuous phase (lemon juice). Therefore, emulsions that undergo Ostwald ripening can be stabilized by decreasing at least one of these three factors.

3. Materials and methods

Oil-in-water emulsions (50% v/v) were prepared as follows: a lemon juice polysaccharide solution was first prepared by slowly dispersing 1% w/v arabic gum and 0.5% w/v xanthan gum (control), and different concentrations of modified starch (or maltodextrine) and xanthan gum with composition summarized in Table 1. After, the olive oil was added stirring it with a vortex (2200 rpm) for 2 min. The resulting crude emulsion was then homogenized for 1 min at 9500 rpm using Ultra-Turrax T25 homogenizer (IKA Instruments, Germany) equipped with a dispersing tool. Benzoic acid was added at a concentration for 1% w/v in the continuous phase to lemon juice.

Table 1. Emulsions composition olive oil-lemon juice (50% v/v) studied and optimal fitted for mechanisms of stability loss for the studied ($\bar{a}^3$ = droplet diameter (μm^3) and t = time(days)).

VIII	-	0,5	-	$\bar{a}^3 = 173{,}76\ e^{0{,}0267t}$

3.1. Image analysis

The measurement of emulsions droplet size distribution was carried out during a storage period 63 days. Images acquisition was conducted using an optical microscope (Eclipse E200, Nikon) with 400× magnification coupled with digital camera (Media Cybernetics, QImaging) linked to a personal computer. The images were focused in such a way as to enhance droplet contours. Afterwards, a step to suppress objects connected to the image border, and a hole-fill procedure were performed. Application of operations, such as erosion (to remove small debris) and reconstruction, produced the final binary image. These image processing were developed using the Matlab® v.7.0.4 (The Mathworks, Natick, Mass.) package and were fully automated. A micrometer and appropriate software, Image-Pro® Plus 5.0, were used for calibration of the droplet size. For each 7 days an average of 25 different pictures from different samples were analyzed. The quantification step from image analysis supplies a statistical analysis of the data providing the total number of analyzed objects, the average droplet diameter and its standard deviation as well as the particle size distribution (Freire et al, 2005; Trindade et al, 2008). It also provides the particle roundness and its distribution, useful detecting if other objects than droplets are being analyzed.

4. Results and discussion

The emulsions are formed from two immiscible liquids, olive oil-juice lemon that added of emulsifiers in ratios appropriate to remain themselves steady a long time. Analysis realized through digital image processing permitted the accomplishment of the stability of emulsions studied. The emulsions droplets size was carried out during 63 days. For each 7 days an average 25 different pictures from each sample was analyzed varying of 250 the 1800 droplets. The quantification step from image analysis supplies a statistical analysis of the data providing the total number of analyzed objects, the average droplet diameter and its standard deviation as well as the particle size distribution. It also detects if other objects than droplets are being analyzed.

The oil droplets are stabilized against flocculation and coalescence due to strong steric barrier effect arising from polysaccharide blocks protruding towards the emulsion continuous phase from neighboring droplet surfaces, where they are anchored though the more hydrophobic protein moiety of the gum (Dickinson, 2003).

A statistical analysis of the experimental data aiming to assure that no systematic errors (or bias) were made during the particle diameter measurements was also performed for all the samples. Among other issues, it is important to ensure that the program is detecting the smallest droplets and that the samples are randomly analyzed with no preferential droplet size detection (Trindade et al, 2008). When no systematic errors are present, the population of all the studied emulsions follows a Gaussian distribution. During the 63 days of storage, all the samples were visually steady and homogeneous, that is, they had not presented formation of creaming or separation of phases. Although this the results through the image processing shown that some samples already had initiated the process of stability loss.

The molecules of xanthan gum adopt a helical conformation that they can be described as rigid connecting rods without trend to associate resulting in a thickener behavior. The most important property is ordered state of the macromolecule; therefore the xanthan gum can always be used in the electrolyte presence. These characteristics become xanthan gum appropriate as acid thickener and stabilizer agent in acid pH, as dressing salad in general (Multon, 2000; Fonseca, 2008). The sample control was characterized as steady during 63 days of storage, because of mechanism loss of stability wasn't detect, therefore as it can be seen in fig. 1a the evaluation of droplet size remains around a specific value. This can be explained since the sample was characterized as homogeneous in table 2 and this sample was chosen for comparative in this study due to the good results gotten in the works carried out by Paraskevopoulou and collaborators in 2005 and 2007.

The emulsions content mixture of xanthan gum with maltodextrin (emulsions V, VI and VII) and the emulsion VIII with only xanthan gum had the biggest cube diameter when compared with the results of the emulsions that contained xanthan gum and modified starch. In agreement with Dickinson (2003), emulsifiers are surface-active ingredients that adsorb to the surface of emulsion droplets and prevent them from aggregating. Maltodextrins are not particularly surface-active, and so their main stabilizing action in oil-in-water emulsions is believed to be through viscosity modification or gelatinization of the aqueous continuous phase surrounding the oil droplets. The starch-modified enzimatically contain hydrophobic as well as hydrophilic groups, the starch molecules are attracted to the interface between the water and the oil droplets in an emulsion. As a result, a tougher, more cohesive, more continuous, and less easily disrupted film is formed about the oil droplet. This makes it more difficult for the dispersed phase to coalesce and separate (Wurzburg, 1986).

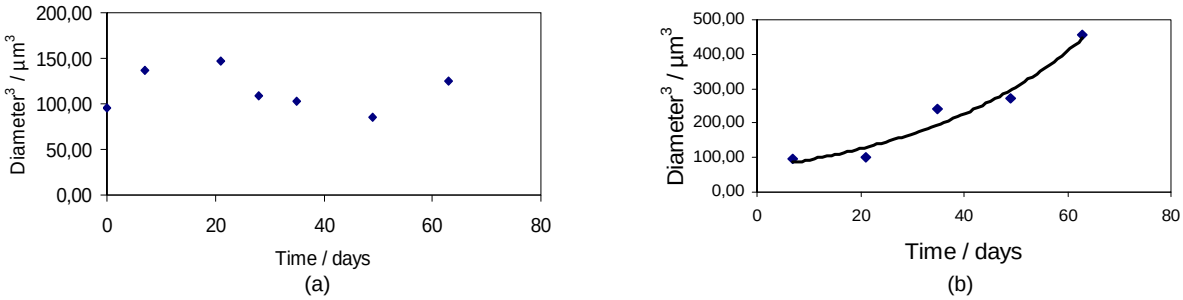

Fig.1. Droplet size evolution as a function of time for emulsion control (a) and emulsion III (b).

It was observed that in accordance with the data presented in table 1 and table 2 samples II and IV had exponential growth of droplets characterizing mechanisms of stability loss by coalescence. The modified starch, such octenyl succinate anhydride starch, is amphiphilic macromolecule. It offers properties that have many applications within the formation and stabilization of dispensed food systems such emulsions (Modig et al, 2006). The result from distribution of the droplet size populations (table 2) showed the emulsions III and V had been characterized as heterogeneous and presented droplets growth since the values of size to 63 days increased in contrast with the initial time. In figs. 1b these sample show an exponential growth what characterizes an increase of droplet size and probable loss stability by coalescence mechanism.

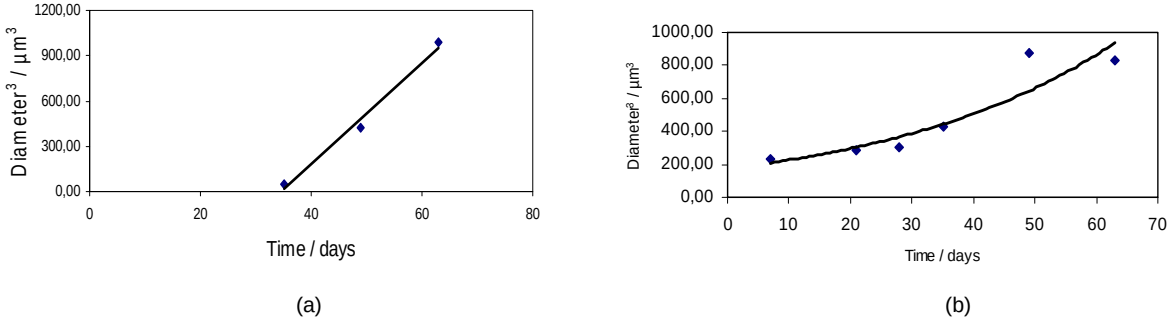

Fig. 2. Droplet size evolution as a function of time for emulsion VII (a) and emulsion VIII (b)

Sample I that contain lesser ratio of modified starch and xanthan gum, as well samples VI and VII (fig. 2a), that contain different ratios of xanthan gum and maltodextrin, had a linear growth of the droplet size characterizing the beginning of stability loss by molecular diffusion, as can be visualized in table 1, through the fitted equation. In accordance with Klinkesorn (2004), the molecular characteristics of maltodextrin, such as concentration and chain length, affect the stability of oil-in-water emulsions. Already sample VIII (fig. 2b) that contain only 0.5% xanthan gum show exponential growth of droplet size however during the 63 analyzed days all samples were homogeneous.

5. Conclusions

The image processing procedure showed to be a good method to the evaluation of oil in water emulsions stability. Analysis of the evaluation of the mean droplet size during 63 days indicated that coalescence is more common amongst the samples, the mean diameter droplets were greater in the samples with maltodextrin and with only xanthan gum and although this, during the storage time studied, no samples presented separation of phases. It can be conclude that the polysaccharides xanthan gum, maltodextrin and starch modified, have the ability for the stabilize oil-in water emulsions. The emulsifiers influence allowed the characterization the system along time besides to contribute to the development of more consistent formulation.

Keywords: Biomolecules, N_α-benzoyl-L-arginine ethyl ester hydrochloride (BAEE·HCl), IR, NMR, DFT calculations.
Topic: Advancing the chemical engineering fundamentals.

Abstract

High level molecular modeling and experimental studies by IR and ^{1}H NMR spectroscopies on an L-arginine derivative, N_α-benzoyl-L-arginine ethyl ester hydrochloride (BAEE·HCl) were carried out.

A systematic conformational search on the less expensive semi-empirical PM3 Potential Energy Surface (PES) of the two tautomers of BAEE·HCl was done. The lowest-energy conformations obtained with the PM3 method were afterwards optimized using the density functional theory (DFT) method and the B3LYP/6-31++G(d,p) level of approximation.

The IR spectrum of BAEE·HCl was recorded in the range 4000–600 cm^{-1}, at room temperature. The ^{1}H NMR spectra of BAEE·HCl was recorded in DMF-D_7, at 25ºC.

The information provided by the theoretical methods for the most stable conformers, in combination with the experimental data, allowed a detailed characterization of the molecular structure of BAEE·HCl.

1 Introduction

In recent years, there has been a growing interest in developing new materials for biomedical applications that can mimic some of the functions of biomolecules (Zhang *et al.*, 2007). Polydepsipeptides, copolymers of α-hydroxy acids and α-amino acids, are promising materials for that end. These copolymers present an amide (–CONH–) and an ester linkage (–COO–) in the main chain. From the point of view of pharmaceutical and biomedical applications, these materials represent particularly promising systems, since they have the ability to establish strong biospecific intermolecular hydrogen bond interactions (through their amide groups) with cell components. Hydrogen bonds involving the amide groups may also enhance mechanical and thermal properties of polydepsipeptides compared to the related polyesters, while degradability is ensured by the presence of ester groups (He *et al.*, 2003, Deng *et al.*, 2007). Thus, it is of great importance the investigation of their properties, not only at the macroscopic, but also at the microscopic level. In this context, vibrational and NMR spectroscopies, combined with molecular modeling methods, have been shown to be a valuable approach in the development and characterization of new materials (Strittmatter and Williams, 2000, Zhang *et al.*, 2007).

* Corresponding author. Tel + 351-239-798760. E-mail:anafs3@eq.uc.pt

Despite the promising capabilities of polydepsipeptides, these materials have been studied very scarcely. In fact, they have essentially been investigated as models to predict some of the properties of polypeptides and proteins, due to their structural similarity. For example, the study of polydepsipetides has allowed the investigation of the role of hydrogen bonds in the helical structure of peptides (Ingwall *et al.*, 1976, Zhang *et al.*, 2007).

In this work, molecular modeling calculations and experimental studies by IR and ^{1}H NMR spectroscopies on an L-arginine derivative, BAEE·HCl, were carried out. This compound is an appropriate model to better understand some of the polydepsipeptides properties, since its structure comprises an amide and an ester bond. The study of small model systems can stimulate and provide crucial data for the development of better, more efficient and reliable computational methods to be applied for more complex systems. To the best of our knowledge, no studies have been reported on this compound hitherto.

2 Materials and Methods

Computational Details

A systematic conformational search on the semi-empirical PM3 Potential Energy Surface (PES) of two tautomers of BAEE·HCl was performed to generate a sequence of conformations sorted by their relative energies. The most stable structures were afterwards submitted to geometry optimization and to magnetic shielding tensors and harmonic vibrational calculations through quantum chemical methods. These calculations have been performed within the DFT framework at the B3LYP/6-31++G(d,p) level of theory in vacuum, using the Gaussian03 package (Frisch *et al.*, 2004).

Experimental Details

BAEE·HCl (purity ≥ 99%) was purchased from Fluka and used without any further purification.

The IR spectrum of solid BAEE·HCl (4000–600 cm^{-1}, at room temperature) was obtained, with 4 cm^{-1} spectral resolution, using a Bomem (MB104) Fourier Transformer spectrometer equipped with a Zn/Se optics. The solid BAEE·HCl was pressed in a KBr pellet (Sample:KBr ratio – 1:400).

^{1}H NMR spectra of BAEE·HCl in DMF-D_7 was obtained on a Unity 500 MHz Spectrometer using a 5 mm broadband NMR probe. Each spectrum consisted of 32 averaged scans and acquisition parameters included 36k points covering a spectral width of 6 kHz, a 30º radiofrequency pulse and a total repetition time of 10 s. Digital zero filling to 64k and a 0.5 Hz exponential were applied before Fourier transformation. Samples were prepared by dissolving 10 mg of BAEE·HCl in 600 μL of the deuterated solvent.

3 Results and Discussion

Theoretical Calculations on the Structure of BAEE·HCl

A thorough conformational search on two BAEE·HCl tautomers (see Figure 1) has been performed.

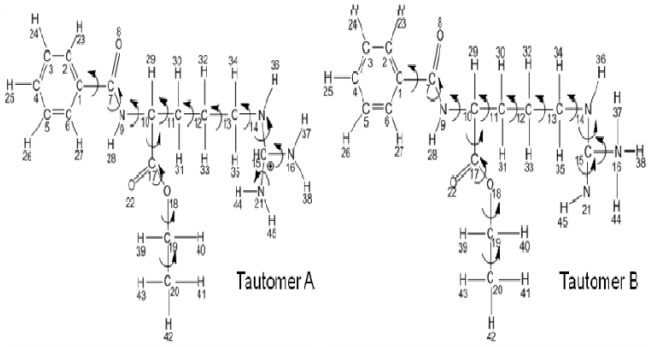

Figure 1 – Schematic representation of the tautomers of BAEE·HCl considered for conformational search. The single bonds indicated by the arrows were chosen for rotation.

For each tautomer shown in Figure 1, fourteen different internal rotation axes that can give rise to conformational isomers were considered in the conformational search procedure, yielding a quite large number of conformers for these compounds. Thus, our first approach was to perform a systematic conformational search on the PES of each tautomer by semi-empirical PM3 method. This strategy allowed the selection of the most stable set of conformations to be submitted to further refinement by more sophisticated theoretical approaches.

The optimized PM3 structures, with relative energies up to *ca.* 3 kJ mol^{-1}, which accounts for fourteen structures for tautomer A and four structures for tautomer B, were used as starting point for DFT calculations carried out at the B3LYP/6-31++G(d,p) level of theory. According to this method, nine conformers, with relative energies up to *ca.* 9 kJ mol^{-1}, were found for tautomer A, whereas for tautomer B only three different conformers were obtained, with relative energies up to *ca.* 2 kJ mol^{-1} (see Table 1).

Table 1 – Relative energies and molecular dipole moments for the most stable BAEE·HCl conformers obtained at the B3LYP/6-31++G(d,p) level of theory.

Tautomer	Conformer	ΔE(kJ mol^{-1})[a]	$\|\mu\|$(D)
A	I.A	0.00	10.34
	II.A	1.37	10.40
	III.A	1.60	10.48
	IV.A	1.63	10.39
	V.A	3.23	10.35
	VI.A	9.32	8.60
	VII.A	65.11	20.76
B	I.B	0.00	6.40
	II.B	1.52	6.24
	III.B	1.82	6.40

[a] The calculated energies for the most stable conformers are -2704385.26 kJ mol^{-1} and -2704220.65 kJ mol^{-1} for BAEE·HCl tautomer A and tautomer B, respectively.

From Table 1 one can observe that the conformers of tautomer A present a higher value of dipole moment than the conformers of tautomer B. This is indicative that tautomer A is more stabilized by polar solvents and this will be the form that will occur predominantly in polar media. It also should be mentioned that the most stable structure of tautomer B (I.B) is less stable than the most stable structure of tautomer A (I.A) by almost 165 kJ mol^{-1}. These facts suggest that the occurrence of tautomer B should be much less probable when compared with tautomer A.

The structures of the most stable conformers, for both tautomers, are depicted in Figure 2.

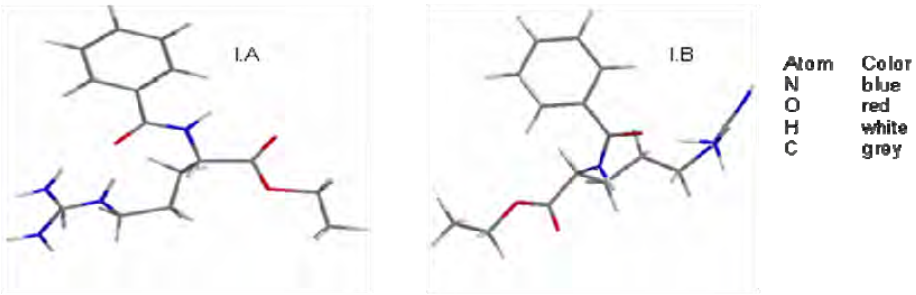

Figure 2- Structures of the most stable conformers of tautomers A and B of BAEE, as predicted by the B3LYP/6-31++G(d,p) calculations.

The most stable DFT conformers for both tautomers have a tendency to form a folded structure (Figure 2). These structures are stabilized by intramolecular H-bonds formed between the guanidine group [$NH_2C(=NH)NH–R$] and the carbonyl oxygen atom of the amide linkage. The remaining obtained low energy conformers follow the same trends.

Based on X-Ray diffraction data (unpublished preliminary results) it is known that in the crystalline phase these BAEE molecules adopt an unfolded structure (see Figure 3). For the isolated molecule, this structure is more energetic than the folded ones by almost 40 kJ mol^{-1} (see Table 1). Thus, the stabilization of this structure in the crystal phase should be explained by a network of intermolecular H-bonds and packing effects.

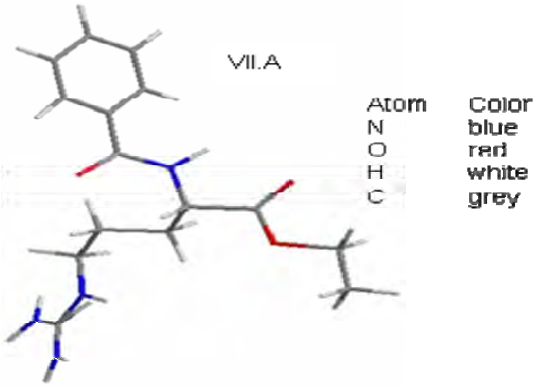

Figure 3- Structure of BAEE present in the solid.

Infrared Spectrum of BAEE·HCl

Figure 4 shows the experimental FT-infrared spectrum of solid BAEE pressed in a KBr pellet in the wavenumber range 3750–600 cm^{-1}, recorded at room temperature. The simulated [B3LYP/6-31++G(d,p)] infrared spectrum of BAEE is also presented (see Figure 3 for the structure chosen in these simulations).

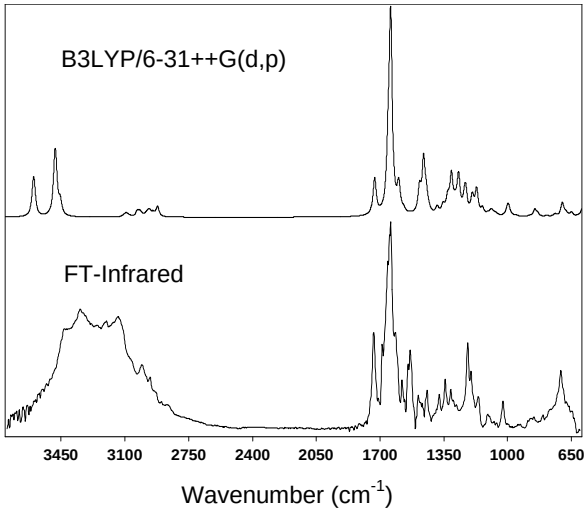

Figure 4- Bottom: experimental FT-infrared spectrum of BAEE·HCl; Top: simulated infrared spectrum of BAEE (see Figure 3) in vacuum calculated at the B3LYP/6-31++G(d,p) in the harmonic approximation. The calculated wavenumbers were scaled down by a factor of 0.965. For the simulation, Lorentzian functions centered at the scaled calculated wavenumbers and with bandwidths at half-height equal to 20 cm^{-1} were used.

Table 2 summarizes some representative experimental and calculated vibrational modes and respective assignments.

Table 2 - Observed (polycrystalline sample pressed in a KBr pellet) and B3LYP/6-31++G(d,p) calculated representative IR data for BAEE.

Experimental	Calculated B3LYP/6-31++G(d,p)		Approximate description
Wavenumbers (cm^{-1})	Wavenumbers (cm^{-1})[a]	IR Intensities (km mol^{-1})	
			GUANIDINE GROUP
3348[b]	3603	136.8	νNH_2 as.
	3599	86.4	νNH_2 as.
	3494	7.4	νNH_2 s.
	3485	214.6	νNH
	3480	166.3	νNH_2 s.
			AMIDE GROUPS
	3455	71.5	νNH_{amide}
			CARBONYL GROUPS
1734; 1711	1729	194.9	$\nu C{=}O_{Ester}$
1688	1654	235.7	$\nu C{=}O_{Amide}$
			GUANIDINE GROUP
1657; 1649;1642	1643	523.1	δNH_2
	1640	523.7	δNH_2
1617	1598	131.2	δNH_2

[a]The B3LYP/6-31++G(d,p) calculated wavenumbers were scaled by a single factor of 0.965.
[b] Broad band whose maximum is at 3348 cm^{-1}.

Since the experiment was done in the solid phase, the simulated spectrum of BAEE was obtained by considering an optimized structure similar to that present in the crystalline phase (see Figure 3). Considering that the calculation is referred to the isolated molecule in vacuum, thus not accounting for crystalline effects (force field, intermolecular H-bonding), the agreement between the experimental and calculated spectra is quite acceptable in a fairly large spectral range.

^{1}H NMR Spectrum of BAEE·HCl

Table 3 summarizes the calculated GIAO [B3LYP/6-31++G(d,p)] and experimental ^{1}H NMR chemical shifts, with respect to TMS, for BAEE.

Table 3- Comparison between calculated B3LYP/6-31++G(d,p) and experimental chemical shifts ^{1}H NMR (ppm) for BAEE, in DMF-D_7.

Protons	Calculated B3LYP/6-31++G(d,p)		Experimental
	I.A	VII.A	
$N\text{-}H_{amide}$	7.81	7.23	8.64
N-H	10.80	4.66	8.22
NH_2/NH_2	4.60/4.51; 7.35/4.38	4.71/4.69;4.59/4.55	7.58
$C\text{-}H_{orto}$	7.63	8.22	7.85
$C\text{-}H_{para}$	8.05	7.99	7.31
$C\text{-}H_{meta}$	7.90	7.76	7.24
$C\text{-}H_{methine}$	4.01	4.83	4.30
$CH_{2\ ester}$	4.70	4.36	3.92
$CH_{2\ (1)}$	3.16	3.20	3.11
$CH_{2\ (3)}$	2.41	1.76	1.79
$CH_{2\ (2)}$	2.22	2.37	1.54
$CH_{3\ ester}$	1.41	1.40	0.98

These results are indicative that the quality of the calculated chemical shifts values is dependent on the presence of H-bonds. In fact, it is for the protons that can actually be involved in intermolecular H-bonds (not accounted in the theoretical calculations) that the agreement between theoretical and experimental results is worse.

4 Conclusions

In this work DFT calculations performed at the B3LYP/6-31++G(d,p) level of theory and IR and ^{1}H NMR spectroscopies were used to investigate the molecular structure of an L-arginine derivative, BAEE·HCl.

The obtained results show that, in the vacuum, the conformers of this compound adopt a folded structure, stabilized by intramolecular H-bonds.

The overall results also clearly suggest that the tautomer A is the predominant species both in the solid and in solution.

Keywords: Blood rheology, Numerical modelling, non-Newtonian
Topic: Advancing the chemical and biological engineering fundamentals

Abstract

A three-dimensional model of the aorta bifurcation of the iliac arteries was used to study numerically the blood rheology influence on the hemodynamics, by using the Carreau-Yasuda model to account for the shear-thinning behaviour of blood. The simulations were carried out with the finite volume method, using the FLUENT computational software. A non-Newtonian model for the fluid viscosity has been implemented for assessing the recirculation zone, and also the velocity and wall shear stress distributions. The vicinity of the iliac bifurcation was characterized by complex flow patterns, such as separation of flow and recirculation, which are believed to play an important role in the atherosclerosis lesions.

1 Introduction

Cardiovascular diseases, such as atherosclerosis, are the major cause of death in the developed countries, and are normally associated with complex blood flow patterns. This disease is characterized by the adhesion of lipidic plaque on degraded endothelium or regions of low wall shear stress (WSS) resulting in the stiffening and thickening of the artery, or stenosis. This occurs mostly in the arteries bifurcations and curvatures, like aorta, iliac, coronary, carotid and femoral arteries. The recirculation, stagnation and separation of the blood flow and the low wall shear stress, which contribute to the plaque deposition, are affected by different factors, such as the artery geometry (Carneiro et al., 2008a) and blood rheology (Carneiro et al., 2008b).

The Computational Fluid Dynamics (CFD) analysis of hemodynamics in complex artery geometries has become an important tool in research. In most of CFD simulations, blood is modelled as a Newtonian fluid, particularly in large arteries, where the influence of shear thinning properties is not so significant. However, the rheological model for blood viscosity is a key factor in the simulation of hemodynamic flows. Rheology models of varying complexity have been proposed to capture the shear-thinning behaviour of blood (Abraham, 2005, Chen and Lu, 2006, Owens, 2006). Gijsen et al. (1999) proved experimentally that the blood flow should be simulated by the Carreau-Yasuda model in the carotid arteries, at both low and high shear stress. It was suggested that the non-Newtonian properties of blood are an important feature in the hemodynamics, which affect the interaction between the fluid and the vessel. This interaction plays an important role in vascular biology and pathophysiology.

The work reported in this paper aims to simulate numerically the influence of the blood rheology, by using the Carreau-Yasuda model, of the hemodynamics on the abdominal aorta bifurcation into the iliac arteries.

2 CFD model

2.1 Space discretization

The flow patterns are described by differential equations that are solved by the finite volume method. This method requires the domain discretization into control volumes. The geometry and the computational mesh were created using the GAMBIT software. A schematic representation of the three-dimensional geometry, considered in this investigation, and the relevant details are given in Figure 1. To reduce the computational time, symmetry is assumed in the medium planes y and z, reducing the computational domain by 75%.

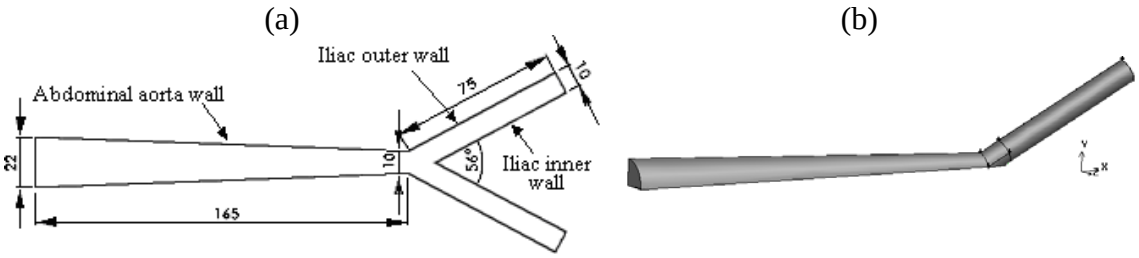

Figure 1. Geometry of the abdominal aorta in the iliac arteries: (a) medium z plane, (b) three-dimensional view.

The abdominal aorta bifurcation of the iliac arteries is modelled as a rigid wall with a circular cross section. This approach enables the subsequent model validation with experimental data.

The number of control volumes is a balance between the desired low computational time and a high precision. The domain was decomposed into four connected subdomains. Specifically, two of these are at the bifurcation region, to refine the local mesh, where higher velocity gradients are expected. Boundary layers were considered at the cross section throughout the entire domain, to refine the mesh near the walls, at the inlet and in the vicinity of the bifurcation. The resulting computational domain for this model was built with 13376 hexahedral elements, such as depicted in Figure 2.

Figure 2. Computational mesh of the model (inlet and z=0 planes).

2.2 Mathematical model

The FLUENT is a computational fluid dynamics software that solves the three-dimensional equations for mass (equation 1) and momentum (equation 2), assuming conservation for each variable:

$$\nabla \vec{v} = 0 \tag{1}$$

$$\frac{\partial}{\partial t}(\rho \vec{v}) + \nabla \cdot (\rho \vec{v}\vec{v}) = -\nabla p + \nabla \cdot (\bar{\bar{\tau}}) \tag{2}$$

where $\vec{v}$ is the fluid velocity vector, ρ is the density, p is the static pressure and $\bar{\bar{\tau}}$ is the stress tensor. The turbulence k-ε model is described by the equations 3 and 4:

$$\frac{\partial}{\partial t}(\rho k) + \nabla(\rho \vec{v} k) = \nabla\left[\left(\mu + \frac{\mu_t}{\sigma_k}\right)\frac{\partial k}{\partial x_j}\right] + G_k - \rho\varepsilon + S_k \tag{3}$$

$$\frac{\partial}{\partial t}(\rho \varepsilon) + \nabla(\rho \vec{v} \varepsilon) = \nabla\left[\left(\mu + \frac{\mu_t}{\sigma_\varepsilon}\right)\frac{\partial \varepsilon}{\partial x_j}\right] + C_{1\varepsilon}\frac{\varepsilon}{k}G_k - C_{2\varepsilon}\rho\frac{\varepsilon^2}{k} + S_\varepsilon \tag{4}$$

where k is the kinetic energy, ε the dissipation rate, μ the viscosity and μ_t the turbulent (or eddy) viscosity. G_k represents the generation of turbulence kinetic energy due to the mean velocity gradients. $C_{1\varepsilon}$ and $C_{2\varepsilon}$ are constants. σ_k and σ_ε are the turbulent Prandtl numbers for k and ε, respectively. S_k and S_ε are user-defined source terms.

2.3 Boundary conditions

The fluid was considered incompressible, non-Newtonian, with the density of 1057 kg/m^3. The inflow is laminar and the generated turbulence was simulated with the k-ε model with enhanced wall treatment. An uniform inlet velocity of 0.234 m/s was assumed. The outflow is equally distributed by the two iliac arteries. The abdominal aorta bifurcation of the iliac arteries is modelled as a stationary wall with no-slip shear condition.

2.4 Numerical discretization and solution

In the finite volume method the partial differential equations are approximated by a set of algebraic equations over the computational domain that is subsequently solved. It was used the standard scheme to solve pressure equation and the second order upwind scheme to solve momentum, turbulence kinetic energy and turbulence dissipation rate equations.

Solutions are obtained iteratively, solving the equations sequentially, using the segregated solver with the SIMPLE algorithm. The convergence is accepted when the residuals are below 1e-05.

3 Blood rheology

The blood, a liquid tissue, circulates in the vascular blood system, maintaining the organism living. It is a complex medium composed by plasma, a Newtonian fluid, and a suspension of various cells, such as erythrocytes, leucocytes and platelets, which are related to its microscopic structures, as aggregation, deformation and alignment of the erythrocytes (Chen and Lu, 2006).The blood cells are about 45% of blood by volume, forming a non-Newtonian fluid, with a shear-thinning viscoelastic behaviour. The rheological model for blood viscosity is a key factor in the simulation of hemodynamic flow. To study the flow patterns that promote the atherosclerosis development the flow was modelled as a non-Newtonian fluid described by the Carreau-Yasuda model.

The shear viscosity (η) is a function of the shear rate $(\dot{\gamma})$ this being written as:

$$\dot{\gamma} = \sqrt{\frac{1}{2}\overline{\overline{D}}:\overline{\overline{D}}} \tag{5}$$

with

$$\overline{\overline{\tau}} = \eta\left(\overline{\overline{D}}\right)\overline{\overline{D}} \tag{6}$$

and

$$\overline{\overline{D}} = \left(\frac{\partial u_j}{\partial x_i} + \frac{\partial u_i}{\partial x_j}\right) \tag{7}$$

where $\overline{\overline{D}}$ is the deformation rate.
The non-Newtonian Carreau-Yasuda shear thinning model used is:

$$\eta = \eta_\infty + \left(\eta_0 - \eta_\infty\right)\left[1 + \left(\dot{\gamma}\lambda\right)^a\right]^{(n-1)/a} \tag{8}$$

where η_0 and η_∞ are, respectively, the upper and lower limiting values of the fluid viscosity, n is the power-law index, λ is the time constant. In this work, the Carreau-Yasuda model parameters, obtained from Gijsen et al. (1999), are: $\eta_0 = 22 \times 10^{-3}$ kg.m^{-1}s^{-1}, $\eta_\infty = 2.2 \times 10^{-3}$ kg.m^{-1}s^{-1}, $a = 0.644$, $n = 0.392$ and $\lambda = 0.110$ s.

4 Results and discussion

The equations and the numerical procedure described above were applied throughout the abdominal aorta bifurcation into the iliac arteries. The velocity distribution, in the vicinity of the bifurcation, is shown in Figure 3.

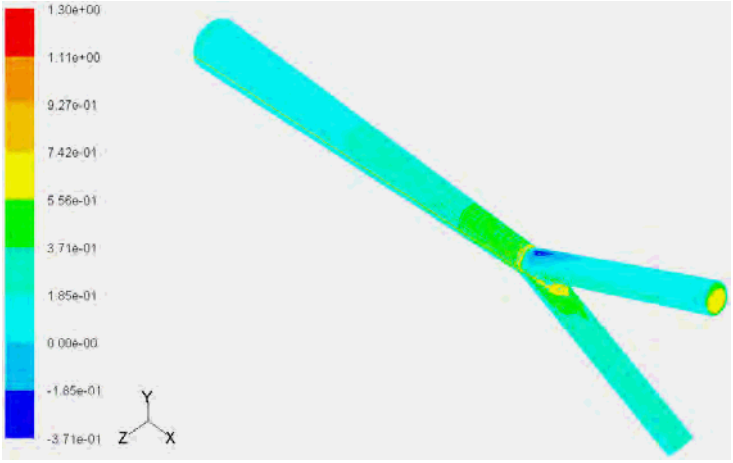

Figure 3. Velocity distribution.

The velocity increases along the abdominal aorta reaching the maximum velocity of 1.2m/s, just downstream the bifurcation. A recirculation zone is developed downstream the bifurcation with flow separation. The recirculation zone disappears and the maximum peak velocity shifts from the inner wall to the iliac artery center, due to the flow development. The wall y^+ is a non-dimensional parameter that measures the refinement mesh at the wall. The wall y^+ distribution, is showed in Figure 4, throughout the geometry.

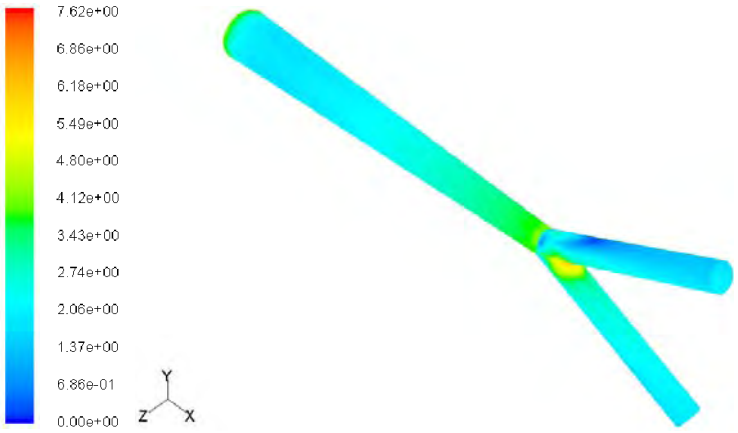

Figure 4. Wall y^+ distribution.

As it is almost less than 5, it indicates that almost of the elements are enough refined. Thus, the present calculations are catching the high gradients expected near the wall. Just for the beginning of the inner wall (177.6-179.3 mm), the wall y plus exceed the limit of 5 (only 1.2% of the elements are from 5 to 6.3). Figure 5 illustrates the detailed velocity vectors, at medium plane z.

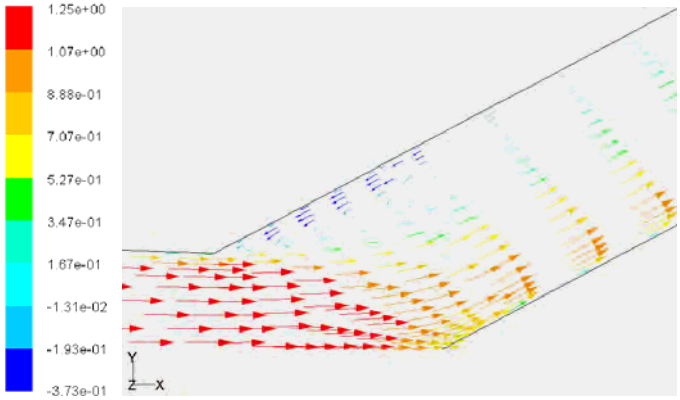

Figure 5. Velocity vectors in the vicinity of the iliac bifurcation.

The flow split into the recirculation zone and the main flow field, that shifts from the center of the aorta to the inner wall of the iliac artery. The recirculation zone is located near the outer wall, from 168.0 to 192.5 in the axial direction, with a length of 24.5 mm. Velocity profiles were obtained at different line locations (at x= 150, 165, 175 and 185 mm, x_1, x_2, x_3, x_4 respectively) in the medium z plane (Figure 6) and can be observed in the Figure 7.

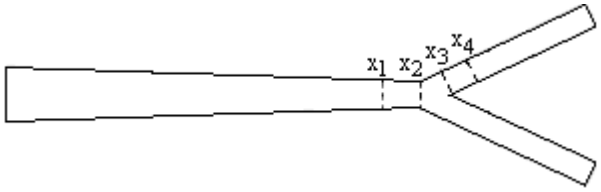

Figure 6. Location of the cross sections for velocity profile analysis.

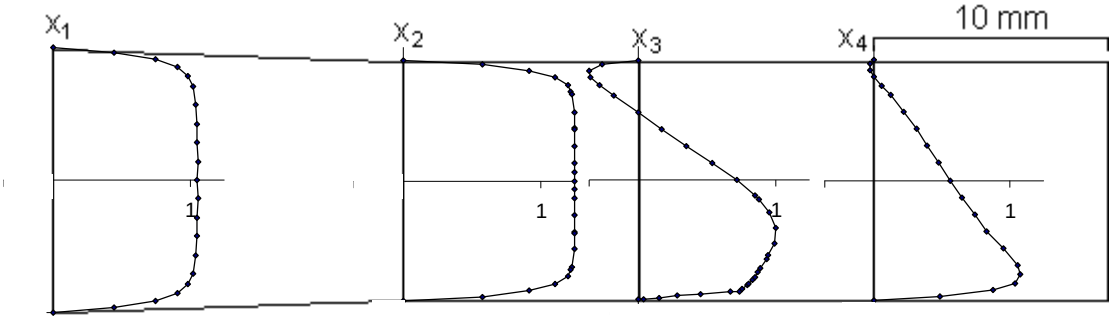

Figure 7. Velocity profiles (m/s) at x_1, x_2, x_3 and x_4.

At x=150 mm the axial velocity has no influence of the bifurcation, but at 165mm there are two slight peaks corresponding to each branch. It indicates the flow separation. Downstream the bifurcation, at the axial position of 175 mm, there is a recirculation zone near the outer wall, due to the flow separation. At the axial position of 185 mm, the recirculation zone is much smaller. Figure 8 shows the WSS distribution along the abdominal aorta and into the iliac arteries.

The WSS increases along the abdominal aorta up to the iliac bifurcation, and decreases along the iliac arteries. However, the maximum peak is obtained at the entrance of the inner iliac artery. At the outer wall, there is a sharp decrease approaching zero in the vicinity of the iliac bifurcation, due to the recirculation zone. The appearance of this low WSS coincides with early intimal thickening in the abdominal aorta.

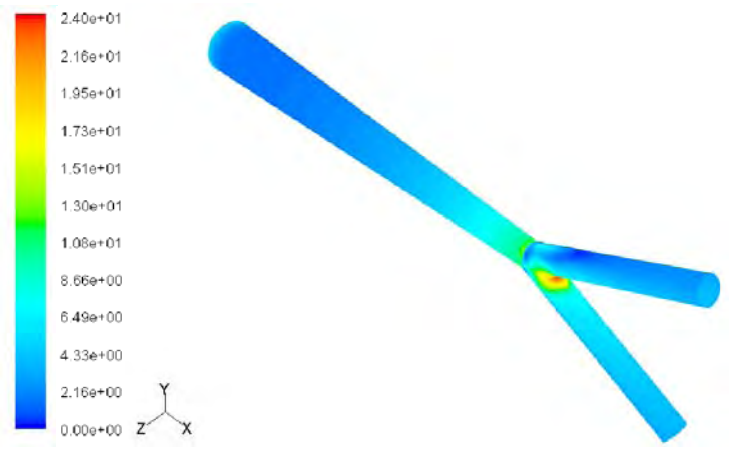

Figure 8. Wall Shear Stress distribution.

5 Conclusions

A numerical CFD model to simulate the blood flow dynamics has been implemented. The flow was modelled as a shear thinning non-Newtonian fluid, described by the Carreau-Yasuda model. There is flow separation and a recirculation zone in the vicinity of iliac bifurcation. The wall shear stress values decreases at the iliac outer wall, in the recirculation zone. These observations are consistent with the observed clinically. The non-Newtonian model assumption is valid for hemodynamic simulations in the abdominal aorta. Further studies should consider the flow unsteadiness to analyse the wall shear stress oscillation through the cardiac cycle.

Topic: Study of Cerebrospinal Fluid Dynamics in a Computational Model of Stenosed Aqueduct

Abstract

In this study we evaluate the cerebrospinal fluid (CSF) dynamic using computational fluid dynamic (CFD) analysis in an anatomical 2D model of a ventricular system. The anatomical basis of our simulation was generated from Magnetic Resonance Imaging (MRI). Stenosed aqueduct, leading to an obstructive hydrocephalus was modeled and the results of CSF velocity in the aqueduct and CSF pressure in the lateral ventricle were compared with those in the normal condition. Modeling the ventricles as flexible components based on solid-fluid interaction analysis for hydrodynamic study is a new approach in our work, enabling a more accurate simulation of CSF flow. The CSF production rate is considered pulsatile and relates to arterial pulsation in the choroid plexus. Since the CSF is a Newtonian fluid, the CFD software was applied to solve the equation of the continuity and momentum for CSF flow. Also the brain tissue was modeled as an elastic compartment. The mesh boundary of the CSF was immersed in a marker and-cell staggered grid to take into account fluid-solid interaction in ADINA software packege. Increase of velocity and an up to two-fold pressure drop were observed due to aqueduct stenosis.

1 Introduction

The cerebrospinal fluid (CSF) has several functions, such as physical support, excretion, intracerebral transport and control of the chemical environment of the central nervous system (CNS). CSF is mostly located in the ventricular system and the subarachnoid space (SAS) and in part is produced by the choroid plexus [1,2]. Pathologic conditions of the cerebrospinal fluid space are usually of a critical nature. Hydrocephalus - an abnormal accumulation of CSF in the brain - is the most prominent of a number of such conditions. Mostly, hydrocephalus is treated by surgical placement of a shunt. There is a need for intelligent shunts that can adjust themselves dynamically to different operating conditions and thereby reduce the number of shunt revisions a patient has to undergo [3]. The aqueduct of Sylvius is a narrow channel connecting the third and fourth ventricle (Fig 1). It is a narrow pathway for CSF flow and hence maybe an important site for development of hydrocephalus.

Therefore, a better understanding of the local hydrodynamics (pressures, velocities, strains, etc.) and the interaction between the CSF and the surrounding brain matter could be valuable for neurosurgeons to predict the efficiency of a highly invasive operation. Also, the computer model could be used to help the medical practitioner decide whether a patient should be shunted and what kind of shunt should be used. With advances in computing, work has been undertaken using CFD to model CSF flow and understand its nature [4-6]. These novel representations yield the distribution of CSF pressure and velocity. Advances in MRI have made it possible to capture significant parts of the geometry of the CSF system, such as the ventricles and their connecting

pathways. Thus, the possibility exists to set up a CFD model of the ventricular space based on accurate geometric information. However, CFD calculations based on accurate ventricular geometry are not straightforward due to the complex shape of the domain. These challenges are compounded by meshing and loading problems in the presently available software packages. These factors strengthen the need for 2D or simple 3D models of human ventricular system (HVS) [3,6,7]. Fin and Grebe [8] have published a three-dimensional CFD model of the aqueduct of Sylvius based on MRI anatomy scans; they found that the deformability of the walls has a strong influence on the pressure drop. In recent work, Kurtcuoglu *et al* [3] evaluate the CSF hydrodynamic in a stenosed aqueduct. In their new approach [9] the cerebrospinal fluid flow was studied in a model of the third ventricle of the brain and the aqueduct of Sylvius, derived from magnetic resonance imaging (MRI) scans, using CFD detailed quantitative information of the flow field in his spaces. This increase in ICP was observed by authors [10-11].

All these models include some simple approximations for their geometries, boundary conditions or input and output values such as CSF constant production rate and rigid condition for the HVS. None of the present models consider the real pulsatile flow pattern underlying choroid plexus expansion, synchronized with the heart beat, the importance of which has been previously described [10-12]. Moreover, for the purpose of simplicity all current models neglect consideration of the solid interaction effect, further limiting their accuracy.

Therefore, the fundamental limitations of recent simulations increase the necessity for the development of sophisticated and comprehensive models. In the present study, an idealized 2D geometry of the HVS from the MRI data, based on our previous study [13] with perfect boundary conditions around the model was constructed. Evaluating the CSF pulsatile hydrodynamic in a stenosed aqueduct in a 2D model based on Fluid–solid interaction analysis in the obstructive hydrocephalus is a new approach in our study. As this is one of the very first reported attempts to model the CSF space and behavior for hydrocephalus case, driven in a practical manner by pulsatile inflow and FSI boundary conditions for HVS, we believe that the qualitative and quantitative data on the pressure and flow patterns in the ventricular system are reliable.

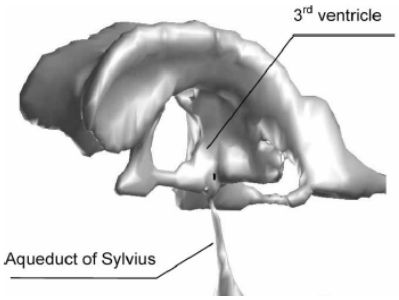

Figure 1: Three dimension representing of

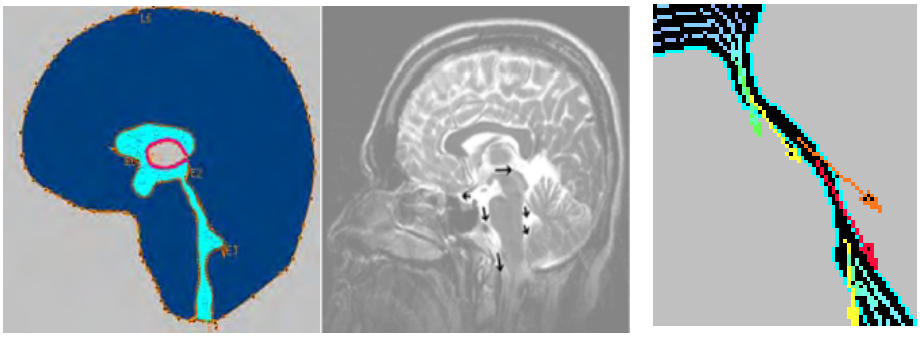
2 Material &Method

Our aim is to use the physical principles of the fluid flow and solid material to quantify intracranial CSF hydrodynamics in the hydrocephalus condition. The procedure is performed in three stages. In step one, MRI techniques are used to accurately define the ventricle geometry. In step two, the MR image is converted into an accurate two-dimensional surface with two models of normal and stenosed aqueduct that are imported into CFD analyzer software. Mesh generation is then used to partition these spaces into a large number of small finite elements. In step three, CFD software solves the equations of fluid motion and solid tissue numerically over the brain geometry.

Table I: Parameters used for CSF fluid and brain tissue

Parameters	value	references
E-Young modulus	14-30 kPa	[13]
ν-Poassion's ratio	0.49	[11]
μ-CSF viscosity	0.001003 (Pa.s)	[11]
ρ-CSF density	1000-1007 kg/m^3	[4,11]
ρ_w-brain tissue density	Specific gravity: 1.02	Web

Figure 2 shows the 2D model of the HVS with and without stenosis. The JPEG pictures were imported to the CATIA 5.16 software. The models in IGES format were meshed in ADINA software (ADINA^{TM}, version 8.2, Automatic Dynamic Incremental Nonlinear Analysis, Watertown, MA). Solid components have been constructed in ADINA and the fluid segment in ADINA-F domain. The values of physical constants used in our model are depicted in Table I. For the solid, a rule-based mesh of 10065 point and 3665 rectangular solid elements of the plane strain type and for the fluid sub domain, a rule-based mesh of 1734 points and 300 rectangular elements were used in normal model.



(a) (b) (c)

Figure 2: (a) 2D model of normal case (b) the MRI scan and (c) a model of 50% Stenosed aqueduct

The elements are arranged so that the aspect ratios are reduced in elements which are under compression to achieve higher compression strength. This avoids potential issues with overlapping of solid and fluid elements in the ALE mesh when deformation in the compression direction is imposed to fluid elements. ALE formulation and leader and follower points are used to keep the mesh quality in fluid elements during the solution time. A mesh with rectangular elements will lead to a good convergence.

CSF motion is described by the equations of mass and momentum conservation for an incompressible Newtonian fluid. These conservation balances lead to a system of partial differential equations known as the continuity and the Navier-Stokes equations. The governing equations for CSF flow are given in vector form by equations (1) and (2) as shown below. The surrounding tissue was modeled as an elastic compartment and for mathematical modeling the Arbitrary Lagrangian-Eulerian (ALE) formulation is used as the governing rule. This yields in formula (3). For solving the problem with Fluid-Solid interaction (FSI), the compatible kinematic and dynamic conditions in solid–fluid boundary should be defined.

Conservation of mass:

$$\nabla.\mathrm{u} = 0 \qquad (1)$$

Conservation of momentum:

$$\left(\left(\mathrm{u} - \mathrm{u}_{\mathrm{g}}\right).\nabla\right)\mathrm{u} = -\frac{1}{\rho}\Delta\mathrm{p} + \upsilon\nabla^{2}\mathrm{u} \qquad (2)$$

Lagrangian-Eulerian (ALE) formulation:

$$\frac{\partial \tau_{ij}^{s}}{\partial x_{j}} = \rho^{s}\frac{\partial^{2} d_{i}^{s}}{\partial t^{2}} \qquad (3)$$

Many studies confirm the pulsatile CSF production pattern relate to the heart beat and its effect on CSF hydrodynamic [8,10]. The bulk CSF production is implemented as input flux at the choroid plexus. This amount is considered 600 ml/day. The frequency of the pulsatile motion is set to 1 Hz approximating the normal cardiac cycle [10].

Therefore the CSF generation in choroid plexus is as follows:

$$q(t)=q_{bulk}+q_{ulse}(t) \qquad (4)$$

$$q_{bulk}=constant \qquad (5)$$

$$q_{ulse}(t)=\alpha[\sin(\omega t-\pi/2)-1/2.\cos(2\omega t-\pi/2)] \qquad (6)$$

The expansion of the vascular bed also causes the displacement of CSF from the cranium into the spinal SAS. For simplification we considered a partial pressure (zero value) at the end of Magendie foramina [4]. The results of the CSF analysis are the flow rate, velocities, and intracranial pressure (ICP) gradients of CSF in the ventricular system. Obtaining the volume changes of lateral ventricle (LV) from FSI condition is the new approach which was accessible with a deformable system modeling.

3 Results

Fig 3 shows the pressure contour for both cases. The ICP is highest in the LV and lowest in the Magendie foramina during systole. The pressure gradients within HVS never exceed 3 Pa. The highest CSF velocity occurs within the cerebral aqueduct reported as -2.5/+8 mm/s and the pressure drop along the region reaches 1.5 Pa in systolic time for normal case. However, there are a number of regions within the HVS that have CSF flow velocity about zero. In the hydrocephalus case, the results of pressure drop and velocity magnitude of the aqueduct region are almost two times larger than the normal condition. Volume changes of the LV of about 5% were observed in the case of hydrocephalus. Moreover the stenosis also affects the CSF flow pattern. While clinical evidences also validate the reverse flow of CSF in the aqueduct in diastolic time [11], the observation showed that there is no backflow in diastolic time in the case of hydrocephalus.

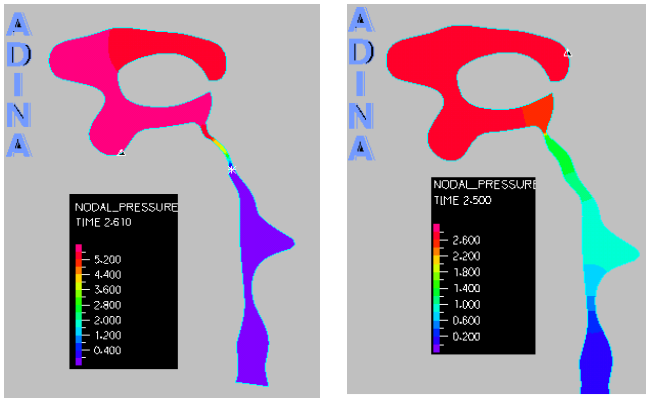


Figure 3:Pressure distribution in normal (left) and stenosed model (right)

The results of CSF pressure and velocity are depicted in Table II of both conditions for comparison.

Table II: CSF pressure and velocity in HVS for normal and Stenosed case

parameter	Normal	Stenosed	Published difference
Aqueduct velocity	-2.5 - 8.5 mm/s	0-6 mm/s	20%-50% [11,3]
Magandy velocity	3 mm/s	4.5 mm/s	
Monro velocity	2 mm/s	2 mm/s	
AS pressure drop (Pa)	4	1.1	2-10 times
Total Pressure drop (Pa)	5.8	2.6	10%-50% [11,3]
Expansion Vertical	5%	1%	2 times

4 Discussion

Linninger *et al* [11] are currently, to the best of our knowledge, the only group to have published a 2D, CFD model of the intracranial system with the base of CSF pulsatile production in order to obtain the CSF hydrodynamic pattern. However, in their model the approximation of boundary conditions remaines; a 2D model of the HVS considering surrounding brain tissue as intracellular fluid is an example. Therefore, in this study we declare a model with fewer limitations and more accuracy for simulation of CSF flow that is able to calculate ventricular wall displacement and evaluate hydrocephalus condition for the first time.

The main difference between the model with and without stenosis lies in the amplitude of the lateral ventricle (LV) displacement, which decreased while the LV volume increased. In the present configuration with the aqueduct cross-sectional area reduced 50% a maximum relative pressure increase of 46% is observed (Fig 4).

The stenosis also led the velocity to increase in the aqueduct. At the smallest cross section, the maximum velocity increased by 50%. Hence, aqueduct stenosis might not only indirectly damage the ventricular walls through the development of hydrocephalus, but also directly increase the amplitude of the CSF pressure oscillation and velocity magnitude. This shows that single ventricles or pathways should, in general, not be modeled detached from the remainder of the system. The results are in good agreement with Kurtcuoglu's stenosed model [3].

Topic: Advancing the chemical and biological engineering fundamentals.

Abstract

Over the last years, allergic diseases, particularly asthma, have been acquiring an increasing importance in the developed countries, due to the rising of its prevalence and morbidity and the economic burden associated. In the preventive and urgent treatment of asthma, the oral pharmacological therapeutics assumes a major role. Therefore, this paper will report another step further to the research been undertaken at the University of Minho, to understand the behaviour of drug flow inside a spacer device, combined with pressurized metered-dose inhalers (or pMDIs), based on the use of Computational Fluid Dynamics (CFD) tools to study multiphase flows inside a Volumatic® spacer device.

1 Introduction

For children with less than seven years, the main mechanism of drug distribution has been the use of pMDIs coupled with spacers, since it minimizes the problems of a poor technique of inhalation associated with the use of pMDIs. Indeed, they are often reported to achieve a better drug delivery to the lungs than pMDI alone (O'Callaghan and Barry, 2003).

Spacer devices have a port at one end to which the pMDI is attached and a mask or mouthpiece fitted at the other end. These devices constitute a volume into which the patient actuates the pMDI and from which the patient inhales, without necessarily having to coordinate both actions. By acting as an aerosol reservoir, these devices slow the aerosol velocity and increase transit time and distance between the pMDI actuator and the patient's mouth, allowing particle size to decrease (Newman, 2005).

Thus, it is essential to identify all the spacer characteristics that may optimize the drug distribution to the low respiratory tract combined with a reduced drug loss inside the spacer, in order to achieve more efficient treatments in young children.

The purpose of the present study is to use CFD tools in order to develop a tridimensional computational model of the Volumatic® spacer able to predict the flow patterns during the respiratory cycle, in order to compare with the experimental results.

An Eulerian-Lagrangian approach has been taken in simulating the dispersed phase. The drug droplets are treated as inert particles.

2 The Analysed Spacer

The selected spacer for the CFD analysis, reported in this paper, was the Volumatic® (750 ml, Glaxo Wellcome Inc.), as highlighted in Figure 1. The Volumatic® is a high volume spacer made only of polycarbonate that is susceptible to the electrostatic charge. On the other hand, it is one of the most commonly used spacers in all countries as well as in the Portuguese public hospitals.

Figure 1 – The Volumatic® spacer.

3 Model and Numerical Formulation

The geometric model used in the simulations was created in Gambit™. A computational mesh of finite volumes was created for the spacer, and the boundary conditions were defined: inlet, outlet and wall. The meshes were imported to the FLUENT™, where the continuity and momentum equations were solved, as well as, the turbulence equations. The software also allowed the solution processing.

3.1 CFD Model

Figure 2 highlights different views of the Volumatic® spacer. Due to the symmetrical shape of the spacer and in order to reduce the processing time, the computational domain was reduced to one quarter.

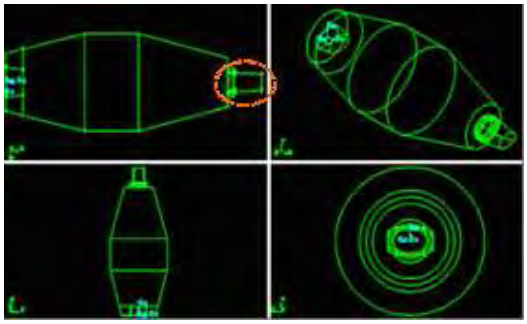

Figure 2 - Representation of the Volumatic® spacer, with the mouthpiece region located in the first view.

3.2 Mesh

The numerical mesh was created with a number of elements that did not compromise the precision of the results and, simultaneously, allowed reasonable computational times. Figure 3 shows the final mesh generated for the Volumatic® spacer, using the Hexahedral/Wedge Cooper scheme with different intervals, resulting in a 3D computational grid with 65326 hexahedral elements.

(a)  (b) 
Figure 3 - Computational grid for the Volumatic®, with (a) the body and (b) the mouthpiece.

3.3 Mathematical Model

The air flow is considered incompressible, Newtonian, in transient state and turbulent.The mass conservation equation, often called the equation of continuity is expressed as follows (FLUENT INC., 2005):

$$\frac{\partial u_i}{\partial x_j} = 0 \qquad (1)$$

in which u_i is the mean velocity in the direction i, with $i = x, y \text{ and } z$.

The velocity field is described by the Navier-Stokes equations (equation 2). They describe the principle of momentum conservation for a Newtonian fluid in turbulent regime (FLUENT INC., 2005):

$$\rho \frac{\partial u_i}{\partial t} + \rho u_j \frac{\partial u_i}{\partial x_j} = -\frac{\partial p}{\partial x_i} + \frac{\partial}{\partial x_j}\left[\mu\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} - \frac{2}{3}\delta_{ij}\frac{\partial u_l}{\partial x_l}\right)\right] + \frac{\partial}{\partial x_j}\left(-\rho\overline{u_i' u_j'}\right) + S_D \qquad (2)$$

where ρ is the air density, p the static pressure, μ the air viscosity, the term $-\rho\overline{u_i' u_j'}$ is called the Reynolds stresses and the last term represents the source terms due to the presence of particles/droplets.

Turbulent flow was simulated through the renormalization-group (RNG) *k-ε* model with enhanced wall treatment.

In Fluent, the trajectories of a discrete phase particle (droplet) are predicted by integrating the force balance on the particle which is written in a Lagrangian reference frame, for the x-direction in Cartesian coordinates, as:

$$\frac{du_D}{dt} = F_D(u - u_D) \qquad (3)$$

where u_D is the particle (droplet) velocity. The first term in the right side of equation (3) accounts for the drag force and F_D is the drag force, given by:

$$F_D = \frac{18\mu}{\rho_D d_D^2}\frac{C_D \,\mathrm{Re}}{24} \qquad (4)$$

where μ is the molecular viscosity of the fluid, d_D is the droplet diameter and ρ_D is the droplet density.

3.4 Boundary Conditions

The air inlet velocity in the spacer was calculated based on the respiratory cycle performed by the patient during the inhalation. Figure 4 shows, in detail, the inhaler adaptor face (in grey) where the air inlet occurs during the inspiration.

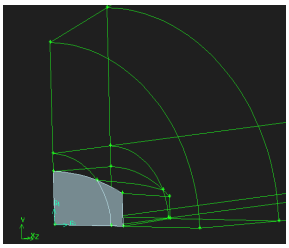

Figure 4 - Representation, in grey, of the zone defined with the boundary condition of velocity inlet in the Volumatic®.

This zone corresponds to the inlet boundary condition where the function of the respiratory velocity of a child (as expressed by Boron, 2003), has already been shown elsewhere for two tested spacers (Abreu et al., 2008a, b). Figure 5 shows this sinusoidal function and also the time instants reported the study of the periodic air inlet, namely 0.4 s (ascending phase), 1 s (maximum velocity inlet), 1.6 s (descending phase), 2 s (beginning of expiration), and 4 s (beginning of inspiration).

The fluid was taken as air at atmospheric conditions. The dispersed phase was defined in the mathematical model as a continuous injection of inert particles with an inlet velocity of 40 m/s.

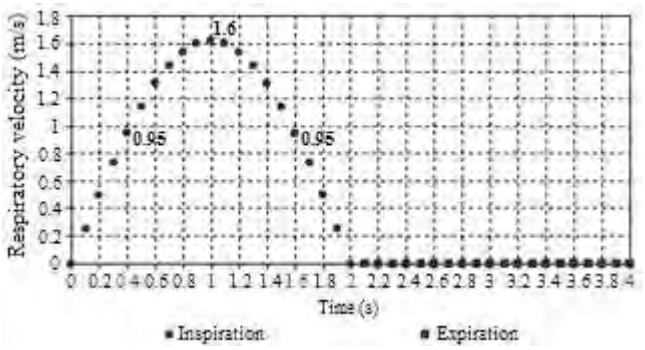

Figure 5 - Periodic velocity in a respiratory cycle, defined in the inlet face of Volumatic®.

3.5 Solution Procedure

In this study, the differential equations for pressure and velocities were solved in a sequential manner, using the SIMPLE (Semi-Implicit Method for Pressure-Linked Equations) algorithm (FLUENT INC., 2005). The air flow was assumed as transient and the first order implicit method was used in the discretization of the temporal derivative. The second order implicit method was applied in the momentum and turbulence equations discretization. FLUENT™ solves the continuity and momentum equations in every control volume of the domain (FLUENT INC., 2005). The mass and momentum conservation is tested at the end of each iteration, and the solution is accepted when the defined convergence criterion (in this case 10^{-3}) is achieved.

4 Results and Discussion

Figure 6 represents the axial velocity along the centerline of the Volumatic® spacer, considering only the continuous phase (black profile) and the biphasic flow (red profile), respectively, for the instant of 0.4 s after the beginning of the respiratory cycle.

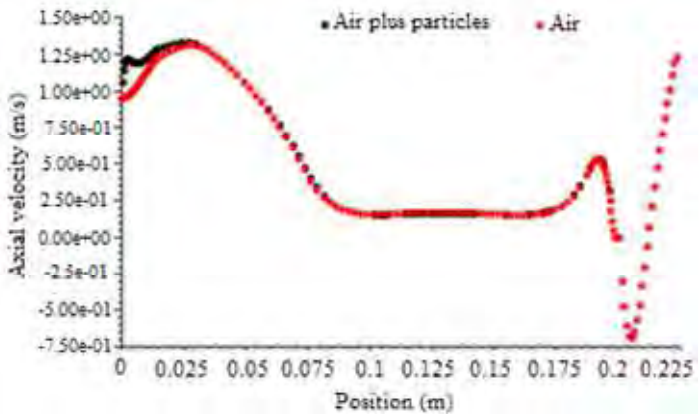

Figure 6 - Comparison between the profiles of axial velocity along the centerline, considering only the continuous phase (black profile) and the biphasic flow (red profile), respectively, for the instant of 0.4s.

It is possible to observe that the profiles of axial velocity along the centerline associated with the monophasic and biphasic flow are practically overlapped with only a small difference on the initial part of the spacer, where particles are injected. On the other hand, it is also noted the existence of recirculation region in the two profiles, between, approximately, 0.2 m and 0.218 m (corresponding to the zone of the mouthpiece).

The profiles of axial velocity inside the Volumatic® spacer for the evaluated five instants of the respiratory cycle are depicted in Figure 7.

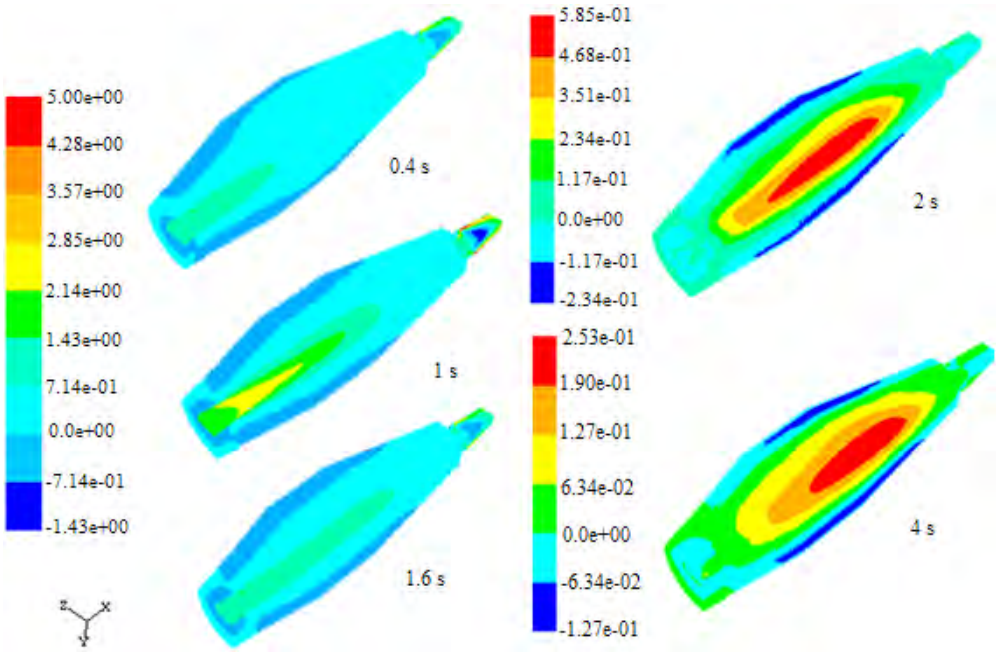

Figure 7 - Isokinetic profiles of axial velocity (m/s) in the Volumatic®.

It is observed that for the three instants of the inspiratory cycle, as the flow moves towards the final part of the spacer its velocity decreases, and increases again close to the cylinder that connects the spacer's body and mouthpiece, reaching the maximum velocity near the wall of the mouthpiece. As expected, the velocity reaches a maximum value, of approximately 5 m/s, when the inlet velocity is also the highest, which

happens after 1 s. On the other hand, the maximum velocity reached in the mouthpiece, after 0.4 s and 1.6 s, is approximately the same and assumes a value of 3 m/s. Also according to Figure 7 there are no significant differences detected for the recirculation zones in the three studied instants of inspiration. These zones are essentially localized next to the top of the wall of the spacer body.

For the instant of 2 s after the beginning of the respiratory cycle, as observed in Figure 5, the expiratory period performed by the patient starts and lasts till the instant of 4 s. In this instant, an anti-return valve located on the mouthpiece prevents the air entry through the adapter.

In opposition to the instants previously analysed, the highest velocity at 2 s (approximately 0.6 m/s) is located in the central part of Volumatic® (see Figure 7). This observation reveals that the closing of the valve, which occurs during the expiration, is being correctly simulated, since the fluid is forced to remain inside the spacer during this period and the velocity in the zone of the mouthpiece is near zero.

At the end of the respiratory cycle (see again Figure 7), it is observed that the fluid inside the spacer is practically stagnated, with a maximum velocity of about 0.25 m/s, located in the constant section of the Volumatic®'s body.

These numerical results are being compared with the experimental results obtained in vitro concerning the deposition of salbutamol sulphate in the spacer, through a simulator of the respiratory tract (Abreu et al., 2008c).

5 Conclusions

From the results obtained so far using Fluent™ simulations, it is possible to conclude that the spacer shape influences the air flow. Several recirculation zones were observed in the spacer for different instants of the respiratory cycle. These zones are essentially localized next to the wall of the spacer body, in other words, in these zones it happens a higher deposition of drug particles.

Computational Fluid Dynamics (CFD) behavior of Water Flow in a Packed Column Filled with Spherical Particles

Bardia Hasanzadeh[1],Morteza Baghalha[1*], Hamed Shahsavan[1], Seyed A. Monemian[2]

[1] Sharif University of Technology, Department of chemical and Petroleum Engineering
[2] University of Tehran, School of Chemical Engineering

Keywords: Simulation, Computational Fluid Dynamics, Packed Column, Porosity.
Topic: Multi-scale and/or multi-disciplinary approach to process-product innovation

Abstract

Water flow behavior in a packed column was modeled based on computational fluid dynamics. The parameters of Ergun's equation were modified by applying the CFD results into the empirical Ergun's equation. The range of Reynolds number considered in the present CFD work was far wider than that already obtained experimentally that are reported in literature.

Introduction

Nowadays expensive process operations can be simulated by Computational Fluid Dynamics (CFD) with considerable reduced expenses. The modeling of flow patterns in porous media has attracted many attentions due to the complication of simulation (Puncochar et al., 2002, Nemec et al., 2005). Ergun's equation (1952) explains the pressure drop in a random structured bed. He showed that the equation satisfies the experimental data for cylindrical, spherical and crushed packing in a wide range of Reynolds numbers. In the present work, the pressure drop of fluid water was investigated in a packed column of spherical particles as well as the effect of roughness of the wall. Also, validity of experimental parameters of Ergun's equation was verified using CFD. Finally, the analytical data were compared to experimental data.

Modeling and Simulation

The geometry of porous media was generated in Solid Works software as the preprocessor. Figure 1 (a) depicts the geometry of porous media. It is composed of a column packed with spherical particles with free spaces at the beginning and the end of the column.

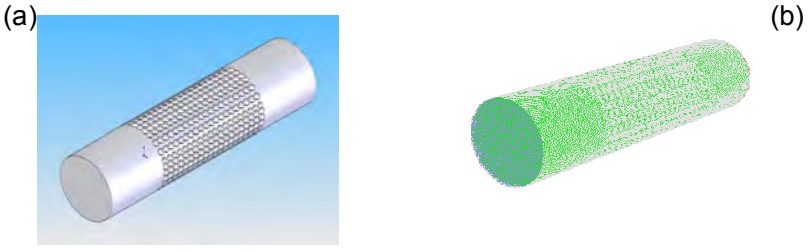

Figure 1. The geometry (a) and meshing (b) of column packed with spherical particles

The free space at the beginning makes the inlet stream to be uniform and such a space at the end of column prevents the formation of vortices. The mechanical characteristics

* Corresponding author. Tel (+98-21) 6616-4577 E-mail: baghalha@sharif.edu

of the model is as follows: total length: 0.6 m, porous length: 0.298 m, Inlet (outlet) empty space: 0.151 m, bed to particle diameter (D/dp): 9.625 and porous volume of the bed: 46.9 %. The arrangement of the packing is a state between random arrangement and ordered one. The contact area between the spherical particles is defined to be a circle i.e., the packing is not complete spheres in agreement with experimental conditions.

After meshing of such a complicated volumetric model (see Figure 1 (b)), the meshed geometry was examined to ensure the agreeable quality of the meshing. Then, it was exported to Fluent software as the processor. The solver was three-dimensional double precision (3ddp) and due to incompressibility of the water, the solving method was selected as implicit segregated. The flow calculation was done using $K-e$, laminar and Realizable $K-e$ models. After determining the physical properties of the fluid and the boundary conditions, the problem should be initialized. The solving procedure was iterated until the convergence criteria were obtained.

Results and Discussion

The present simulation results in 28 descritized points that half of them are related to the smooth wall condition and the others are related to the glass lined wall with roughness height of 0.3 mm. The solver took 5 h to converge for any of these points. Experimental parameters of Ergun's equation were modified by the CFD. Also, the analytical data were compared to experimental data based on a previous work done by Rumpf et al. (1971). As observed in Figure 2, the analytical data fits well the experimental data. It is noticeable that Ergun's equation overestimates the pressure drop.

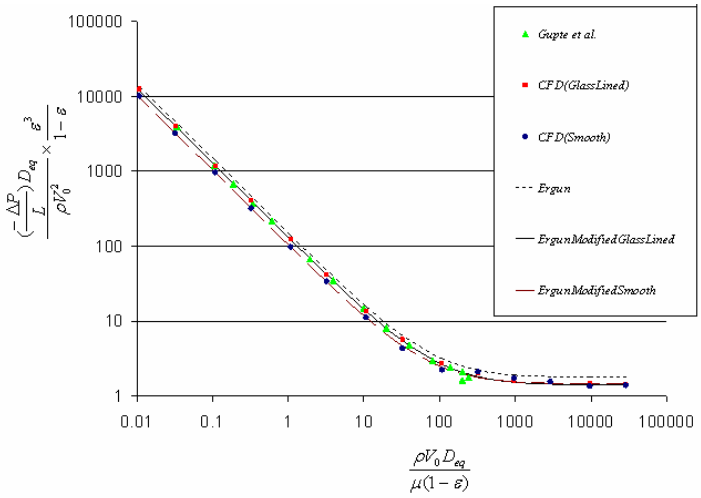

Figure 2. Comparison between experimental (Rumpf et al., 1971) and analytical data

Conclusion

Water flow behavior in a packed column was modeled based on computational fluid dynamics. The parameters of Ergun's equation were modified by applying the CFD results into the empirical Ergun's equation. The range of Reynolds number considered in the present CFD work was far wider than that previously existed in literature. The obtained CFD results were in good agreement with the available experimental data in literature.

Abstract

Liquid phase SFE has been carried out mainly in packed extraction columns, with structured packings particularly of the gauze type. Structured packing performs very well during extractions under these conditions, mainly due to their relatively large surface area and free volume. Nevertheless, there are also important disadvantages such as high cost, low capacities at high flow rates, premature flooding, and entrainment of the liquid phase due to low density differences [1]. The assessment of the real efficiencies of these packings poses extreme difficulties related to the moderately high pressures involved in these processes. Computational Fluid Dynamics (CFD) can be used to characterize the complex multiphase flow inside the packed bed and evaluate the influence of the shape and geometry of the packing on the hydrodynamics and mass and heat transfer rates in the SFE packed column [2]. The final objective of our work is to model the complex transport phenomena present in SFE columns with structured packing in order to predict rates and to optimize the process. The first stage, presented here, consists in an accurate modelling of the hydrodynamics inside the relatively complex geometry of the structured packing. The current paper presents a CFD model to predict the pressure drop in these columns; the results are compared to a wide variety of experimental data available in the literature.

This model was applied to the study of Sulzer EX structured gauze packing. For that purpose two different geometrical models were developed. A simpler one which consists of two contacting corrugated packing sheets (two packing sheets model), includded in a box. This geometry tries to mimic the volume existent between two packing sheets.The other one, more complex, which consists of thirteen packing sheets forming a packing element (packing element model).

To validate the geometric model comparisons were drawn between simulation results and the data of Stockfleth and Brunner [12,13], Meyer [14] (carbon dioxide at 313K,10.1<P<13.1) and Olaño *et al* [15] for data obtained with air at ambient pressure.

1 Introduction

Liquid phase SFE has been carried out mainly in packed extraction columns, with structured packings particularly of the gauze type. The assessment of the real efficiencies of these packings poses extreme difficulties related to the moderately high pressures involved in these processes. Computational fluid dynamics (CFD) can be very helpful to characterize the multiphase flow inside the packed bed and evaluate the influence of the shape and geometry of the packing on the hydrodynamics and mass and heat transfer kinetics of the SFE packed column. One main and very important advantage of using CFD simulation is its potential to reduce the extent and number of experiments required to describe such a type of flow.

Among the numerical investigations on the flow behaviour in structured packing, Hodson *et al.* [3] used CFD to simulate the flow pattern of the vapor phase on the micro-scale. Van Gulijk [4] presented a simplified “Toblerone” model of a packing sheet to investigate the transversal dispersion behaviour in structured packing. Von Scala et al. [5] centered their

study on the hydrodynamics and energy transfer inside structured packing; for that purpose they produced a model incorporating three different types of flow: inside the valleys of the corrugations, flow crossing the valleys, and ideal mixture. The proposed geometry was rather simple and the calculations were made for four staggered packing elements. Based on van Gulijk´s work, Higler *et al.* [6] and van Baten et al. [7,8] studied the liquid phase mixing and mass transfer within a catalytic packed bed reactor which contained Katapak-S structure. Petre et al. [9,10] considered the structured packing layers as the combination of four representative elementary units (REU), simulated the hydrodynamics in each REU using three-dimensional CFD and reconstructed the overall pressure drop in single gas-phase flow. Haghshenas *et al.* [2] modelled a whole packing module and determined its pressure drop, these authors also studied the mass transfer inside structured packing by using a two sheet model in counter-current gas-liquid flow.

The final objective of our work is to model the complex transport phenomena present in SFE columns with structured packing in order to predict rates and to optimize the process. In this first stage, a very accurate modelling of the single phase hydrodynamics inside the relatively complex geometry of the structured packing is presented. The porosity of the gauze packing is explicitely taken into account using a porous media formulation and considering the specific thickness of the packing sheets.This very detailed model can run under both laminar and turbulent flow conditions and for supercritical fluids. To our knowledge this is the first time that a packed supercritical extraction column is modeled with such detail. Another important issue is the compromise between a three-dimensional model of the entire packing, and which will be much more CPU time consuming and a model of just one or two layers of packing which will yield results much faster. Here we present these two CFD models to predict the dry pressure drop in SFE columns; the results are compared to a very wide range of experimental data available in the literature.

2 Problem formulation and numerical simulation

As indicated above, two CFD models are used to predict the dry pressure drop of a structured packed column running at supercritical conditions. The structured packing inside the column is SULZER EX, with the characteristics listed in Table 1.

Column internal diameter: 24mm	
Packing	SULZER EX
Material	Gauze
Fractional void volume, ε	0.86
Specific surface area, a_s [m^2/m^3]	1710
Particle diameter, d_p [mm]	0.4912
Hydraulic diameter, d_h [mm]	1.886
Inclination angle, α [deg]	45

Table 1- Geometric data of SULZER EX structured gauze packing

The characteristic diameter of the channels, d_p, and the hydraulic diameter, d_h, are defined as follows:

$$d_p = \frac{6(1-\varepsilon)}{a_s} \quad (1)$$

$$d_h = \frac{4\varepsilon}{a_s} \quad (2)$$

where ε is the fractional void volume of the packing and a_s is the specific surface area.

The two proposed geometrical models for the simulation consist (i) of two contacting corrugated packing sheets (two packing sheets model), included in a box, and (ii) of thirteen

packing sheets forming a packing element (packing element model). The first geometry tries to mimic the volume existent between two packing sheets, and the second tries to mimic a whole packing element.

The commercial CFD software package, Fluent v.6.3, was used to predict the velocity profiles and pressure drop inside the packing. Under turbulent flow conditions, a modification of the standard k-ε model [11] was employed with standard wall functions. This modified turbulence model differs from the standard one in that it contains a new formulation for the turbulent viscosity and a new equation for the dissipation rate. In all of our simulations the fluid was considered to be Newtonian, incompressible and isothermal, the properties of the fluid were assumed constant and its thermophysical properties were taken from NIST Database.

The geometry of the first model corresponds to two packing sheets included in a box. A bottom-up strategy was used to generate the computational grid. First the vertices of the grid were defined, then the vertices were linked by lines, the lines generated surfaces and finally the surfaces originated volumes. This computational domain is composed of about 1 million tetrahedral cells (applying a mesh with hexahedral cells turned out to be very difficult due to the extreme complexity of the geometry). The smallest element of the grid has a dimension of 0.31mm. Figure 1 shows a top view of the Sulzer EX packing. The region within the white rectangle is modelled by the grid shown on the second part of the figure.

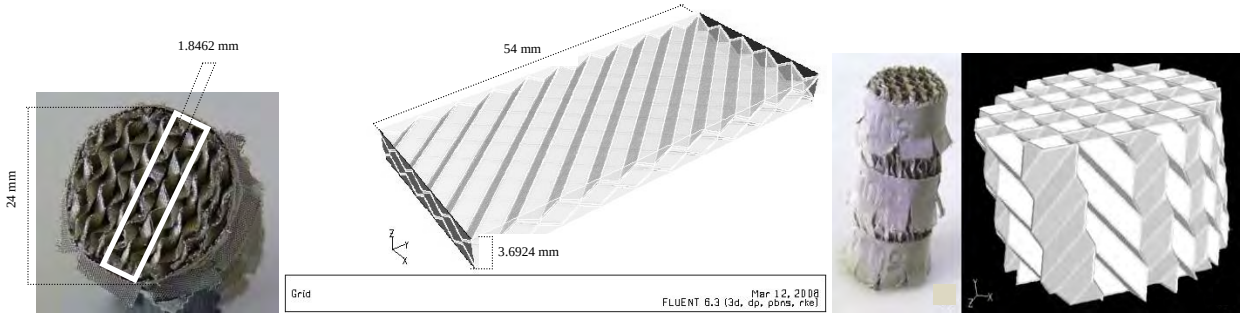

Fig. 1- Sulzer EX packing and computational grids

The walls of the box in the *x*-direction are modelled as solid walls with no-slip boundary condition while the walls in the *z*-direction are modelled as translational periodic to account for the effect of neighbouring packing sheets. At the bottom, the gas inlet is defined as velocity inlet with an imposed uniform velocity profile. At the upper side, the gas exit was defined as pressure outlet boundary condition. The packing sheets have a thickness of 0.31mm and were modelled using the porous media formulation of FLUENT [11]. This porous media formulation incorporates an empirically determined flow resistance in the region of the model defined as porous. In essence this is nothing more than an added momentum sink in the governing momentum equations. It was also assumed that there is continuity of the velocity vectors across the porous media interface.

The second model or packing element module, consists of thirteen porous sheets stacked together forming a packing element contained in a cylinder to mimic the column wall. Due to computational power constraints only one third of the actual packing element was modelled (see third part of Fig.1).

The porosity of the porous sheets was modelled by the addition of a momentum source term to the standard fluid equations for the computational cells corresponding to the sheets. The permeability, α, which contributes to the viscous loss term, and the inertial resistance factor, f_R, were determined experimentally as discussed below. The boundary condition at the wall of the column was defined as a no-slip boundary condition.

To derive the input data for the porous region, we measured experimentally the pressure drops produced by water flowing inside a straight empty tube and flowing in the straight tube with a single sheet of the packing. Measurements of the pressure drop were made for

several liquid velocities and the data was represented in a plot of pressure drop versus flow Reynolds number. The mass flow rates of water were measured by simply measuring the volume of liquid falling into a collecting vessel during a determined time interval.

The actual pressure drop, Δp, produced by the packing sheet was obtained by subtracting the empty tube pressure drop from the one obtained for the tube plus the packing sheet. The coefficients for the viscous and inertial resistance factors of the porous sheet were obtained by fitting the experimental data to:

$$\Delta p = -\left(\frac{\mu}{\alpha}u + \frac{1}{2} f_R \rho u^2\right)\Delta s \qquad (13)$$

where Δs is the thickness of the sheet. From the fitting the following values were obtained $1/\alpha = 1.26\times10^{10}$ and $f_R = 6214.58$.

3 Results and Discussion

In order to validate both computational models we proceeded to simulate the pressure drops measured by different authors, Stockfleth and Brunner [12,13], Meyer and Brunner [14], and Olaño et al [15].

3.1 Data of Stockfleth and Brunner and Meyer and Brunner, Two Packing Sheets and Packing Element Models with CO2 at supercritical conditions

Similar to the pressure drop in tubes, the pressure drop over the packing is a function of the resistance factor and the dynamic head. In the next plot one can see a comparison of the experimental results obtained by these authors and the ones generated in the simulations:

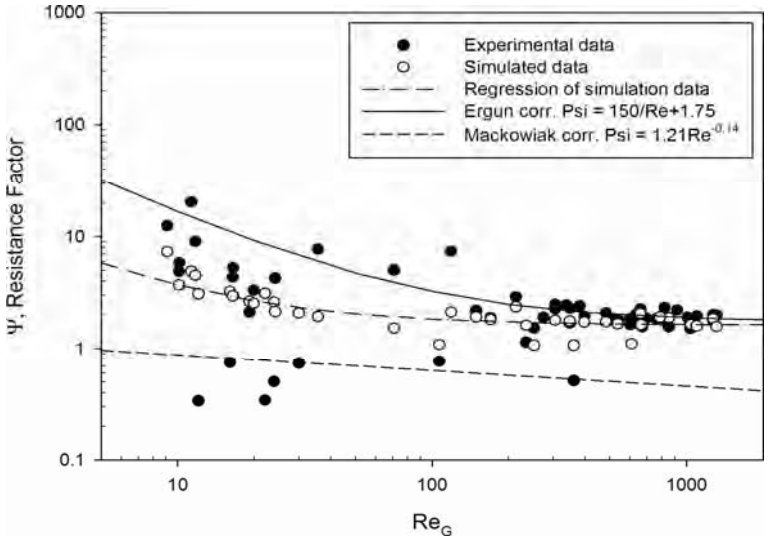

Fig. 2 - Comparison between experimental and simulated resistance factors. Data of Stockfleth and Brunner, Meyer and Brunner.

In the above plot you can see that the resistance factors calculated are well within the experimental data, moreover, they show much less scattering. In the same plot there are represented the regressions of Ergun, Mackowiak and another one developed based on the simulated data. This last correlation is simply an Ergun type correlation, fitted to our simulated data and whose parameters have taken the following values:

$$\Psi = \frac{20.992}{\mathrm{Re}} + 1.632$$

3.2 Data of Olaño, Two Packing Sheets Model – air at ambient pressure

This data concerns the dry pressure drop of Sulzer Ex packing for air at ambient pressure. In this case, the packing had slightly different dimensions, the column where the study was conducted possessed a smaller diameter than the ones considered previously, and the crimp height of the corrugation was unknown, so we decided to rescale the computational grid in order to simulate the packing with smaller diameter. The results for the predicted and experimental pressure drops are shown in Figure 9. In this case, the experimental points were simulated both using the laminar model and the realizable k-ε turbulence model. Both assumptions in the simulation model generated data able to follow the trend of the experimental data, but, as expected, the laminar model showed a better performance in the low Reynolds number data while the realizable k-ε model performed better at the highest Reynolds number data. In the same figure is also plotted a trend line for the experimental data. This line shows at which Reynolds number occurs the transition from laminar to turbulent flow (a line fitted to the last data would have a higher slope indicating a stronger dependency of the pressure drop on the flow conditions). Looking at the figure it is possible to see that the transition occurs when Re is about 500; after this value the adapted turbulence model chosen performs very well.

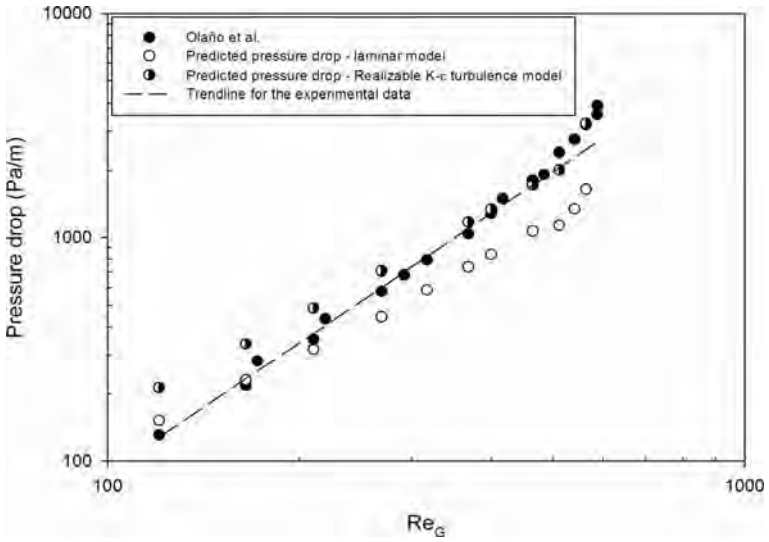

Fig. 3- Comparison between predicted and experimental pressure drops for the data of Olaño et al

4 Conclusions

Two very detailed computational models were presented for the estimation of the pressure drop caused by Sulzer EX packing. The first one being a simple representation of two packing sheets and assuming periodicity perpendicularly to the main flow direction and the second one a partial packing module, this one with periodicity in the flow direction. In both models, which can simulate either laminar and turbulent flow, the packing thickness and its permeabilty are taken into account.

Simulations were carried out to determine the pressure drops of Sulzer EX at various gas mass flowrates and various conditions of pressure (0.1 to 30 MPa) and temperature (298 to 393K) and good agreement was found between predicted and experimental pressure drops. The flow field inside the structured packing is also analyzed.

Even though the dry pressure drop is a very important factor in the design of supercritical fluid extraction columns and is used in many correlations for the determination of wet pressure drop, alone it is not enough to determine their hydrodynamics. Our next step will be to modify and test these models against real extraction conditions where liquid is flowing

countercurrently to the supercritical solvent. This implies a study of the simultaneous heat and mass transfer in the column.

Abstract

The application of computational fluid dynamics (CFD) in industrial operations has been increasing not only in the design of new equipment, but also in the optimization of that already existing. The present work shows a set of three-dimensional two-phase and adiabatic conditions using the two-fluids model for the calculation of gas-solid flow in high-flux risers with two different geometries, one with a height of 10m and an internal diameter of 76mm, and the second with a height of 18m and an internal diameter of 50mm. The k-epsilon model was applied to consider the influence of turbulence on the gas phase. The four-lump and ten-lump kinetic model schemes were used to predict the catalytic cracking reactions in the two different reactors. The riser with a height of 10m and an internal diameter of 76mm had two entrances, one for particle inlet and one for the organic materials. The size of the mesh for this case was 584,000 control volumes. The second riser studied with geometry a height of 18m and an internal diameter of 50mm had one entrance for vapor, one for organic materials, and a third for particle inlet. The mesh generated for this geometry had 650,000 control volumes. The numerical results of gas-solid dispersion flow in a high-flux riser were compared with the experimental data from the work of Pärssinen and Zhu (2001), the four-lump scheme for the mass concentration of chemical species was compared with the work of Ali et al. (1997), and the ten-lump scheme was compared with the work of Nayak et al. (2005). The catalytic cracking reaction models have an important role in the prediction of all phenomena present in the reactor. The simulated results show that the kinetics models are important not only for the variation in the gas phase and the temperature profiles inside the reactor, but also because these parameters interfere directly in the dynamic behavior of the gas-solid flows.

1 Introduction

A fluidized catalytic cracking unit (FCCU) consists in a riser reactor, where the catalytic reactions occur, and a regenerator, where the catalyst is reactivated. The main purpose of the riser is to put into contact hydrocarbons and catalyst particles, causing the catalytic cracking reactions. The cracking process converts the hydrocarbons fed into products with a higher commercial value. Although this equipment is widely used, phenomena in risers have not been entirely explained. They are operated with a high concentration of particles in a fluidized bed regime (fast transport regime). The adoption of fluidized beds is related to the catalytic cracking of gasoil in gasoline. Cracking had previously been done in fixed bed reactors.

Multiphase flows are more difficult to predict and analyze because their phases can assume complicated configurations (Hanratty et al., 2003). The phases do not mix uniformly and interactions (on a small scale) between the phases can have a strong effect on the macroscopic properties of the flow. The formation of heterogeneous structures in gas-particle systems (e.g., clusters) strongly affects the gas-solid contact and transport processes in dense fluidized beds. These structures depend on the overall forces acting on the particles. The drag force plays a fundamental role in the coupling of gas and particles. Zhang and Reese (2003) propose a new equation for the mean drag force that considers not only the solids volumetric fraction, but also the

Corresponding author. Phone + 55 19 3521-3963. E-mail:mori@feq.unicamp.br

random fluctuations in the particle movement.

In the modeling of chemical reactions, the use of groups of chemical species (or *lumps*) is common. A lump is the representation of a group of chemical species that have similar chemical properties. Thus, the catalytic cracking reactions that occur concurrently between numerous chemical species can be modeled as reactions between a fewer number of lumps (Farkas, 1999). The advantage of this procedure is the small number of chemical species and of reaction rates that have to be calculated separately, requiring a data bank for their calculation, and proportional computational resources. In the literature simulations that apply lumps to model the catalytic cracking of hydrocarbons, in gas-solid reaction systems (Ali and Rohani, 1997; Ali et al., 1997), or three-phase systems (Nayak et al., 2005) are mainly one-dimensional. However, one-dimensional simulations cannot provide realistic solutions for radial distributions and are not able to properly handle some phenomena, such as particle reflux and swirls in a turbulent flow, and one-dimensional balances cannot be applied at the entrance region due to the high nonhomogeneity and turbulence in this region.

This article shows the influence of cracking models on the fluid flow through simulations with and without calculating reactions and with different cracking models. The finite volume method was utilized.

2 Mathematical Modeling

For simulation of the flow inside the reactor, the flow of two phases was considered: the particulate phase, formed of catalyst particles, and the gaseous phase, which is a mixture of water vapor and organic compounds. The formation of new products and consumption of the existing ones alter the physicochemical properties of the gaseous phase. Both phases are fed at different temperatures; thus, at the bottom of the reactor, high temperature gradients exist.

Gas-solid systems can be modeled by several techniques. One consists in modeling each phase separately with the established equations for one-phase flows with a moving surface between them. However, when the phases are well mixed, as in many industrial operations, these cases require an average procedure to make solution of the equations possible.

Ishii (1975) divides the models for solution of fluid flow problems into two categories: diffusion models and two-fluid models. A diffusion model is formulated considering the mixture to have one transport equation for the continuity, momentum and energy, and a diffusion equation. A two-fluid model consists in two equations for the continuity, momentum and energy, one for each phase. In this work, the Eulerian-Eulerian approach was also applied. The *k-epsilon* model was applied to take account of the turbulent behavior of the flow. The equations of the model are given in the Appendix section.

3 Chemical Kinetic Models

Several models are being proposed for the calculation of catalytic cracking reactions. The advances in both the analytical techniques and mathematical routines for determining the parameters lead to the progression from simple models with three and four lumps, to more complex models with ten, twelve, and more lumps.

The four-lump kinetic model classifies the hydrocarbon fractions into four groups, as illustrated in Figure 1a. Oil cracking follows a second-order kinetics, while gasoline cracking follows a first-order kinetics. Parameters for the determination of reaction rates and heat were found in Ali et at. (1997).

Analogously, the ten-lump model describes the relationship of ten groups of hydrocarbons – four light hydrocarbon groups, four heavy hydrocarbon groups, coque and gasoline (Figure 1b). Parameters for the determination of reaction rates and heat were found in Nayak et at. (2005).

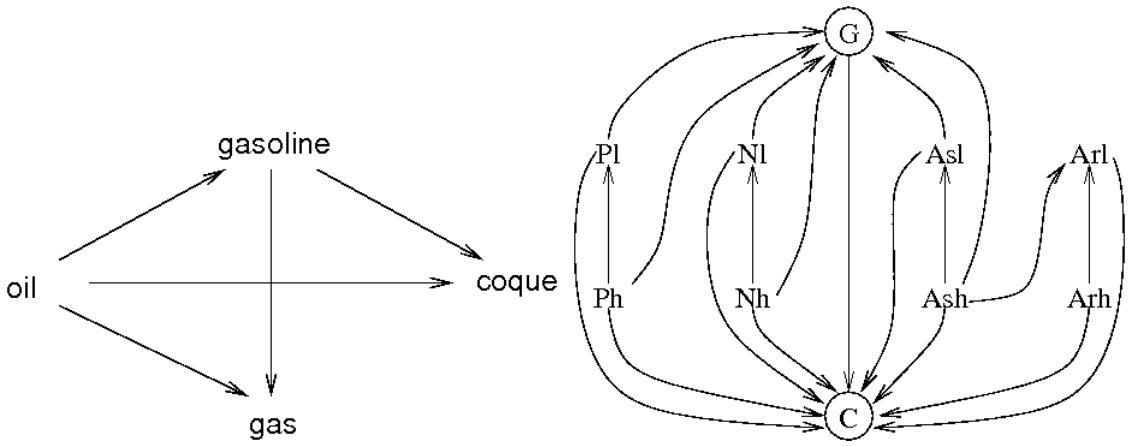

Figure 1. Kinetic models: (a) four lumps and (b) ten lumps

3 Meshes

Several three-dimensional meshes were elaborated with two different geometries. All had a first volume (at the walls) thickness of about 1mm, which provided the value of y+ needed for the turbulence model. The first geometry, shown in Figure 2a, had a height of 10m and an internal diameter of 76mm, and was based on the equipment presented by Pärssinen and Zhu (2001). It is a combination of a cylindrical duct with a lateral junction that has the purpose of injecting the catalyst, and ends in a curve. A construction known as “O-Grid” was applied for the generation of a higher quality mesh. Meshes of different sizes were tested, and the mesh chosen for the simulations had 584,000 control volumes. The second geometry, shown in Figure 2b, had a height of 18m and an internal diameter of 50mm. It is also a combination of a cylindrical duct with a lateral junction, and terminates with another junction that forms a 90 degrees angle with the main duct. It has two more entrances inside the reactor for vapor and feed inlet. These details made the elaboration of the meshes more difficult, which was solved with an “L-Grid” construction for the curved inlet. The final mesh had 650,000 control volumes.

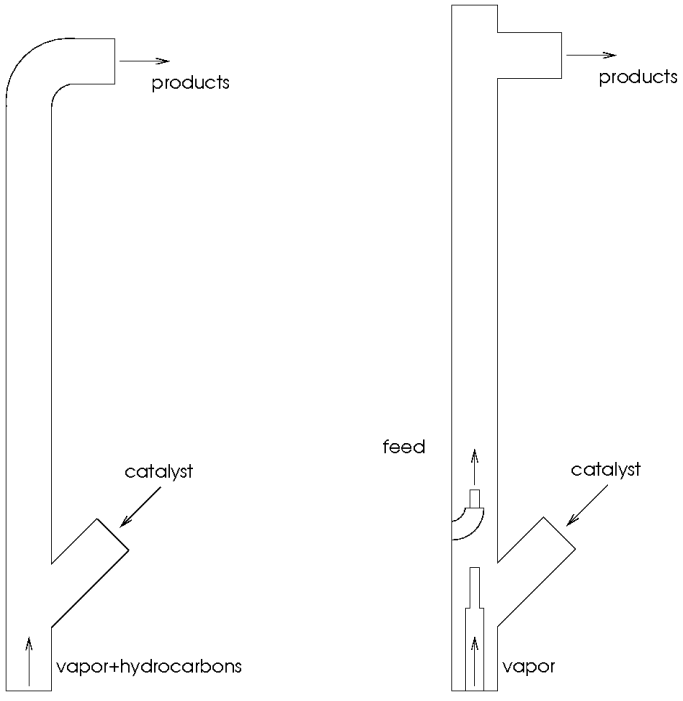

Figure 2. Geometries utilized

4 Results

Figure 3 shows the concentration profile of hydrocarbons calculated with the four-lump model for geometry A. The values obtained follow the same trends as the experimental ones (given by Ali et al., 1997), but the conversion was a little lower than expected (i.e., the final values of the products do not reach the experimental values). One possible explanation for this behavior could be the heat transfer model: chemical reactions are greatly influenced by temperature.

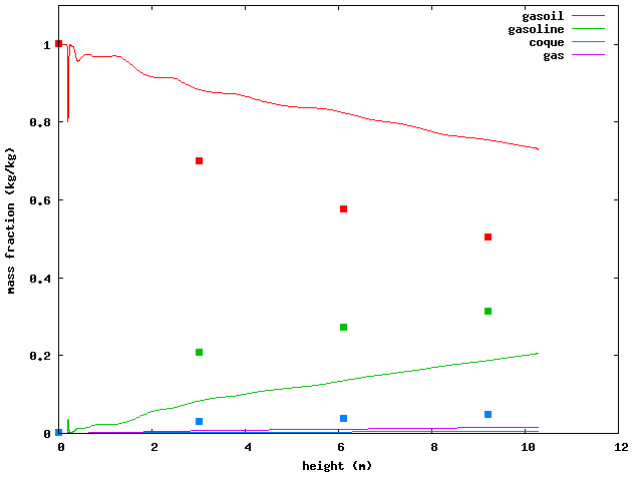

Figure 3. Hydrocarbons conversion

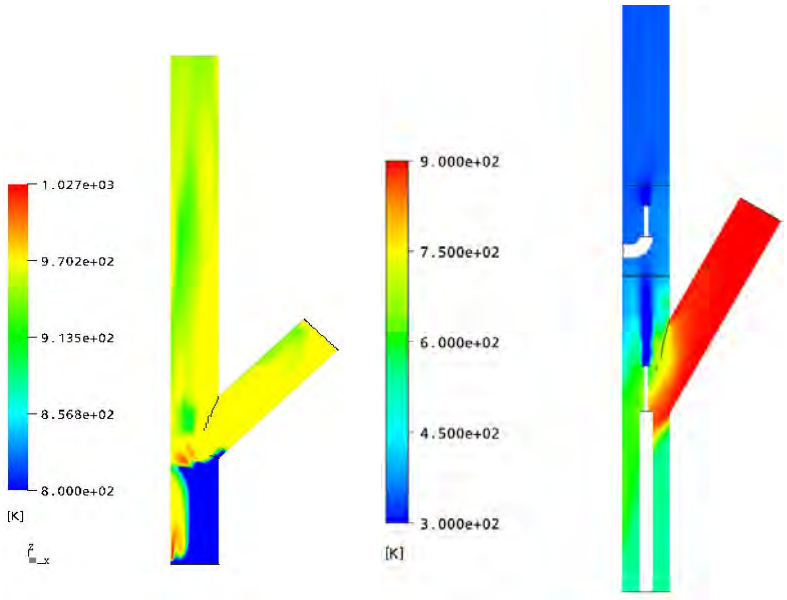
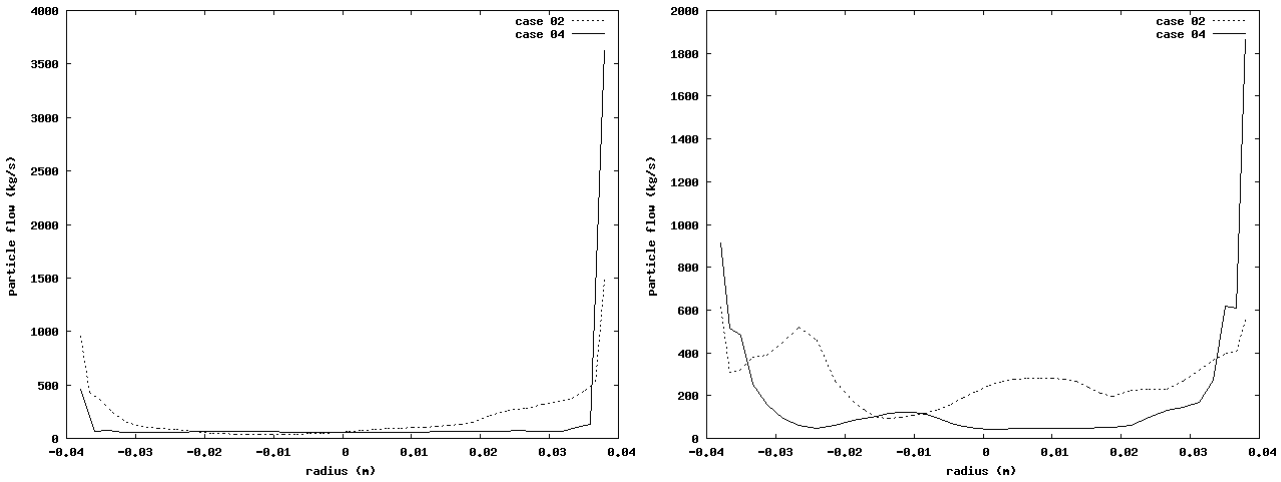
In Figure 4 the gas-phase temperature maps calculated for the two geometries considered are shown. In both cases it could be seen that these values are influenced by the temperature of the particle phase. In Figure 4a, more heat is transferred to the gas phase, whereas the temperature after contact with hot catalysts is higher than the temperature in Figure 4b.



(a) (b)

Figure 4. Temperature maps

The behavior of the flow with reaction (labeled as case 04) compared with the flow without reaction (case 02) are shown in Figure 5. When the composition of the gas phase varies, its properties are not the same because it depends on the properties of each chemical species. Figure 5a shows the flow in the lower section of the reactor at a height of 1.53m. There are few differences between the profiles, but these are greater at higher heights (Figure 5b) because there are more products formed in this region.



(a) (b)

Figure 5. Comparison of flows at heights of 1.53m and 9.42m

5 Conclusions

The simulation of a reacting gas-solid fluid flow, coupling the four-lumps and ten-lumps kinetic models with the two-fluids model, was calculated for two different riser configurations in the CFX package. Simulation of the reacting flows resulted in conversions a little lower than what was expected, but with the same trends, thereby showing them to be different from simulations without chemical reactions. More studies can be done on the heat transfer model coefficient, and on the dynamics of the flow at high temperatures.

Keywords: CFD, Euler-Euler, rectangular bubble column
Topic: CFD & Chemical Engineering.

This contribution deals with CFD Euler-Euler simulation of laboratory scale rectangular bubble column. Horizontal profiles of gas holdup obtained from simulations are compared with experimentally measured profiles using optical fibre probe.

Goal

The goal of the presented contribution was two-fold. Goal 1 was to examine effect of interphase forces and turbulent models on simulation results and effect of front-rear flow field symmetry assumption. Goal 2 was to compare simulated horizontal profiles of gas holdup with profiles measured with optical fiber probe.

Experiments

Experimental column width was 20 cm, measurements were done for column thickness (D) 4 and 10 cm. Ungassed liquid height (H) was 25 and 50 cm. Water and air were used as liquid and gas phase. Gas distributor consisted of one line of 33 orifices (0.5 mm orifice diameter, 5 mm distance between two neighbouring orifices). Experiments were done for air flow rates 800, 1200 and 1800 l/h. Gas holdup profiles were measured at height 11, 21, 31 and 41 cm above the gas distributor. There were 19 measuring points in horizontal profile with distance 1 cm. Local gas holdup at each point was measured for 2 minutes - the obtained values are 2 minute time averages.

Simulations

Euler-Euler model was used for the simulation of gas-liquid flow in the bubble column. Model equations were solved using commercial code Fluent 6.2. In Euler-Euler model all involved phases (gas, liquid) are treated as interpenetrating continua (see e.g. [1], [2], [3]). There is continuity and momentum equation for each particular phase. These equation sets for each phase are coupled together through pressure, phase volume fractions (which sum to unity) and interphase force terms like drag, lift, added mass force. Closure relations for the interphase forces are needed to solve the equations. Also turbulence has to be modelled. The equations for phase q have the following form [1], [2]:

$$\partial(\alpha_q \rho_q)/\partial t + \nabla . (\alpha_q \rho_q \mathbf{u}_q) = 0 \qquad (1)$$

$$\partial(\alpha_q \rho_q \mathbf{u}_q)/\partial t + \nabla . (\alpha_q \rho_q \mathbf{u}_q \mathbf{u}_q) = -\alpha_q \nabla p - \nabla .(\alpha_q \tau_q) + \alpha_q \rho_q \mathbf{g} + \mathbf{F}_{qp} \qquad (2)$$

*Corresponding author. Email: simcik@icpf.cas.cz

where α_q is volume fraction of the phase q. Here $\tau_q = \tau_{l,q} + \tau_{t,k}$ is effective stress tensor which contains not only the contributions from viscous effects ($\tau_{l,q} = \mu_q (\nabla \mathbf{u}_q + \nabla \mathbf{u}_q^{\mathrm{T}})$, but also the contributions from velocity fluctuations arising from averaging - $\tau_{t,k}$ – turbulent stresses. This (turbulent) term can be modeled as ($\tau_{t,q} = \mu_{t,q} (\nabla \mathbf{u}_q + \nabla \mathbf{u}_q^{\mathrm{T}})$, where $\mu_{t,q}$ is turbulent viscosity. Turbulent viscosity was calculated with k-ε turbulence model, which solves transport equations for turbulent kinetic energy and dissipation rate, see [1] for details. Last term in (2) $\mathbf{F}_{qp}$ is the total force (N/m^3) exerted on phase q by phase p (if there are more than two phases then the force is contribution from all other phases) – interphase force. Interphase coupling terms satisfy the following relation:

$\mathbf{F}_{qp} = -\mathbf{F}_{pq}$

We did 3-dimensional transient simulations of the flow field in the bubble column. One set of simulations was done assuming front-rear symmetry of the flow field, another set was done without this assumption (full 3D). Gas inlet was modelled using velocity inlet boundary condition with gas velocity set to 41cm/s and gas void fraction adjusted to obtain required flow rate. Constant static pressure was prescribed at the outlet boundary. The outlet boundary was 25-50cm above the level of ungassed liquid. Three version of k-ε turbulence model were tested (standard, RNG and realizable). Also simulations with different combinations of enabled interphase forces (drag, drag + lift, drag + added mass, drag + lift + added mass force) were run to see how they influence the output. Drag coefficient was modelled according to [4]. Added mass coefficient (when used) was set to 0.5. Influence of the lift coefficient value (from -0.3 to 0.5) on results was examined. If not said otherwise, the lift coefficient was 0.5.

Simulations results presented here were done on 5x5x2.5mm, timestep was 0.005s. Time averaged horizontal profiles of gas holdup were compared with experimental data. Profiles obtained from simulations were averaged over 60s time interval. Time averaging was started after 30s to let the flow field reach a pseudosteady state.

Results

Results are shown in the following figures. See Fig.1 for comparison between full 3D and front-rear symmetric simulation, Fig.2 for comparison of different versions of k-ε turbulence model, Fig. 3 and 4 for the effect of various combinations of interphase forces considered in simulations, Fig.5 for effect of lift coefficient value, and Fig. 6, 7, 8 and 9 for comparison between simulations and experimentally measured gas holdup profiles. See Conclusions for brief discussion of the results.

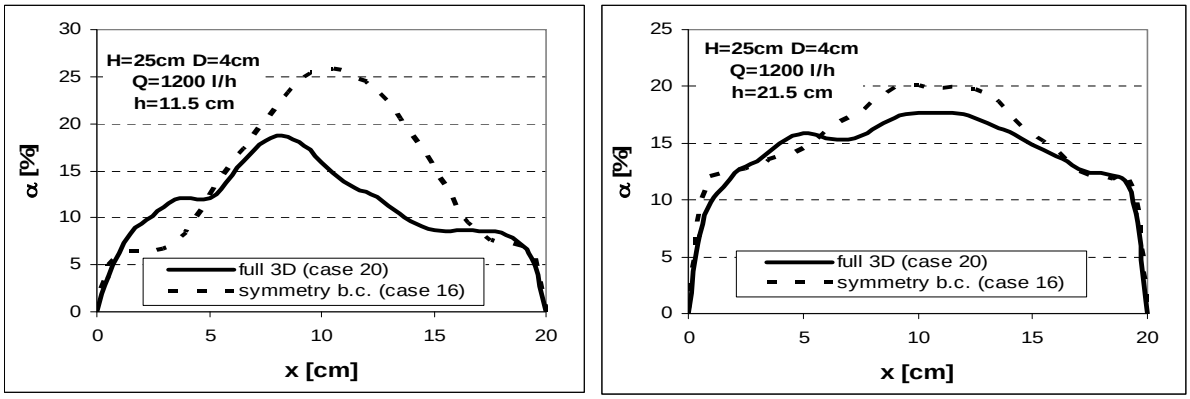

Fig. 1: Gas holdup profile (at h=11.5 and 21.5cm), full 3D vs. symmetry b.c. simulation, air flow rate 1200 l/h

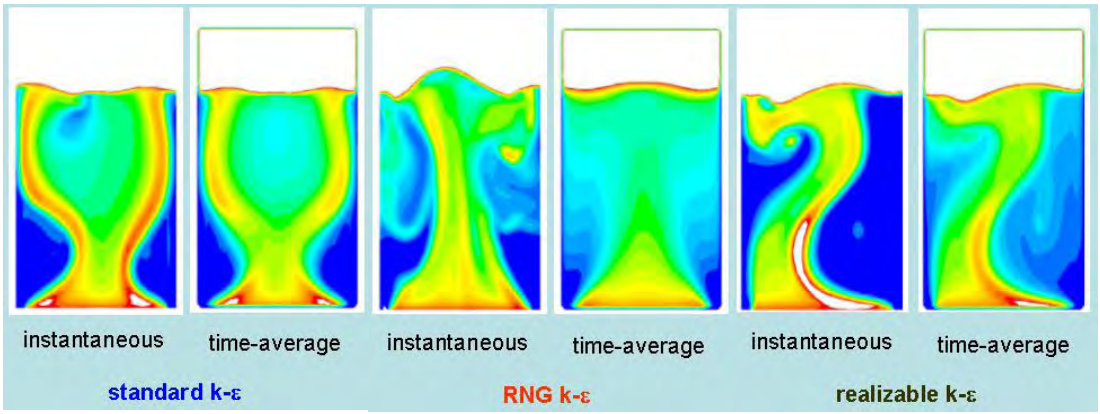

Fig. 2: Instantaneous and time-averaged gas holdup fields (blue...clear water, red...50% holdup) calculated with different turbulent models under otherwise same conditions, H=25cm, D=4cm, Q=1200l/h, symmetry b.c.

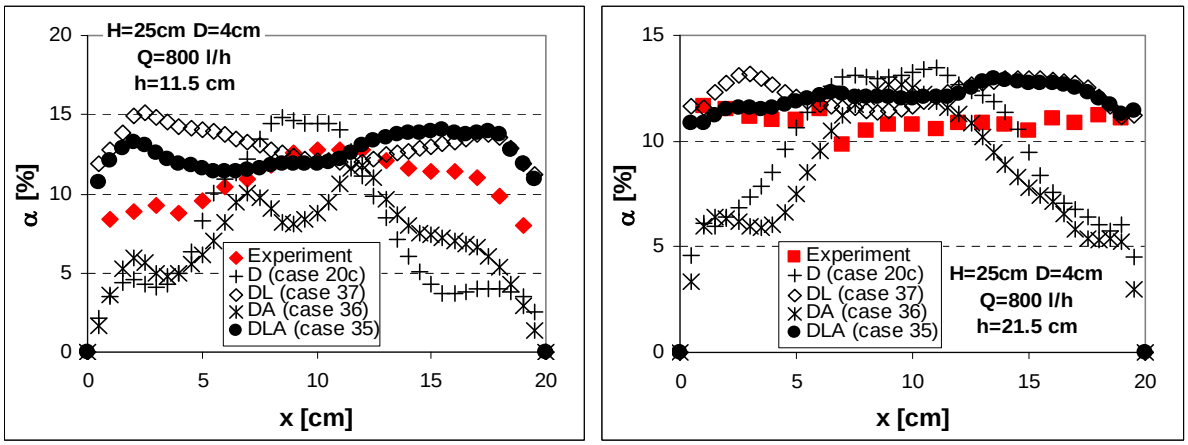

Fig. 3: Time-averaged gas holdup profiles (at h=11.5 and 21.5cm) obtained with different combinations of interphase forces (D-drag, L-lift, A-added mass), H=25cm, D=4cm, Q=800 l/h

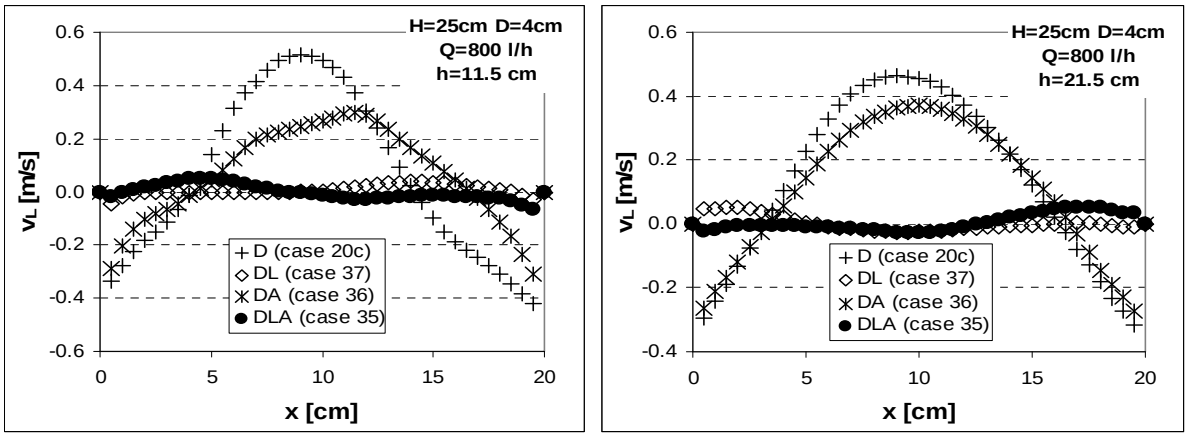

Fig. 4: Time-averaged profiles of vertical liquid velocity (at h=11.5 and 21.5cm) obtained with different combinations of interphase forces (D-drag, L-lift, A-added mass), H=25cm, D=4cm, Q=800 l/h

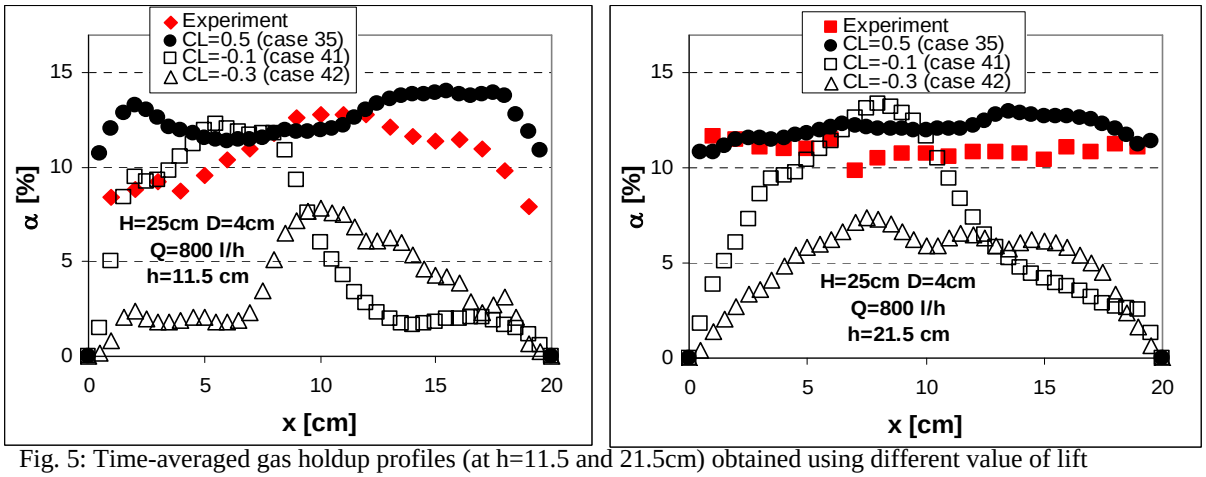

Fig. 5: Time-averaged gas holdup profiles (at h=11.5 and 21.5cm) obtained using different value of lift coefficient

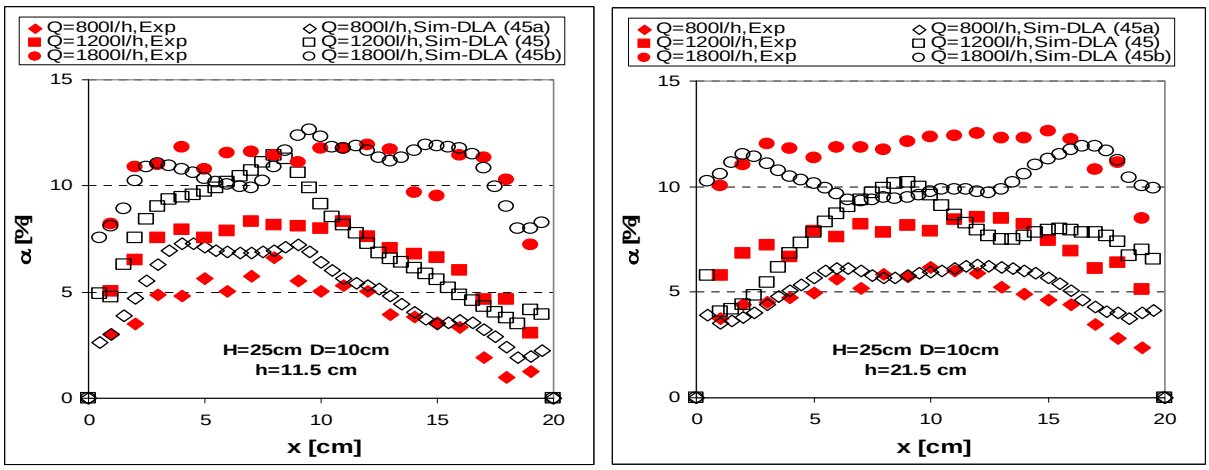

Fig. 6: Time averaged gas holdup profiles (at h=11.5 and 21.5cm): simulation vs. experiment (for different gas flow rates Q, drag, lift and added mass force included in simulations

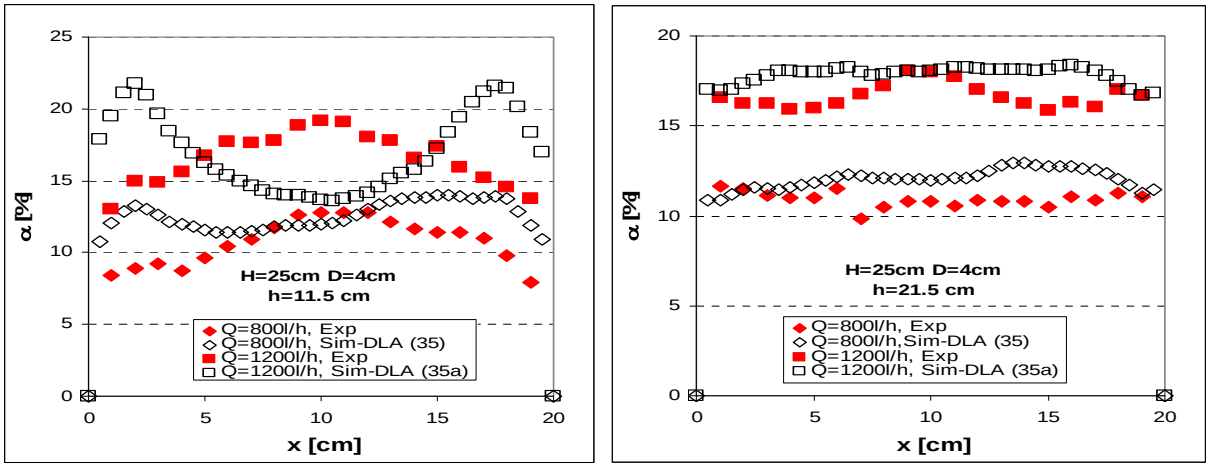

Fig. 7: Time averaged gas holdup profiles (at h=11.5 and 21.5cm): simulation vs. experiment (for different gas flow rates Q, drag, lift and added mass force included in simulations

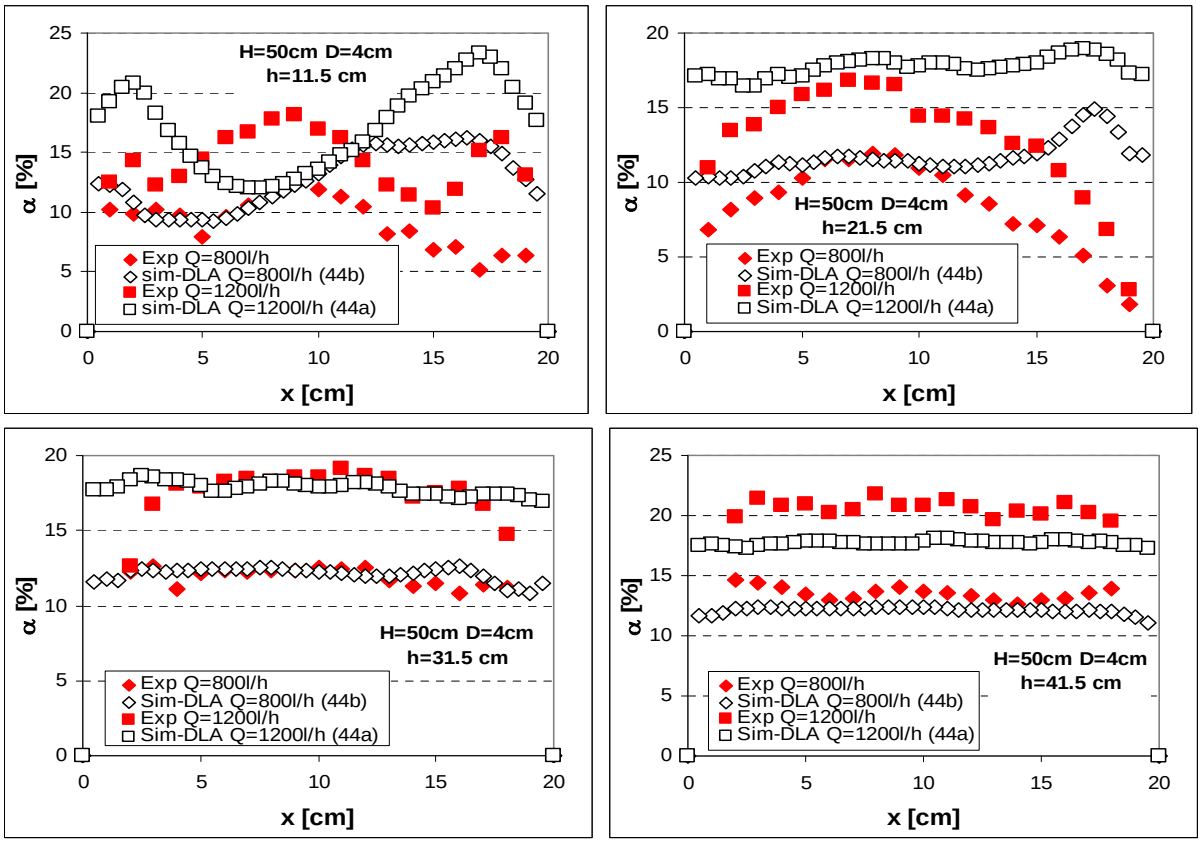

Fig. 8: Time averaged gas holdup profiles (at h=11.5-41.5cm): simulation vs. experiment (for different gas flow rates Q), “fine grid”, drag, lift and added mass forces included in simulations

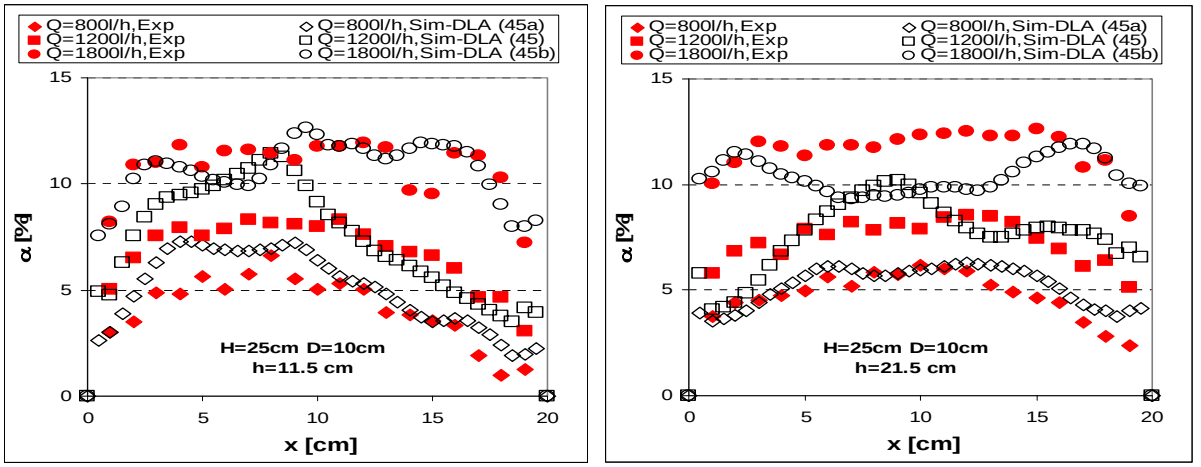

Fig. 9: Simulated (white marks) and experimental (red marks) holdup profiles at two heights h above gas distributor for air flow rates 800, 1200 and 1800l/h. Ungassed liquid level 25 cm, column thickness 10 cm.

Conclusions

Goal 1. The difference in gas holdup profiles calculated with and without the front-rear symmetry assumption was often larger than 20 %, thus the symmetry assumption is not recommended for column simulation even when the column thickness is only 4cm. Each of the simulations using different version of k-ε turbulence model predicted qualitatively different results – two different steady flow fields in the case of standard and realizable model, unsteady flow field in the case of RNG model. RNG k-ε model gave best agreement with experiments. Lift force (lift coefficient values) significantly influenced simulation output, influence of the added mass force was smaller.

Goal 2. Qualitative agreement between simulations and experiments was reached, when drag, lift and added mass force were accounted for.

Keywords: Healthcare Management, Decision Support System, Job-Shop Scheduling
Topic: Systematic methods and tools for managing the complexity.

Abstract

In this paper a decision support system, based on a scheduling model, is presented. A case study is described based on an imaging clinic of a private hospital. The case study is discretized in a set of jobs J and resources R, based on Job-Shop Scheduling Problem (JSSP) methodology (Brucker, 2004). Jobs are composed of a sequence of tasks that follow precedence relations, according to the job requirements, which restrain some tasks to start until others are completed. It is considered that tasks cannot be interrupted (non-preemptive scheduling) and resources can perform more than one task simultaneously (cumulative scheduling). Furthermore, it is considered in this research that each task establishes restrictions in the resource allocation and may have to be processed in more than one resource, denoted as multiprocessor tasks. These restrictions impose limits in resources selection according to their capabilities (each resource may have more than one capability, denominated as multipurpose machines) and their use in the job (the selection of the resource may be limited to one that was used in a previous task). Additionally, the set of resources have elements that exhibit the same capabilities - machine repetition. Resources may also have different processing requirements for different tasks - multimode machine (Brucker and Knust, 2006). The selection of a resource may restrict the choice of another resource in the subsequent tasks. The objective of the developed model is to describe accurately a clinical workflow.

1 Introduction

In the last decades, the healthcare sector has experience substantial transformations. An unequivocal example is the increasing demand for healthcare services as a result of demographic growing. Other reasons for these transformations are the development of the technology applied to healthcare, patients' mobility and the increasing volume of clinical information. Combined, these factors impel the healthcare providers to diminish their costs and improve the quality, and the efficiency, of their services (Martins et al., 2007).

Mammography is a reference technique in breast cancer trace, analysis and definition of nodules and other breast lesions, as well as in the evaluation and foil of micro-calcifications (benign and malign). Comparatively to breast ultra sound, which does not allow the detection of breast micro-calcifications (although it may be complementary to mammography), mammography allows the detection of malign breast lesions with high sensitivity in a premature stage and a better definition of breast nodules also called infraclinic breast lesions (Kasper et al., 2005; Schwab, 2001). For these reasons, mammography departments evidence high workloads which allied to the clinic workflows stochastic nature, make these departments an evident case study.

An overview over clinical workflows leads to the choice of Job-Shop to deal with the scheduling in the healthcare environment. If patients are considered as jobs each patient has to follow a given path, and has to be treated at varied stations, to reach discharged, the job end. The case study is discretized in a set of jobs *J* and resources *R*, based on Job-Shop Scheduling Problem (JSSP) methodology

[*]Corresponding author. Tel. +351-22-508-1695. E-mail: mendes@fe.up.pt

(Brucker, 2004).

The JSSP generalizes the Flow-Shop Scheduling Problem. There are n jobs $J_j(j=1,\ldots,n)$ and m machines $\{M_1,...,M_m\}$. The job j is composed of n_j tasks $A_{j,i}(i=1,\ldots,n_j)$, linked by precedence constrains. Each task $A_{j,i}$ has a machine $\mu_{i,j} \in \{M_1,...,M_m\}$ and a processing time $p_{i,j}$ associated. The problem is to find a feasible schedule that fulfills some objective function. Only a few JSSP can be solved based on polynomials, or pseudo-polynomials time dependency, meaning that most of the JSSP are $\mathcal{NP}$-hard.

In this paper, a case study of a mammography department from a private imaging clinic is considered. The clinic is located in the north of Portugal but its name will not be mentioned due to ethical reasons.

2 Methodology

In this section, it is presented the methodology applied to the mammography department. All the information was gathered aiming the characterization of the mammography processes to simulate its operation with the developed algorithms. In this sense, all the activities associated to the exams were object of characterization according to:

- **Involved tasks identification** – name, time distribution need for accomplishment, operating mode and human, physical and technical resources required;
- **Resources characterization** (human, technical and physical) – competences/technical specifications, work load, availability, team working/technical interdependences;

To better understand the resources utilization at this department, it was investigated and characterized 1760 medical exams, which took place from January 2nd to April 27th of 2008.

The collected data evidences a characteristic pattern concerning the exams frequency by weekday, as seen in Figure 1.

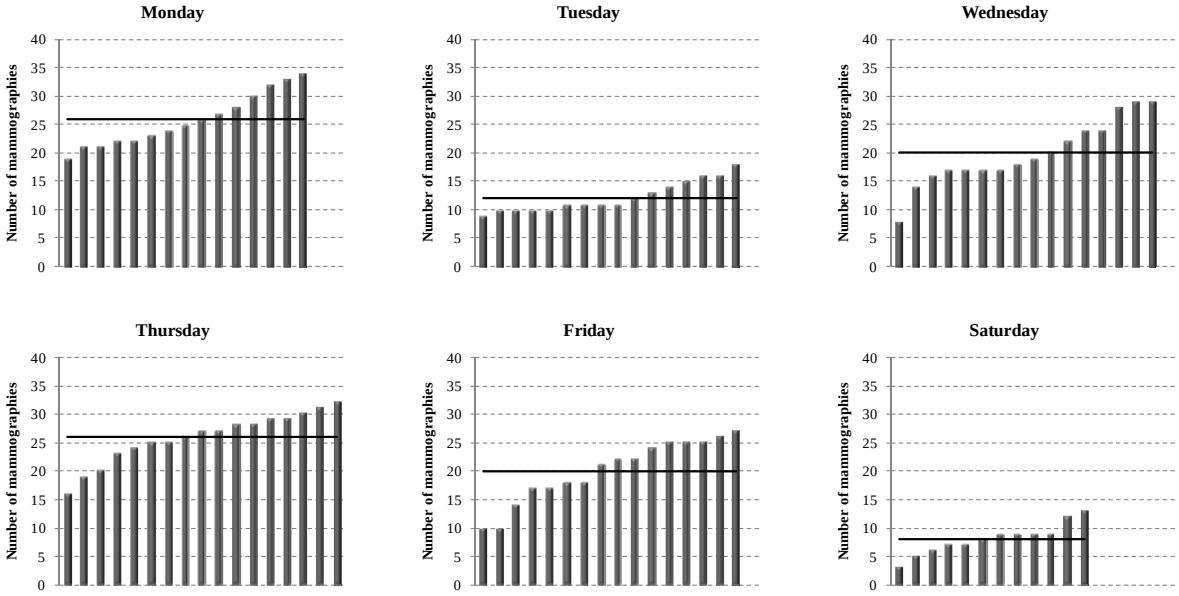

Figure 1: Workload histogram by weekday.

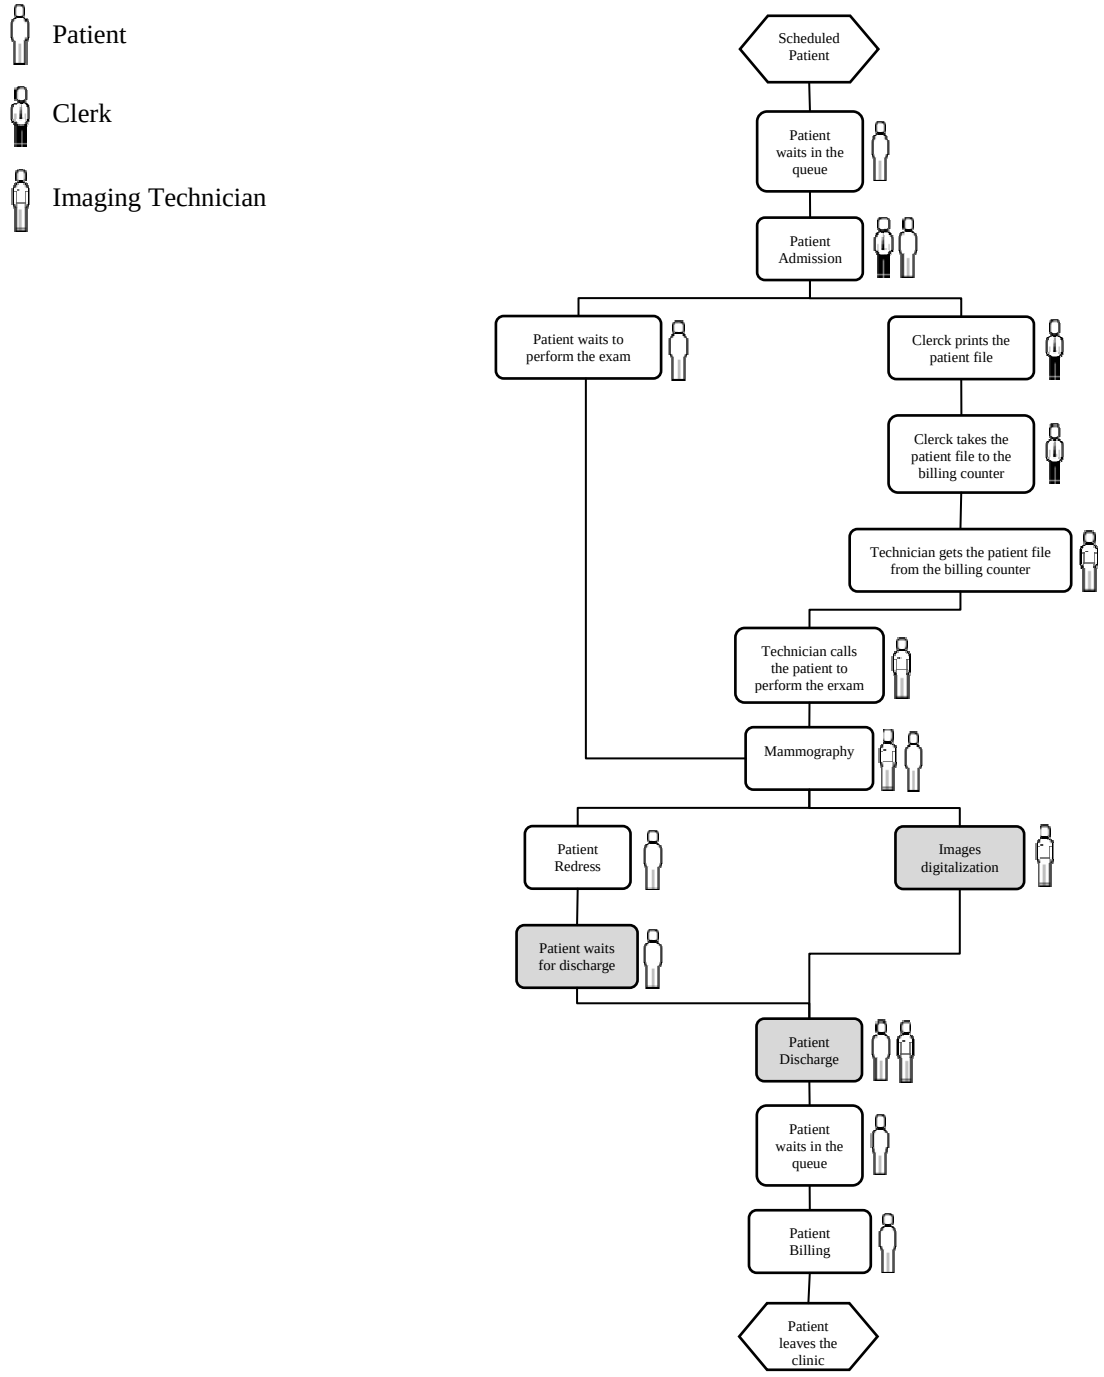

Figure 2: Mammography workflow in the case study Clinic.

Considering each activity as stand-alone processes, i.e. performed by the same resources (human, technical and physical) in the same time space, it was possible to model the department workflow, schematized in Figure 2. The data collected to define the activities time distribution was fitted to a Normal Distribution $X \sim N(\mu, \sigma^2)$, as presented in Figure 3.

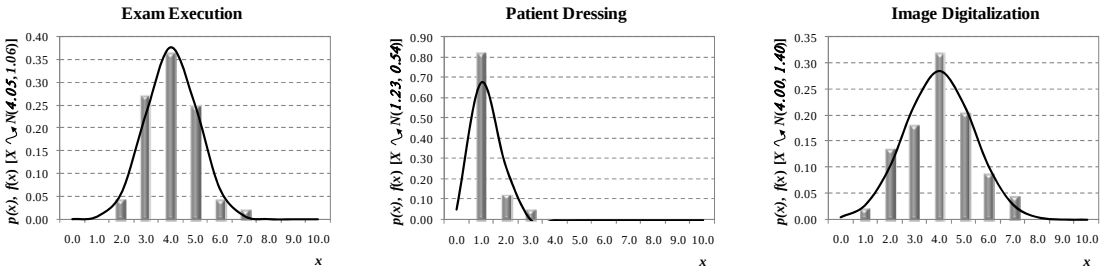

Figure 3: Sample approximation to a Normal Distribution $X \sim N(\mu, \sigma^2)$.

3 Results and Discussion

The developed algorithms were applied to the mammography department current workflow and to the workflow reengineered to embody a digital mammography system instead of an analog. Theoretically, when an analog system is replaced by a digital the activities represented with grey background in Figure 2, meaning that the completion time required to perform the exams should diminish and, because a patient waiting activity is removed from the workflow, their waiting time ought to be reduced as well.

Table 1 Simulation parameters and results, for the current workflow.

Week Day	Work Load	Total Completion Time, hh:mm:ss	Total Waiting Time, hh:mm:ss
Monday	26	04:25:42	01:50:09
Tuesday	12	02:06:33	00:52:35
Wednesday	20	03:18:27	01:41:19
Thursday	26	04:26:09	01:28:17
Friday	20	03:29:07	01:33:04
Saturday	8	01:28:14	00:28:15

The simulation parameters are based in the data collect in the department. The workload simulated was defined from the real workload average, with the intention that the simulation runs represent a typical workweek of the department. According to Figure 1, the simulation parameters were defined as presented in Table 1.

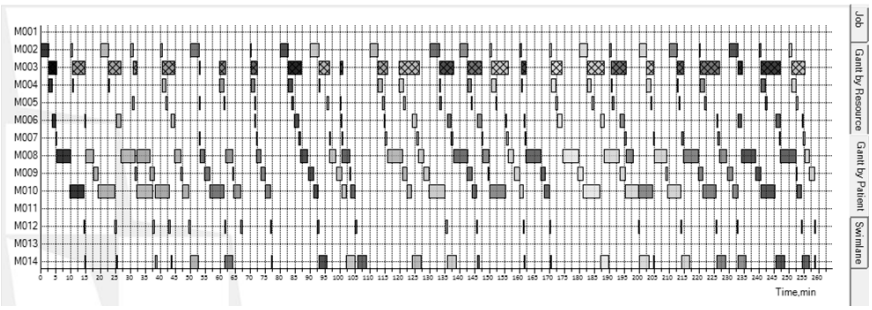

Figure 4: Graphical output of simulation results: Gantt chart by process.

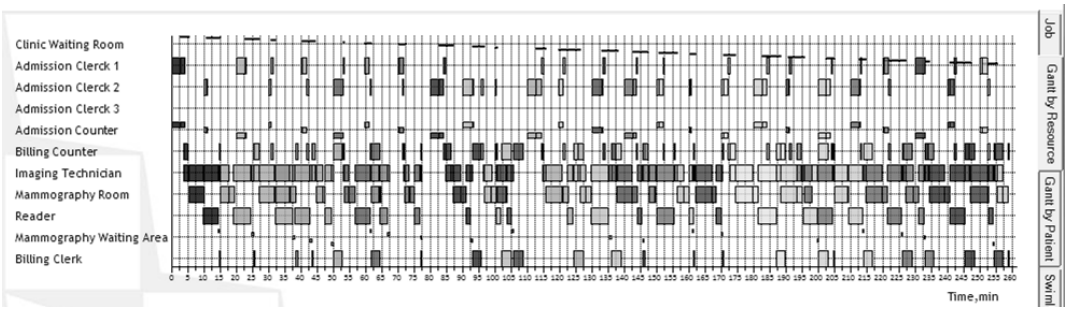

Figure 5: Graphical output of simulation results: Gantt chart by resource.

As expected, the total completion time presented values in the three to the four hours range, which is in agreement with the experimental data, as the technician eight hours of work are shared by the mammography and the densitometry departments. The waiting times were expected to show high values because the patient has to wait while the images are digitalized, activity that lasts approximately the same time as the mammography exam. This fact was confirmed by the simulation results shown in Table 1. In Figure 5 and Figure 5 are presented the Gantt charts originated by the developed simulation system. These charts exhibit the activities' time distribution and the resources utilization, respectively.

The simulation runs performed with the reengineered workflow, are given in Table 2. According with these results, the implementation of a digital mammography system allows average gains, in the total completion time, of 35 % (week based), being the maximum achieve on Saturdays with 41 % and the minimum on Wednesdays with 30 %.The major gains in the total waiting time of the patients are achieved on Wednesday, with 56 %. Saturday is the day of the week when the gains concerning the waiting time are less significant, 25 %. This is due to a higher availability of the resources as a result of the low workload evidenced by the department. In average, the gains in the total waiting time are of 43 %.

Table 2 Simulation parameters and results, for the reengineered workflow.

Week Day	Work Load	Total Completion Time, hh:mm:ss	Total Waiting Time, hh:mm:ss
Monday	26	02:58:35	00:59:14
Tuesday	12	01:20:47	00:24:50
Wednesday	20	02:17:42	00:43:51
Thursday	26	02:57:56	00:52:47
Friday	20	02:16:24	00:55:48
Saturday	8	00:51:53	00:21:17

4 Conclusions

The developed algorithm associated with the modeling strategy evidenced a high accuracy simulating clinical workflows. The model allowed the evaluation that modifications in the workflow and existing resources have in the process productivity and quality, taking the total completion time and total waiting time as metric, respectively. Therefore, it reveled to be a powerful decision support tool for healthcare management.

Topic: Sustainable process-product development through green chemistry

Abstract

Hydroxyapatite (HAP) is one of the inorganic components of the hard tissues of living bodies such as bones and teeth. HAP is a calcium phosphate based bio-ceramic, which has been used for several years in medicine and dentistry because of its excellent biocompatibility with human tissues. The success of its application in these fields depends upon factors such as the composition, crystallinity, size and morphology of HAP particles. This paper describes work performed regarding the synthesis of this compound by a wet method comprising the direct precipitation of orthophosphoric acid solution and a calcium hydroxide solution. The synthesis was performed in a laboratory reactor, 700 mL in capacity, instrumented and controlled using a computer interface, so that the influence on process variables could be assessed. The influence of these parameters was, therefore, evaluated in terms of the required composition and morphology of HAP formed particles, analysing them by FTIR, XRD, SEM and EPMA for determination of the Ca/P ratio. From the obtained results, it can be concluded that HAP particles having suitable properties for use in medicine, could effectively be prepared by this technique, provided that a good control of the involved process variables is maintained.

1 Introduction

Hydroxyapatite (HAP) is described as $Ca_{10}(PO_4)_6(OH)_2$ and was identified as the mineral component of bone and teeth. Being a bioactive mineral it has a crystalline structure similar to the existing minerals in bones which makes its synthesis process particularly interesting [1]. Synthetic HAP precursors can be obtained by several processing routes, such as precipitation, sol-gel or hydrothermal. Some of these techniques do not allow a rigorous process control which can result in obtaining different HAP structures other than those occurring in human body [7]. The aqueous precipitation synthesis of HAP is based on the reaction of calcium hydroxide and ortophosphoric acid [5] - [9], as follows:

$$10Ca(OH)_2 + 6H_3PO_4 \rightarrow Ca_{10}(PO_4)_6(OH)_2 + 18H_2O$$

It is important to maintain the correct molar proportion between calcium and phosphorus, the theoretical value being Ca/P=1.67 [7]. Any changes occurring in the reaction environment, as well as in the rate of drying of the obtained final precipitate will result in changes both in shape and in the size distribution of particulate. Aqueous precipitation is the most common technique for obtaining powder HAP. However, this technique requires a rigorous control of the Ca/P ratio [10]. This was the production reaction selected in this study because of its versatility, ease of implementation and acceptable production costs [11-13]. Apart from that, this method can be possibly scaled-up to the industrial production of HAP, as it can provide the desired stoichiometric composition, as the reaction does not involves other reactants apart from

the ones entering the main reaction and the only by-product is water [7].

2. Experimental

The studied precipitation process uses powdered calcium hydroxide for preparing a aqueous suspension of calcium hydroxide 0.5M. The suspension was then stirred, deaerated with nitrogen and pre-heated in a glass reactor 700 mL in capacity at several test temperatures (20ºC, 40ºC, 60ºC and 80ºC) during 1h, before the acid addition. The orthophosphoric acid solution, 0.3M, was also deaerated with nitrogen and feed into the reactor by means of a peristaltic pump, at a constant rate. The pH control was performed by adding small portions of a NH_4OH solution during the precipitation process. The obtained gel precipitate is then left to rest overnight and is decanted and washed afterwards using distilled water and small portions of a 1mmol solution of orthophosphoric acid, in order to remove the unreacted Ca^{2+} ions, without interfering in the HAP structure. The obtained precipitates are then dried overnight in a oven at 80ºC. In order to evaluate the thermal stability of the obtained HAP powder, they are sinterized afterwards during 1h in a oven at temperatures ranging from 500 to 800ºC. This study also comprised the evaluation of the effects of inert atmosphere, reaction pH media, stirring rate and addition flow rate of acid on the quality of obtained HAP. Regarding product characterisation, the size distribution of synthesised HAP particulate was determined by SEM, JEOL-JSM 5310, using an acceleration voltage of 30kV. The HAP samples were dissolved in water and ethanol and observed at 75x and 1500x magnifications. The HAP samples were also analysed by FTIR, using a Nicolet Impact 400D and by X-ray diffraction, PHILIPS, X'PERT, using Bragg-Brentano geometry, a cobalt anti-cathode at 0.17886nm. The latter analysis were performed in the range 2θ=10-100º, with a rate of 0.025º and an acquisition time of 0.5s/°. The observed phases were indexed by comparison with the distances indicated in the ICDD (International Centre for Diffraction Data) guidelines. This technique allowed for the determination of the crystallite sizes, by calculating the width at half height of the HAP peak of higher intensity, using Scherrer formula after adjustment by a Voigt curve.

3. Results and discussion

The analysis of the IR spectra of the synthesized HAP precipitates showed that all obtained samples are indeed HAP as all exhibits the characteristic peaks in accordance with the theoretical spectra described in the literature [15, 16]. The characteristic detected peaks are: 565-603cm^{-1} and 1035-1093cm^{-1} for the PO_4^{3-}group; 1420-1457cm^{-1} for the CO_3^{2-} group and 3571cm^{-1} for the OH^- group. As a whole, the obtained spectra are quite similar, but some differences exist that can be attributed to changes in operational reaction conditions such as the degree of inert atmosphere and sintering temperature of the HAP precipitates. In fact, a decrease of the intensity of the characteristic peaks for the carbonate group can be observed when the reaction atmosphere is inertized with nitrogen (as well as the deaeration of the used solution is also made) as can be noticed in figures 1a) and 1b) where the peaks at 1419, 1470 and 1637 cm^{-1} are somewhat smaller. Figures 1b), 1c) and 3d) show that, increasing the HAP sintering temperature results in the intensity decrease, and even in the disappearance of the peak characteristic for water (2001cm^{-1}), as the water is suppressed during the sintering process. The same figures show that a decrease in the intensity of the peak characteristic for the carbonate group is also observed with the increase of the HAP sintering temperature, as this temperature increase results in the degradation of any carbonates. This is also related with the decrease of water in the structure as carbonate groups present in the samples are mainly present in aqueous solution. Micrographs obtained by SEM analysis of the HAP precipitates are shown in Figure 2. Regarding HAP morphology, this compound can exist in the acicular or spheroid form [7, 9]. In this particular study it was not possible to determine the exact shape as the particles were strongly agglomerated. Therefore, it was only possible to ascertain the shape of the agglomerates. The HAP crystallites have the tendency to

form agglomerates [17], the global dimensions are in the range of 200 to 400nm, and then the average size of the crystallites is estimated to be in the range of 15-50nm [18]. The obtained X-ray difractograms of the HAP samples are shown in Figure 3. When heated at 500ºC (samples 23 E-H) and at 800ºC (samples 23 I-L), a crystallinity increase occurs when compared with the samples heated at 80ºC (samples 23 A-D). As reported by De-Aza et al. [19], the increase in crystallinity is also shown by the increase of peak intensity and varies directly with temperature increases. Also, as temperature increases, overlapping between peaks occurs, and this is due to the fact that these samples are formed by smaller crystallites. Measured X-ray diffraction data allowed for the determination of crystallite sizes in the range of 18 to 26 nm. SEM analysis of those samples, as shown in Figures 2a and 2b, leads to the conclusion that the first one has a bigger size as bigger crystallites form smaller agglomerates. Thus, the compound present in all samples analysed by X-ray diffraction is HAP ($Ca_5(PO_4)_3(OH)$, and the obtained difractograms do not show significant differences between them. However, samples which were submitted to sintering at a temperature of 800ºC, show a secondary phase of whitlockite ($Ca_3(PO_4)_2$). Apart from this, HAP peaks are much more defined, which is probably due to an increase of size. As previously mentioned, the Ca/P ratio for HAP samples is a basic parameter in what concerns its properties and thermal stability. The obtained results show clearly that the obtained Ca/P ratio is in accordance with the theoretical stoichiometric value of 1.67, as only the HAP phase was formed. Along with the temperature increase, Ca^{2+} is released from HAP structure which leads to the formation of CaO. In this case, the HAP structure is deficient in terms of Ca^{2+} and the Ca/P ratio changes to the characteristic value for whitlockite [15]. It was also noticed that, sample washing does not originate significant differences in the X-ray difractograms, as shown in Figure 3 and in Table 1. The weight loss occurring during temperature increase was also studied by performing thermogravimetric analysis of the HAP samples at sintering temperatures of 80, 500 and 800ºC. In a first stage, until T=80ºC, a weight loss of about 43% takes place, which is due to the evaporation of water trapped within the HAP structure. In a second stage, taking place between 80 and 500ºC, the weight loss is of about 64%, which is now due to dehydroxilation (loss of OH groups) accompanied by calcium carbonate formation. In the temperature range of 500 to 800ºC, the observed weight loss if only of 5%, and can now be attributed to $CaCO_3$ decomposition and release of CO_2 [5]. All samples showed similar variations to the ones described. This behaviour is in accordance with the IR analysis where a decrease of the intensity of the peak characteristic for water and carbonates could be noticed.

Table 1 – Treatment temperature and washing

4 Conclusion

It was found that the main variable influencing the Ca/P ratio is the pH value, as described by Ranito e al. [11]. During this study, the reaction pH initiated at 12, for all tests, decaying slowly with the acid addition until the equivalence point is reached near the completion of the acid addition.

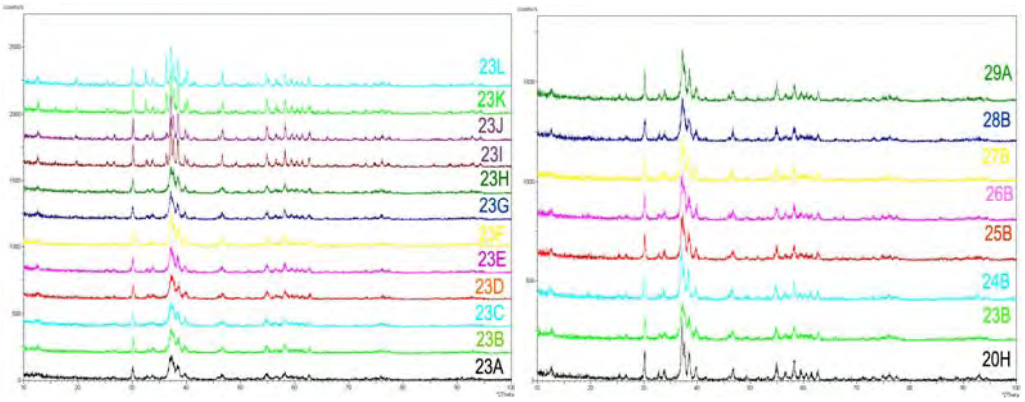

Figure 3 – X-ray difractograms.

Table 2 – T and pH values

Sample	Test T (ºC)	Treatment T (ºC)	pH
20H	80	500	5
23B	40	80	5
24B	40	80	7
25B	40	80	9
26B	40	80	11
27B	40	80	5
28B	40	80	5
29[a]	60	80	5

As it is important that the reactional mixture has the correct stoichiometric quantities, pH has to be controlled effectively, otherwise, at pH levels lower than 7, the formation of calcium monophosphate and dehydrated calcium, which are quite soluble in water medium, can take place [20,21]. Considering the obtained X ray diffraction spectra (Figure 3: samples 23B, 24B and 25B) it can be concluded that the optimum range for pH is from 7 to 9. Also, the analysis of difractograms (Figure 3: samples 28B and 29A) revealed a higher degree of crystallinity for the sample obtained at 60ºC, as indicated in Table 2. Also, the use of deionised water, instead of distilled water for preparation of reagents may lead to the need to use a higher temperature so that to promote the dissolved CO_2 removal. On the other hand, a very high temperature will lead to dehydroxilation and will also increase the energy consumption. The optimal temperature was, then, determined to be 60ºC. Stirring should be mechanical and vigorous in order to promote an homogenous HAP precipitate. An insufficient stirring may allow the formation of monetite and brushite [20,22]. Apart from that, an adequate stirring will contribute to a better pH control of the reactional mixture and promotes a better interaction of the reagents. In the performed tests, the optimal stirring velocity was of 150 r.p.m. At this velocity it is possible to visualise the phase separation involved in precipitate formation. Regarding the acid addition flow rate, the obtained difractograms do not allow to derive further conclusions, but it is expected that lower addition flowrates will lead to bigger crystallites as referred by Saeri et al. [9]. HAP exhibits susceptibility to the substitution of CO_2 in its crystalline structure, as CO_3^{2-} ions could substitute the hydroxyl or phosphate groups, originating then the formation of carbonated HAP [7]. The presence of carbonate ions in the HAP structure diminishes its thermal stability. Thus, in order to avoid this problem, an effective inertization (for instance, using nitrogen) of the reactional medium and reagent used is needed. This effect can be observed in the obtained IV spectra, shown in Figure 1, where a diminishing of peak intensity corresponding to CO_3^{2-}can be noticed. X ray diffraction showed that an increased sintering temperature results in a slight increase of particle size and, therefore, to the formation of crystallites. This could be due to the decrease of CO_3^{2-} ions in the HAP structure and, therefore, to an increased stability. At 800ºC, carbonated HAP experience a significant decomposition [23], and when calcination temperatures are higher than 800º C, the release of Ca^{2+} takes place, thus resulting in CaO oxidation [11], which in turn forms whitlockite, as a secondary phase calcium deficient in the HAP structure. Comparing X-ray analysis with IV spectra it was concluded that the optimal sintering temperature is 500ºC, showed by diminishing the intensity of the peak characteristic for the carbonate group and thus the presence of the HAP monophase. X-ray diffraction allowed to determine the crystallite size in the range of 18 to 26 nm, as well as the occurrence of HAP monophase until a temperature of 500ºC, and additionally a secondary whitlockite phase at 800ºC. The IV spectra of the obtained precipitates showed that all of them are, indeed, HAP; while SEM analysis allowed to identify two types of agglomerates of different sizes. The global conclusion is that the synthesized HAP nanoparticles are structurally identical to biological apatites, which makes the development of this process at an industrial scale very attractive within the scope of bone tissue engineering.

Keywords: metallocene; sol-gel method; SAXS; polymerization; polyethylene
Topic: Multi-scale and/or multi-disciplinary approach to process-product innovation.

Abstract

A series of homogeneous metallocenes (Cp_2ZrCl_2, (^{n}BuCp)$_2ZrCl_2$, (^{i}BuCp)$_2ZrCl_2$, (^{t}BuCp)$_2ZrCl_2$, Cp_2TiCl_2, Cp_2HfCl_2, $EtInd_2ZrCl_2$ and $Et(IndH_4)_2ZrCl_2$) was immobilized within silica matrix concomitantly with its preparation using a non-hydrolytic sol-gel method. Resulting catalysts were characterized by Small Angle X-ray Scattering (SAXS) and nitrogen adsorption. The results show that the silica particle was formed by the aggregation of primary structures having a diameter of about 160 Å. This result suggests that the metallocene is surrounded by primary particles deep inside the silica matrix. The low polymer productivity exhibited by the less active metallocene could be related to the problems of particle fragmentation due to monomer mass transfer limitations along the partially fragmented particle, which would subsequently affect catalytic activity. In order to overcome this problem the metallocene content in the silica should be increased.

1 Introduction

The performance of a supported metallocene might change due to the electronic and steric effects from the carrier. Most of the supported metallocenes exhibit lower catalytic activities and lead to different polymer properties in comparison with the equivalent unsupported complexes (Severn et al., 2005). Despite the fact that the carrier might result in some negative effect on the performance of the metallocene (e.g. lower catalytic activity), it is worth noting that some of the outcomes are desirable including the reduction in the quantity of methylaluminoxane (MAO) used for the catalyst activation. Because of these considerations, the choice of the support and the immobilization method play important role in the performance of the metallocene during the polymerization reaction.

In order to overcome some of the aforementioned problems arising from the metallocene immobilization, several methods have been proposed addressing the support methodology, new supports, or chemical treatments of the support (Severn et al., 2005). In a previous work, we have proposed the immobilization of zirconocenes into a silica matrix concomitantly with the oxide synthesis by a non-hydrolytic sol-gel method (Fisch et al., 2006). The resulting catalysts showed to be active for ethylene polymerization with similar activities to those found in Cp_2ZrCl_2 grafted on commercial SiO_2. As an extension of this previous study, the present work addresses the immobilization of different metallocenes within silica by the proposed method (Fisch et al., 2006) and the characterization of the resulting silica by Small Angle X-ray Scattering (SAXS) and N_2 adsorption (BET isotherm). In addition, the catalysts were evaluated in ethylene polymerization in an attempt to obtain some correlation with the silica structural parameters.

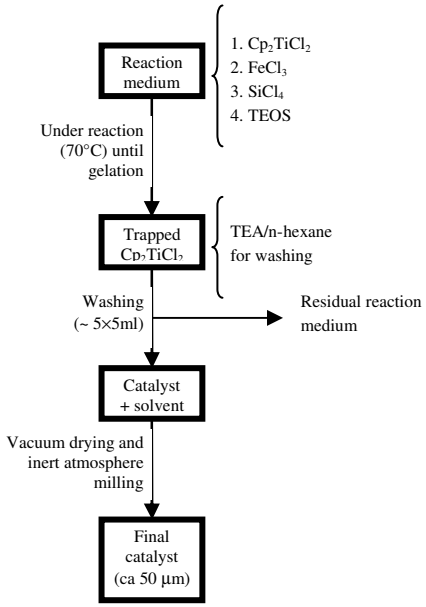
2 Materials and Methods

Catalysts synthesis

All chemicals were analytical reagent grade and the experiments were performed under inert atmosphere using the Schlenk technique. Heterogenization of the metallocenes was concomitantly performed on the silica synthesis and was carried out according to a non-hydrolytic sol-gel route based on the studies of Hay and Haval (1998) and Bourget et al. (1998). However, modifications were performed to avoid metallocene deactivation.

Scheme 1 shows the synthetic route used in this study. Zirconocene (ca. 0.10 g) was dissolved in toluene (1 cm^3), followed by the addition of $FeCl_3$ (0.02 g), $SiCl_4$ (2.5 cm^3), and 5 cm^3 of tetraethylorthosilicate (TEOS). The reaction was performed at 70 °C until gelation. Following, the resulting oxide was washed (20×2 cm^3) with a triethylaluminum (TEA) n-hexane solution (ca. 0.5 wt.%) at room temperature in order to eliminate residual ethoxide groups (dos Santos et al., 2001). The solid was further dried under vacuum for 12 h at room temperature and milled under inert atmosphere (argon) until reaching a diameter of 20-53 μm. A more detailed description of the synthesis methodology and the catalyst characterization can be found elsewhere (Fisch et al., 2006).



Scheme 1: Route for the catalyst synthesis

Catalyst characterization

Rutherford Backscattering Spectrometry (RBS) was used for evaluation of the Zr loadings (wt.-% Zr/SiO_2) in catalysts.

The Small Angle X-ray Scattering (SAXS) experiments were carried out using synchrotron radiation at LNLS (Campinas, Brazil) at wavelength λ= 1.488 nm. The beam was monochromatized by a silicon monochromator and collimated by a set of slits that define a pinhole geometry. A solid-stated CCD detector (MAR 160) was used to collect two-dimensional (2D) images with 2048×2048 pixels located at 6752.5 mm on the sample. The angular range of the scattering curves was 0.02 $Å^{-1} \leq q \leq 0.49$ $Å^{-1}$, where q is the scattering vector ($q = \frac{4\pi}{\lambda}\sin\left(\frac{\theta}{2}\right)$). The data were corrected for sample transmission and background scattering using an empty cell as reference. Samples were placed in stainless steel sample holders closed by two mica windows.

Morphological characterization of silica particles was performed by Nitrogen adsorption-desorption isotherms. Samples were previously degassed (10^{-2} mbar) at 85 °C for 10 h. Adsorption-desorption nitrogen isotherms were measured at -196 °C in a Gemini 2375 (Micromeritics). The specific surface area (SBET) was determined by the Brunauer-Emmett-

Teller equation (P/P0 = 0.05-0.35). The mesopore size and distribution were calculated by the Barrett-Joyner-Halenda (BJH method) using the Halsey standards. A desorption branch was used. Micropore volumes were calculated by the t-plot method, using the Harkins and Jura standard isotherm.

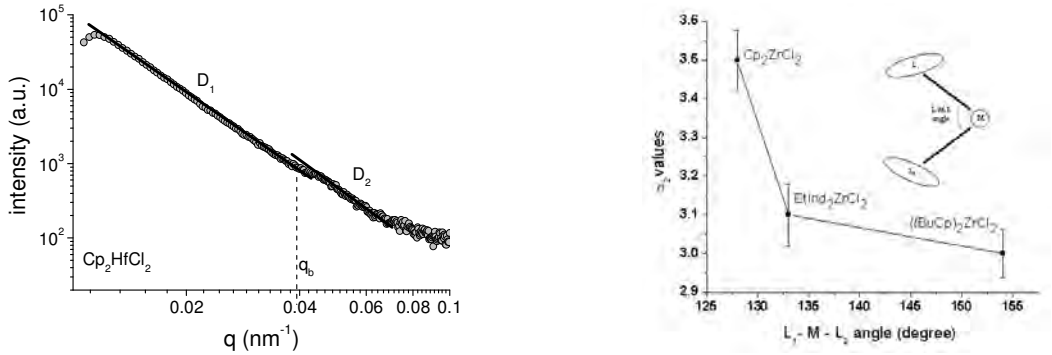
Scanning Electron Microscopy (SEM) was performed in a JSM 5800 (JEOL) microscope, operating between 10 and 20 kV. The samples were coated with a thin layer of sputtered conductive carbon.

Polymerization

Ethylene polymerization reactions were performed in 150 cm^3 of dried toluene in a 300 cm^3 Pyrex glass reactor connected to a constant temperature circulator and equipped with magnetic stirrer and inlets for Argon and the monomer. Methylaluminoxane (MAO) was used as the co-catalyst. For each experiment, a mass of catalyst system corresponding to 10^{-5} M of the metal was suspended in 5 cm^3 of dry toluene and transferred into the reactor under argon. The polymerizations were performed at 1.6 bar of absolute pressure of ethylene for 30 min at 60 °C. Acidified (HCl) ethanol was used to quench the process, and reaction products were separated by filtration, washed with distilled water, and finally dried under reduced pressure at 60°C overnight.

3 Results and Discussion

A typical SAXS profile found for the supported metallocenes is shown in Figure 1, in which two distinct regions are identified as follows: D_1 for $q<q_b$ and D_2 for $q>q_b$. A characteristic length (ξ) corresponding to the spatial scale of the primary particles was estimated as $\xi = 2\pi/q_b$.



(a) (b)

Figure 1: Typical SAXS profile found for the synthesized catalysts (a) and relationship between fractal dimension and the metallocene bit angle (b).

The scattering intensity profile for $q<q_b$ shows characteristics of the particle with dimensions higher than ξ (D_1 region). Conversely, the characteristics of the particle with dimensions lower than ξ are found in the region of the scattering profile where $q>q_b$, which corresponds to the D_2 region. Therefore, information about the influence of the metallocene in the silica structure could be found in this region considering that the organometallic complex is trapped within the interstices formed by the primary particle agglomeration.

In these regions, the scattering intensity (I) is given by $I = A.q^{-\alpha}$ where the exponent α is usually related to a fractal dimension and the parameter A is a proportionality constant. As shown in Table 1, all α_1 values were found to be between 3.1 and 3.4, which represents the interval attributed to surface fractal structures (Hiemenz, 1997). Furthermore, no clear trend can be established between α_1 values and the metallocene structures. Conversely, α_2 values lie between 3.0 and 3.5, with the exception of $Et(IndH_4)_2ZrCl_2$. In addition, a correlation between α_2 values and the ligand-metal-ligand angle of the metallocenes, which describes a steric hindrance measurement of its structure (Cruz et al., 2004), was found as shown in

Figure 1b. Moreover, α_1 values did not show a clear correlation with the steric hindrance of the metallocene.

Table 1: Fractal dimension for catalysts prepared through concomitant metallocene immobilization with the silica synthesis and its performance in ethylene polymerization.

Entry	Catalyst	α_1	α_2	ξ (Å)	R_g (Å)	Metallocene content (wt.% M)	Activity (kg_{pol}/mol_M)[1]
1	Cp_2ZrCl_2/SiO_2	3.2	3.5	157	95	0.50 ± 0.048	2300
2	Cp_2TiCl_2/SiO_2	3.3	3.5	157	98	0.30 ± 0.0039	Traces
3	Cp_2HfCl_2/SiO_2	3.4	3.3	157	92	0.44 ± 0.0033	100
4	$EtInd_2ZrCl_2/SiO_2$	3.4	3.1	157	93	0.27 ± 0.0064	Traces
5	$Et(IndH_4)_2ZrCl_2/SiO_2$	3.1	2.1	153	96	0.27 ± 0.032	Traces
6	$(n\text{BuCp})_2ZrCl_2/SiO_2$	3.1	-	-	106	0.35 ± 0.017	3600
7	$(i\text{BuCp})_2ZrCl_2/SiO_2$	3.4	3.2	161	100	0.30 ± 0.011	Traces
8	$(t\text{BuCp})_2ZrCl_2/SiO_2$	3.1	3.0	157	98	0.19 ± 0.027	Traces
9	Cp_2ZrCl_2/SiO_2[2]	-	-	-	-	0.71 ± 0.058	200
10	Cp_2TiCl_2/SiO_2	-	-	-	-	1.36 ± 0.037	700
11	Cp_2HfCl_2/SiO_2	-	-	-	-	1.45 ± 0.042	1000
12	$EtInd_2ZrCl_2/SiO_2$	-	-	-	-	1.43 ± 0.065	800

1- Polymerization conditions: 1.6 bar of ethylene, Al(MAO)/M= 1000, 60°C, toluene, 30 min.
2- Catalyst particles with diameter 53-100 μm.
Activities of the homogeneous metallocenes under same polymerization conditions: Cp_2TiCl_2: 1150 kg_{pol}/mol_{Ti}; Cp_2HfCl_2: 1750 kg_{pol}/mol_{Hf} and $EtInd_2ZrCl_2$: 3000 kg_{pol}/mol_{Zr}.

The spatial scale of the primary particles, which was estimated by $\xi = 2\pi/q_b$, was found to be about 160 Å for all samples. Therefore, the influence of the metallocene behavior on the primary particle dimension (ξ) was not clearly observed.

It is possible to evaluate the radius of gyration (R_g) of the particles from the SAXS profile (Figure 1a) considering the Guinier regime and obeying the condition $qR_g << 1$, i.e., $q \rightarrow 0$. Table 1 shows that the R_g values are around 100 Å, which are comparable to the value found for the spatial scale of the primary particles ($\xi \approx 2R_g$= 200 Å).

The texture of the catalysts was also analyzed by N_2 adsorption as shown in Table 2. The resulting specific area seems to be dependent on the steric effect of the metallocene itself. On the other hand, the average pore diameter remained roughly constant.

Table 2: Specific area and average pore diameter of the supported catalysts.

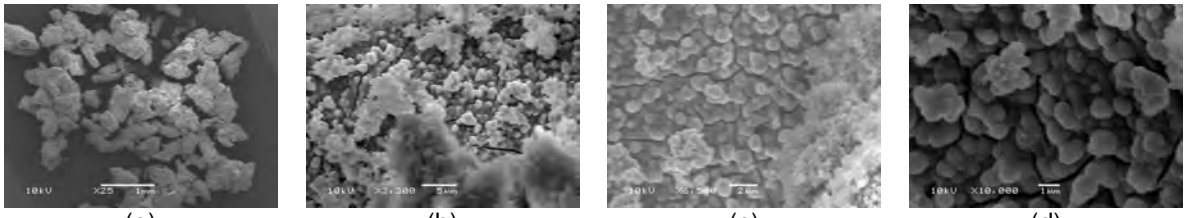
Entry	Catalyst	Specific area ($m^2.g^{-1}$)	Pore diameter (Å)
1	Cp_2ZrCl_2/SiO_2	17 ± 0.040	30
2	Cp_2TiCl_2/SiO_2	29 ± 0.038	31
3	Cp_2HfCl_2/SiO_2	48 ± 0.046	26
4	$EtInd_2ZrCl_2/SiO_2$	170 ± 0.041	26

The catalysts characterization results show that the silica particle produced by a sol-gel method with the concomitant metallocene immobilization could be interpreted using the model of aggregation of the primary structures for the formation of the final silica particle structure (Kuramada et al., 1998; Boukari et al., 1997). Taking into account the presented results, the metallocene seems to be entrapped within the primary structures that form the oxide network, or in other words, the metallocene is surrounded by primary structures. In fact, the deeper location of the metallocene complex could cause quite a different performance for the catalysts.

The catalytic activity in the ethylene polymerization as well as the metallocene content (wt. % M, M= Zr, Ti or Hf) measured by RBS are shown in Table 1. Cp_2ZrCl_2, Cp_2HfCl_2 and $(^n\text{BuCp})_2ZrCl_2$ showed to be actives but, in general way, all catalysts showed poor catalytic activity. $(^n\text{BuCp})_2ZrCl_2$ exhibited a higher activity than Cp_2ZrCl_2, which follows the same trend observed in homogeneous polymerization. The electronic donation by the alkyl chain to the Cp ring, which in turn acts on the Zr center, renders the catalyst site less acidic and

increases the catalytic activity. In addition, no clear correlation between activity and fractal dimension was found.

To complement these results, Figure 2 shows SEM micrographs of the polymer obtained in the ethylene polymerization using catalysts with diameters between 53-100 μm (entry 9 in Table 1). The presence of spherical polymer particles can be observed on the residual non-fragmented catalyst. In this sense, it is possible to observe the importance of catalyst breakup with respect to its activity.



(a) (b) (c) (d)

Figure 2: Micrographs of polymer particle obtained in the ethylene polymerization with Cp_2ZrCl_2/SiO_2. Particle diameter around 53-100 μm (entry 9 in Table 1). Magnification: (a) 25×, (b) 3300×, (c) 6500×, and (d) 10000×.

The reduction in the catalytic activity observed for the resulting catalysts could be attributed to restrictions of monomer access to the active sites due to an inadequate particle fragmentation during the early moments of the polymerization. The pores of the remaining larger pieces of support are full of polymer hindering the access of the monomer to the active sites and leading to a decrease in the catalytic activity. Experimental results addressing this issue have been reported in the literature for supported metallocene catalysts (Hammawa and Wanke, 2007; Zheng et al., 2005), silica-supported Ziegler-Natta catalysts (Ruddick and Badyal, 1997), and Philipps catalysts (Weist et al., 1989). Such studies have shown that the fragmentation is closely related to the physical resistance of the support to break up into many pieces of 0.1 to 20 μm in diameter.

In fact, the activity of the majority of the metallocenes used in the present study is lower than that found in homogeneous Cp_2ZrCl_2 and $(^nBuCp)_2ZrCl_2$ and it might be insufficient to promote an effective rupture of the oxide matrix. Additionally, a huge shell of oxide matrix around the metallocene hinders the breakup of the particle due to the deep location of the metallocene complex into the silica matrix. Under these conditions, monomer mass transfer along the particle radius could hinder the polymerization, which subsequently reduces catalytic activity (Zheng et al., 2005; Ruddick and Badyal, 1997). Taking the aforementioned results, the influence of the particle diameter on the catalyst activity was evaluated by comparing the performance of Cp_2ZrCl_2/SiO_2 with particle diameters of 20-53 μm and 53-100 μm (entries 1 and 9 in Table 1, respectively) in the ethylene polymerization. The resulting activities suggest that the fragmentation hinders the performance of the catalyst when metallocenes of lower activity are immobilized following the proposed methodology.

In an attempt to solve the described diffusion problems, the supported catalysts Cp_2TiCl_2, Cp_2HfCl_2 and $EtInd_2ZrCl_2$ were synthesized with higher metallocene content (ca. 1.5 wt-% Zr) which is possible since the immobilization does not depend on reactions with hydroxyl groups located on the pore surface, such as in the case of the traditional methods (dos Santos et al., 1999). Ethylene polymerization was used to evaluate the performance of these systems as shown in Table 1 (entries10-12). The obtained activities were lower than those resulting from polymerizations with the same homogeneous metallocene (see footnote in Table 1), as expected for most immobilized metallocenes by different methodologies, but much higher than those of the respective catalysts with lower metallocene content (entries 3-4, Table 1). So, it is noticeable that an increase in the amount of metallocene allows the catalysts to break up more adequately during the early moments of the polymerization, and therefore helps to overcome the monomer accessibility hindrance to the active sites in comparison with other studies.

According to the obtained results, it could be pointed out for these catalytic systems that the activity is not related to the particle morphology on the scale of molecular structure of the metallocene complex and its closer surroundings. Conversely, the activity depends on the catalyst fragmentation once the catalytic species have a deep location within the support matrix.

4 Summary

The immobilization of metallocenes within a silica matrix using a non-hydrolytic sol gel route shows that the silica particle was formed by the aggregation of the primary structures with a diameter of about 160 Å. The aggregation process seems to be affected by the metallocene structure which suggests that the organometallic complex is surrounded by primary particles having a deeper location in the oxide matrix. Some metallocenes, which in homogeneous systems are less active, showed a negligible activity when entrapped within the oxide matrix by the proposed method. This result seems to be related to problems of catalyst fragmentation leading to monomer mass transfer limitations along the partially fragmented particle. In order to solve this problem, the amount of metallocene in the catalyst should be increased.

Keywords: red mud, chromium, adsorption, levigability
Topic: Sustainable process-product development through green chemistry - Sustainable & clean technologies

Abstract

This study has involved the investigation of how the sulphuric acid and alkaline-earth metals neutralize the red mud and measurement of zero charge points (ZCP) in the neutralized red mud with the aim of assessing their neutralization level.

Red mud neutralized with sulphuric acid down to pH = 8 was used as adsorbent for Cr^{3+} ions found in tannery effluents. Subsequently the leaching of the chromium bound to the red mud was tried by levigation tests at pH = 3.5. Even though there was a good chromium adsorption onto the red mud neutralized with sulphuric acid, this has resulted from an reversible interaction. Under such conditions, other neutralization types were tried by means of alkaline-earth metals. Trials for red mud neutralization from pH=12.5 down to pH=11 and 9 by means of $CaCl_2$, $MgSO_4$, $MgCl_2$ and combinations of these have led to sludges showing ZCP values below the pH values for the neutralized sludge, in the range of negative charges, proper for positively charged ion adsorption.

Neutralization by alkaline-earth metals has resulted in new solid phases of higher chemical stability, able for chromium seizing.

1. Introduction

90 % of hides processed currently in the world are subjected to tannage with basic chromium salts that give rise unavoidably to a great amount of chrome leather wastes containing about 75-85 % organic matter and not less than 2.5 % Cr_2O_3. Leather wastes containing chromium (LWCC) reach about 25 % of the whole weight of salted hides to be processed, that is a burden for the leather sector performances and success related to the environment protection [1].

Waste processing by hydrolysis and protein reclamation for a variety of viable applications (biofertilizers, surfactants, eco-adhesives etc.) [2] cause the chromium compound transfer (with economically non-convincing applications) into the effluents and sludge, and their treatment and disposal has to be considered from the environmental point of view.

This work suggests an adsorbing material prepared particularly by neutralization of the residual red mud, collected in large ponds from the alumina refining plants [3], to be used in binding the tannery residual chromium in the solid phases and stabilizing it with the view of long term storage.

The environmentally compatible mineral complex resulting from the two noxious wastes is a potential source to obtain embedded compounds or for other applications [4].

2. Experimental

In this study the neutralization by 20 % sulphuric acid at various pH values was chosen.

Method: 20 % sulphuric acid was added to each raw red mud sample of pH = 13.30 while stirring and the pH was recorded after 10 minutes of stirring for every adding until the pH becomes steady, showing such values as 8, 9 and 10, respectively. The resulting dispersions were vacuum filtered, and deposits were dried progressively at 50°C, 70 °C in an oven for 6 hours each and subsequently let stay at 110°C for 3 hours. After cooling samples were mixed in a mortar and sealed in flasks.

For the trials of chromium retention on the neutralized red mud some solutions of basic chromium sulphate of a variety of concentrations within the common range found in the tannery effluents were prepared and the red mud was neutralized to pH =8.

The chromium absorption efficiency was assessed by levigation tests.

Method: Adsorption and levigation tests were carried out at the ambient temperature and at a liquid/solid ratio of 10/1, contact time between phases of 4 hours, under mixing.

Neutralization with calcium and magnesium salts were conducted in different ways because of the slow reactions involved and delayed crystallization in the new solid phases.

Method: 1 mol/L solutions of $MgCl_2$, $MgSO_4$ and $CaCl_2$ were prepared. Small portions (0.5 – 5 ml) of each solution were taken and stirred within the sludge at every 24 hours at pH values of 11.0 – 9.00 under control. Samples both of liquid and solid phase were subjected thereafter to analysis.

Methods of analysis: The pH was measured with Consort C833 ionmeter. Calcium and magnesium were analyzed by complexometric titration. Mineralogical phases were identified by XRD using Dron 2 spectrometer along with their semi-quantitative assessment by Philips PW2400 X-ray fluorescence spectrometer. Chromium in liquid phases was analyzed by Varian AA240FS fast sequential AAS spectrometer.

Zero charge point (ZCP) providing information on neutralization level in the red mud was assessed from the plot of surface charge against the pH values registered in the acidic-alkaline titration, $\sigma = f(pH)$, being the point where the curve crosses the pH axis. With that end in view, the mud neutralized with calcium and magnesium salts were subjected to the potentiometric titration [5] with 0.1 N hydrochloric acid.

Method: Each sample of 0.1 g (weighed on an analytical balance) red mud, raw and neutralizat by calcium and/or magnesium salts, spread by stirring in 100 ml solution of 0.01 M, 0.1 M and 0.5 N NaCl electrolyte and degassed by nitrogen bubbling was subjected to titration with 0.1 N HCl solution of established factor, under the nitrogen atmosphere.

Also, 100 ml electrolyte solution of every concentration degassed previously by nitrogen bubbling was subjected to titration with 0.1 N HCl and 0.1 N NaOH solutions of established factors, under the nitrogen atmosphere.

Data obtained from potentiometric titration were used to compute the surface charge σ, with the following formula (1):

$$\sigma = \frac{\Delta \upsilon \times M \times F \times 100}{S \times A \times V} \qquad (1)$$

where:

$\Delta \upsilon$ = volume of HCl solution used in the red mud sample titration – volume of HCl or NaOH solution used in blank (electrolyte) titration at the same pH value;

M = normality of the titrating solution (0.1 N);

F = 96500 C;

S = specific area of the red mud;

A = amount of red mud weighed on the analytical balance;

V = the electrolyte volume being used (100 ml);

Specific areas of the raw and neutralized red mud samples were measured on an ASAP (Accelerated Surface Area and Porosimetry) 2020 System with nitrogen as analysis adsorbent.

After having the ZCP assessed, the chromium adsorption capabilities of the mud samples neutralized with calcium and magnesium salts were tested by techniques similar to those for mud neutralized with sulphuric acid.

3. Results and discussions

Phase composition was not changed by neutralization with sulphuric acid, the major participation of every red mud constituent being kept unchanged when pH was decreased from the initial one of 12.0-12.5 to 8.0, feature revealed in Table 1.

Table 1

COMPOSITION OF THE MUD NEUTRALIZED WITH SULPHURIC ACID

Composition	**Level in the neutralized red mud, %**		
	at pH = 10	**at pH = 9**	**at pH = 8**
Al_2O_3	Al_2O_3	19.0	18.0
SiO_2	SiO_2	7.4	7.4
P_2O_5	P_2O_5	0.7	0.6
SO_3	SO_3	1.0	1.5
Cl	Cl	1.1	1.2
CaO	CaO	3.3	3.4
TiO_2	TiO_2	8.6	9.2
V_2O_5	V_2O_5	0.2	0.2
Cr_2O_3	Cr_2O_3	0.3	0.3
MnO	MnO	0.1	0.2
Fe_2O_3	Fe_2O_3	50.9	57.8
PbO	PbO	0.1	0.1

Sulphuric acid has neutralized the sodium ions, promoting the $Al(OH)_3$ precipitation as gibsit and was removed as soluble sodium sulphate from the red mud.

No red mud constituent containing calcium dioxide and silicon dioxide (calcium aluminates, calcium silicates, calcium alumino-silicates etc.) has been decomposed and changed molar ratios to other constituents.

Event though the sulphate ion concentration in the solid phase has increased with the neutralization progress, this is only because of including in the alumino-silicate formulae and not the calcium sulphate crystallization. Though, the neutralization process has stabilized the material and increased its ion exchange capability.

Red mud neutralized with sulphuric acid down to pH = 8 was used as adsorbent for Cr^{3+} ions. Trial results are shown in Table 2.

Table 2

CHROMIUM ADSORPTION ONTO THE RED MUD
NEUTRALIZED WITH SULPHURIC ACID

Sample	**Inital Cr concentration, g /l**	**Final Cr concentration, mg/l**	**Cr load in the red mud mg/g**
1	1.7105	3.954	3.954
2	1.3684	1.709	1.709
3	1.0263	1.236	1.236
4	0.6842	0.006	0.006
5	0.3421	0.048	0.048

The random sizes of red mud particles and porosity spreading account for the irregular variation in the output chromium level.

Subsequently the leaching of the chromium bound to the red mud was tried by levigation tests at pH = 3.5.

Data in Table 3 have revealed the strong Cr^{3+} binding on the solid adsorbing phase and reasonable chromium amounts released in the leaching water.

Table 3

DATA ON THE CHROMIUM LEACHING AT pH 3.5

Sample	Cr in the washing I effluent, mg/g	Cr in thr washing II effluent, mg/g	Cr in thr washing III effluent, mg/g
1	33×10^{-5}	37×10^{-5}	0
2	42×10^{-5}	45×10^{-5}	26×10^{-5}
3	13×10^{-5}	40×10^{-5}	80×10^{-5}
4	15×10^{-5}	58×10^{-5}	68×10^{-5}
5	23×10^{-5}	12×10^{-5}	56×10^{-5}

Even though there was a good chromium adsorption onto the red mud neutralized with sulphuric acid, this has resulted from an reversible interaction.

Under such conditions, other neutralization types were tried by means of alkaline-earth metals.

The common calcium and magnesium salts can remove alumina from the diluted alumina solution by binding it as insoluble aluminates and aluminate-silicate compounds with or without captured sodium ions. Such compounds give a high specificity for the heavy metal adsorption.

Trials for red mud neutralization from pH=12,5 down to pH=11 and 9 by means of $CaCl_2$, $MgSO_4$, $MgCl_2$ and combinations of these have led to sludges showing ZCP values below the pH values for the neutralized sludge, in the range of negative charges, proper for positively charged ion adsorption.

Data obtained from the potetiometric titration (acid/base) were use in calculating the surface charges σ required to assess the ZCP, as shown in Figures 1 and 2.

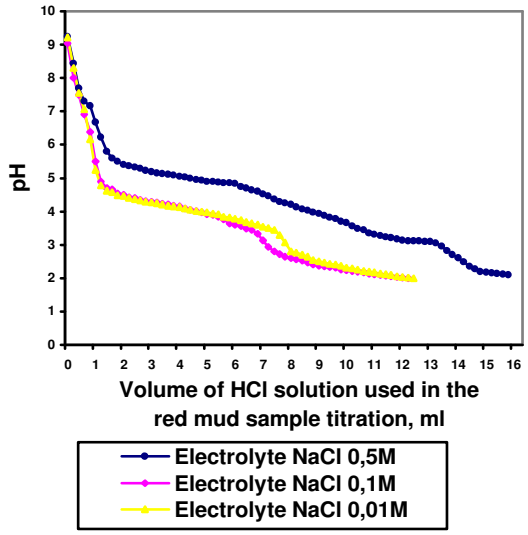

Figure 1. Titration of raw red mud, pH = 12.5, dry

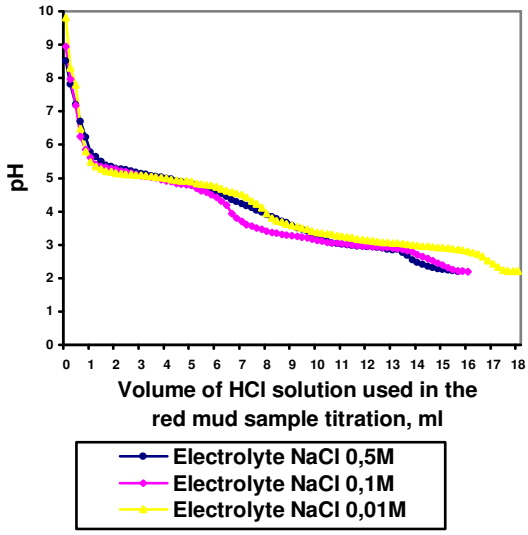

Figure 2. Titration of the red mud, neutralized with $MgCl_2$, pH = 9, dry

ZCPs assessed from the plots σ = f (pH) in Figures 3 and 4 are shown in Table 4.

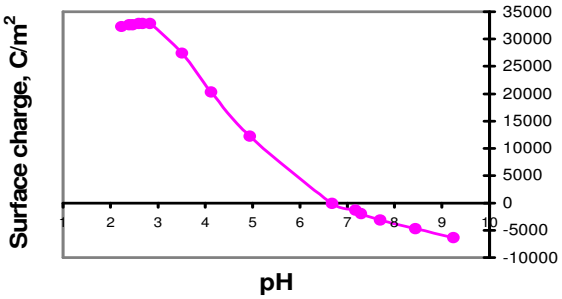

Figure 3. Assessing the ZCP in the 0.5 M NaCl electrolyte solution of the red mud, dry

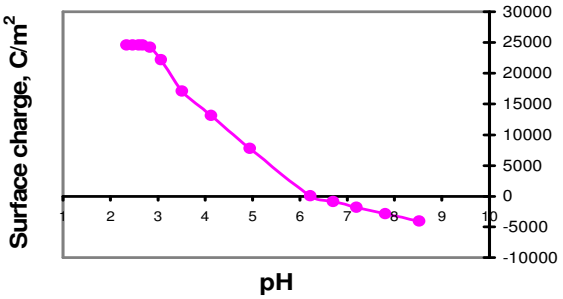

Figure 4. Assessing the ZCP in the 0.5 M NaCl electrolyte solution of the red mud neutralized with $MgCl_2$ at pH = 9

Table 4

ZCP VALUES OBTAINED FROM TRIALS

Ref. No.	Neutralizing agent	Initial pH	Zero charge point for:					
			Wet mud, in NaCl solution			Dry mud, in NaCl solution		
			0.01M	0.1M	0.5M	0.01M	0.1M	0.5M
1	- (raw mud)	12.5	6.25	6.26	6.50	6.05	6.28	6.69
2	$CaCl_2$	11	592	5.89	6.38	6.09	6.44	6.76
3	$CaCl_2$	10.5	5.83	5.93	6.37	5.74	6.39	6.73
4	$MgSO_4$	11	5.58	6.12	6.31	5.88	6.24	6.54
5	$MgSO_4$	9	5.98	6.33	6.38	5.88	6.24	6.52
6	$CaCl_2 + MgSO_4$	11	5.74	6.30	6.37	5.89	6.44	6.56
7	$CaCl_2 + MgSO_4$	9	5.94	5.83	6.34	5.61	6.45	6.53
8	$MgCl_2$	11	6.40	5.89	6.86	6.12	6.42	6.83
9	$MgCl_2$	9	5.62	6.05	6.40	6.28	6.13	6.21
10	$MgCl_2 + CaCl_2$	11	6.76	6.13	7.17	6.50	6.72	6.64
11	$MgCl_2 + CaCl_2$	9	5.71	5.91	6.33	5.84	6.00	6.58

When comparing the ZCP values for the mud samples investigated by potentiometric titration, no significant changes in such parameter based on the concentration the electrolyte wherein the mud samples were spread were found, and these changes fall in the acid range below the initial mud pH, in the negative charge range that is proper for the adsorption of positively charged ions.

Inducing the new solid phase by neutralization with calcium and magnesium salts used in trials has preserved the surface properties of the red mud particles, favourable for chromium adsorption, meaning that the red mud subjected to neutralization with calcium chloride, magnesium sulpahte and magnesium chloride or blends of these can become an adequate adsorbent for chromium.

Even though the red mud can bind the chromium that has been revealed by the values found for ZCP, this was proved not to be enough for a long lasting adsorption under critical conditions such as large pH variation. From the other point of view, use of the red mud waste as such in some applications is unacceptable because of the pH values and very high free alkalinity inducing environmentally adverse action. Considering these, the red mud neutralization is a significant stage, sensitive because of its outcomes for the process of irreversible binding of chromium within the mineral complex making up the red mud.

A comparative review of the ZCPs for the wet and dry red mud samples has revealed a more homogenous variation in the dry mud samples because of the removal of crystallization

water contained in some of the new compounds resulting during neutralization, leading thus to a behaviour lightly different in the acid-alkaline titration.

The mud samples neutralized with magnesium chloride and blend of magnesium chloride and calcium chloride have shown titration curves of very different shapes as compared to the raw mud that suggests some new compounds occurring, as it was predicted.

The tests for chromium adsorption onto the red mud samples neutralized with magnesium chloride and blend of magnesium chloride and calcium chloride have shown adsorption efficiencies above 99 % resulting at a maximum load of cca. 32 mg chromium/1 g mud for the mud sample neutralized with magnesium chloride, and of cca. 30 mg chromium/1 g mud for the mud neutralized with the blend of magnesium chloride and calcium chloride.

Even though the amount of bound chromium above these limits was found in the mud sample, the efficiency has shown a significant decrease, and, therefore, the limits of 32 and 30 mg chromium / 1 g mud, respectively, can be considered the maximum adsorption capabilities for the two neutralized red mud samples.

4. Conclusions

- Red mud neutralization by sulphuric acid is an outstanding solution recommended for its treatment previously to storage in ponds.
- Neutralization by alkaline-earth metals has resulted in new solid phases of higher chemical stability, able for chromium seizing.
- Solid phases induced into the red mud by neutralization have created the premises for a long lasting chromium adsorption so that the resulting mineral complex can be preserved under environmental conditions as an inert waste until some economically viable application would have been developed.
- Simultaneous dumping of two hazardous wastes (residual chromium resulting from the hide processing that is a source of Cr (VI), and highly alkaline red mud resulting from alumina industry) under safe conditions is e solution for rendering the referred two activities environmentally friendly.

Topic: Advancing the chemical engineering fundamentals;
Sustainable process-product development through green chemistry

Abstract

This paper provide an experimental study based on mathematical statistic that is the factorial experiment designs regarding the effects of ultrasounds power on the extraction efficiency of acid solubization of uranium originated from dumps. The operation parameters varied using a 2^{5-1} factorial experiment were the temperature, the pH of the reaction medium, the operating time and the ultrasound power (Şayan and Bayramoğlu, 2004) . The mathematic model obtained through the experimental results processing was determined using the least squares method and it describes dependency of the extraction efficiency on the technical and economical significant operation parameters. Mathematical model optimization was performed using a maximum slope algorithm and it points out the major factors that influence the uranium extraction efficiency, namely: the temperature, the oxidant amount and the ultrasounds power within the range of studied experimental values. Ultrasound utilization has positive effects on radioactive pollution diminution, obtaining extraction efficiencies above 96% respectively 10% much higher values than those obtained in identically conditions but in the absence of the ultrasonic field.

1 Introduction

According to Sevcenco, V.B., Suderrov, B.N. (1961) the main object of activity of hydrometallurgy as technological discipline is the extraction of metals from ores, concentrates, sterile or other different industrial byproducts using the aqueous solutions of some chemical reagents followed by the separation of extracted metal from solution.

The extraction efficiencies rarelly overlap 95 – 98%, which means that about 2 – 5% of useful element remains undissoluted.

In order to intensify the extraction process of uranium from sterile and to transfer it to solution in the present paper the authors use beside the mechanical stirring the ultrasound field.

Ultrasound effects on the chemical reactions improvement were studied by Thompson and Doraiswamy (1999) and Polyukhin (1978), who have developed ultrasounds application in extractive metallurgy. Researches concerning sonochemistry application in extractive metallurgy beside the classic methods conducted to the achievement of rapid and selective extractions of the metals.

The dumps from Banat-Bihor area, where the uranium mining activity was ceased, cause severes problems due to the radioactive pollution to the environment and to the population living near by the affected areas. Therefore many researches concerning the radioactive pollutants recovery using different technologies for soils remediation were performed.

This paper aims to develop a model of ultrasounds effects on uranium dissolution in sulphuric acid medium and to optimize them. The results presented in this paper can provide ground information for a much more detailed study concerning the process development.

2 Experimental activity

Factorial calculus is applied on a large scale to the statistic planning of the experiments in order to develop empiric linear models concerning the process response to operation factors. Models of first order are obtained using a 2^n factorial experiment one where each variable works on 2 levels.

Their optimization is done by performing additional experiments that point out the major factors that influence the extraction efficiency.

Similar papers have demonstrated that the application of this type of experimental project for the useful elements dissolution out of different types of raw materials is valid.

Uranium solubilization experiments were performed on samples of 50 g dump waste (0.03% uranium) with particles of 0.100 mm grinding size, the solid/liquid mass ratio was 1:1 and the stirring velocity was maintained invariable at 500 min^{-1}(Panțuru et al. ,2006).

Experimental conditions were reached in respect to the experimental matrix. Uranium solubilization was performed in two stages; after phases separation by filtration, the residue was washed with water (S/L=1:1, mass ratio).

The efficiency of uranium extraction from the solid samples was determined with formula:

$$\eta = \frac{cU_i.g_i - cU_r.g_r}{cU_i.g_i}.100 \qquad (1)$$

In order to determine the ultrasound power, W_{abs}, the calorimeter method (Margulis et al.,2003), which is used frequently for the determination of adsorbed power at lower frequencies, was applied.

The operation period, t_{us}, of the ultrasound source is rather high (10 minutes per stage) for ΔT measuring (minimum 1^oC). The reaction vat temperature was maintained invariable to the experimentation value using a thermostatic bath.

Ultrasound generator consists into a bath ultrasound UR1 Resch (480 W, 35 kHz), the reaction vat being coupled with a reflux condenser.

The experiments were performed using as extraction reagent sulphuric acid 96% and as oxidant reagent potassium chlorate 0.5%-1% depending on the amount of solid sample used in the test, which provides an oxidation potential between 450 and 500 mV necessary to the dissolution of uranium (Okur,H.,Techin,T,2002).

There were also used specific analytic pure reagents for quantitative determinations of the elements from solid samples and for the quantitative chemical analysis of the solutions and residues formed in the solubilization process. The analytical methods used depend on the analyzed elements content namely: atomic adsorption - using a VARIAN spectrAA-88 adsorption with adequate lamps for the determined elements, colorimetry - using a UV-VIS CECIL 1011 spectrometer, volumetry, gravimetry and HPGe γ spectral method – using an ORTEC multichannel analyser with Ge detector for γ radiations (0-3 MeV)

3. Results and discusions

The studied process factors are: the reaction temperature (A), the reaction medium pH (B), the operation duration (C), the oxidant amount (D) and the ultrasounds power ($W_{abs)}$. These factors, except ultrasounds power, were used in another study of our research team and it concerned the uranium acid solubilization but only under mechanic stirring conditions in order to disperse the solid particles and to increase the solubilization velocity .The factors

levels presented in table 1 are similar to the previously used ones, hence, the performances of those two procedures can be easily compared.

Table 1. The factors used in the ultrasounds field factorial model

Factors	UM	Factor code	Range $x_{jmin} \rightarrow x_{jmax}$	The experiment centre X_{jo}	Δx_j	Level	
						inf. -	sup. +
Temperature	^{0}C	A	40→80	60	20	40	80
pH	-	B	1→1,5	1.25	0.25	1	1.5
Duration	hours	C	6→10	8	2	6	10
Oxidant	kg/t	D	6→10	8	2	6	10
US Power	watt	E	75.58→79.002	77.29	1.71	75.58	79.002

A 2^{5-1} fractional factorial calculus was used in order to develop the first order model with the interaction terms.

The experiments were randomly performed in order to avoid a systematic error. Furthermore, it was performed 2 central reproductions (1^0, 2^0) for experimental error calculation. Experimental results represented in Figure 1 point out the efficiency surface, which is obtained by rising of a vertical line at the intersection point between the temperature and ultrasounds power values.

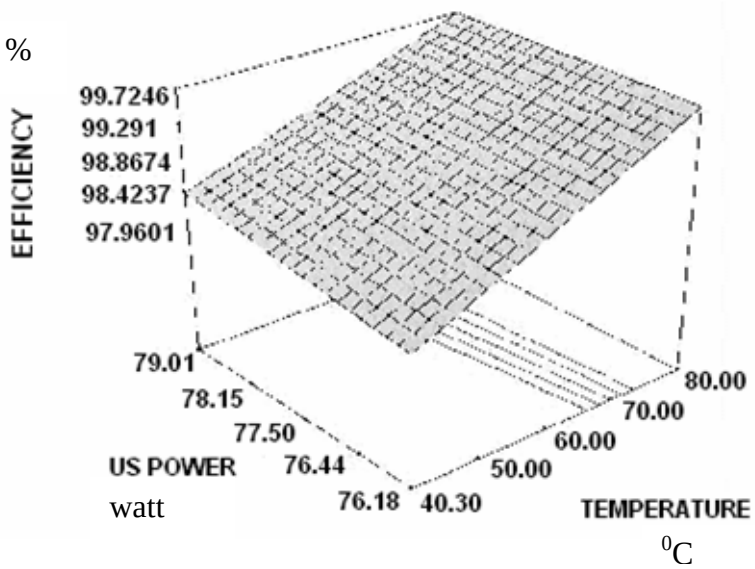

Figure 1. 3D representation of temperature/US power/efficiency interaction

The considered regression models for the selected factors are first order polynomial models that are obtained by variation analysis using Design Expert v.6 program. Hence, after the elimination of the insignificant interactions, the following 2 regression equations were obtained:

The regression equation expressed depending on the codified terms (-1/+1):

$$\eta = 98.739 + 0.981*A + 0.154*B + 0.210*C + 0.260*D + 0.076*E - 0.126*A*B - 0.085*A*C - 0.257*A*D - 0.106*A*E + 0.055*B*D + 0.049*C*D - 0.056*B*E + 0.020*C*E + 0.037*D*E \quad (2)$$

The regression equation express depending on real terms:

$$\eta = 68.910 + 0.388*T + 11.391*pH - 0.316*t - 0.564*Co + 0.260*W_{abs} - 0.025*T*pH - 0.002*T*t - 0.006*T*Co - 0.003*T*W_{abs} + 0.11*pH*Co - 0.131*pH*W_{abs} + 0.012*t*Co + 0.006*t*W_{abs} + 0.011*Co*W_{abs} \quad (3)$$

The coefficients of equation (3) were calculated with the codified values (+1, -1) of the factors and are valid for null values of the factors A, B, C, D, E. These emphasize the medium value

of the efficiency (98.739). The coefficients of equation (3) were calculated using the least squares method. The equation emphasizes the extraction efficiency for certain values of the factors (the studied range).

One can observe that the experimental values of extraction efficiency and the ones determined using the regreassion model have the liniar abnormality of ± 0.02%, and the adjustment accuracy is of 38.73 (to which a value higher then 4 is optimal), obtained in this case and indicates the presence of some data , which aren't affected by experimental errors.

The accuracy of mathematic model is tested through ANOVA variance of analysis and with Fisher's test.

The value of the Fisher's test (F = 217) of the model emphasizes that this is adequate for the experimental data, existing a 4.32% probability that this value to be a simple occurrence.

It is important to point out the fact that in this case the optimization is not necessary because the extraction efficiencies obtained reach maximum values, which determine a high efficiency of ultrasound utilization beside the mechanical stirring one. In order to emphasize the major factors that influence the uranium extraction efficiency namely the temperature, oxidant amount, and ultrasounds power in the studied experimental values range the optimization was achieve.

Design-Expert is a soft that presents an independent module of optimization that permits a numerical or graphical optimization starting with the determined regression models.

The optimization was performed imposing certain values to all the factors within the experimentation domains but on condition that the obtained efficiency is 98-100%.

In table 2 are presented the imposed conditions for the optimization process.

Table 2. Conditions imposed for optimization

Name, MU	Condition	Inferior level	Superior level	Weight
Temperature, ^{O}C	is in domain	40	80	3
pH	is in domain	1	1.5	3
Time, hours	is in domain	6	10	3
Oxidant, kg/t solid	is in domain	6	10	3
US power, watt	is in domain	75.58	79.01	3
Efficiency, %	maximization	98	100	3

In figure 2 is graphically represented (on cube) an optimized solution; it can be noticed that the global optimum – efficiency 100% - (A+D+E-) placed on the cube corner in the front up right, meaning the maximal values of the temperatures ($80^{o}C$), of the oxidant (10 kg/t) and minimal value of the ultrasound power (75.58 W) correspondent to an ultrasound action time of 10 minute per stage.

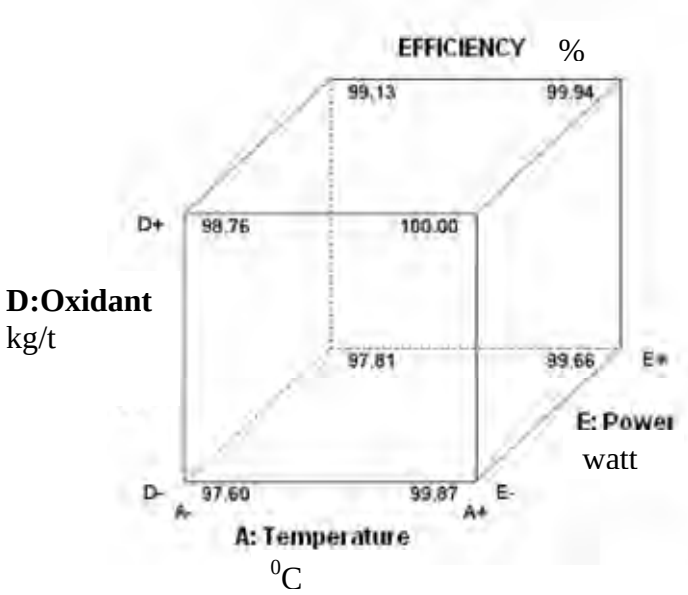

Figure 2. Graphical representation of optimal solution

The minimal value of the efficiency is, in this representation, the value of 97.60 that corresponds to the minimum values of the temperature, the oxidant amount and of the ultrasounds power (A-D-E-) and to the maximum value of the medium pH and of the operation time.

4 Conclusions

The model proposed for the recovery of uranium from waste dumps gets us to the following conclusions, namely:

- the recommended optimal parameters necessary to obtain extraction efficiencies over 96 % are as follows:

- size of beads of 0.100 mm ;

- mass ratio solid/liquid 1 :1 ;

- stirring rotation 500 min^{-1}, in order to hinder the settlement of coarse particles and to provide good conditions for the dispersion of reagents;

- oxidant regent amount, potassium chlorate is 0.75% of the solid amount 8 $kg_{oxidant}/t_{solid}$; this amount is required in order to get in the system a oxidation potential of 450-500 mV ;

- the optimal recommended dissolution temperature is of 50^{o}C ;

- sulphuric acid concentration in uranium bearing solution was correlated to the necessary oxidation potential; the optimal pH is 1, which corresponds to the consumption of a 96% sulphuric acid solution of about 100 kg $_{acid}/t_{solid;}$

- the operation duration was determined to be 2.5 hours in 2 stages ;

- the ultrasounds action duration is of 10 minutes /stage;

- the ultrasounds power is 77 W .

- the extraction efficiencies obtained were with about 10 % higher than the ones in the classic operation case respectively in the absence of the ultrasounds field;

- the ultrasound field action (10 minutes per stage) combined with the mechanical stirring allows the operation time and working temperature diminution with about 33-50%, comparatively to the classic procedure, and the same maximal values of extraction efficiency are obtained therefore the decontamination takes place faster and the electric power consumption is reduced;

- The proposed mathematical model is able to calculate the extraction efficiencies for uranium for any value of considered parameters (temperature, pH of reaction medium, operation duration, oxidant reagent amount, ultrasounds power) only in the range of studied experimental values with a precision of 95%.

This paper emphasizes the major factors that influence the uranium extraction efficiency, namely the temperature, the oxidant amount, the ultrasound power in the studied experimental values range. There are necessary economic analyses in order to establish the costs of ultrasound utilization for waste dumps decontaminations through uranium recovery.

List of symbols:

cU_i –initial concentration of uranium , %
cU_r – uranium concentration in residue, %
g_i – weight of the solid sample, g
g_r – residue weight, g
m – water mass, g
W_{abs} –acoustic power adsorbed by reaction medium, W
ΔT – temperature increasing under ultrasounds source action, ^oC
η - efficiency, %

Topic: 1 Sustainable Process-Product Development through green chemistry.
2 Multi-scale and/or multi-disciplinary approach to process-product innovation

Abstract

The stability of binary mixtures of different particle diameter with a non-porous draft tube located at the bottom of the contactor in a novel combustor conical spouted bed has been studied. In order to design the appropriate length of the non-porous draft tube without any instability or operating drawbacks in conical spouted beds, the length of the draft tube located centrally at a height from the bottom of the contactor has been varied up to a maximum values in which the top of the draft tube is at the same level the upper bed surface.

1 Introduction

In spite of the versatility of the conical spouted beds, there are situations in which the gas-solid contact is not fully satisfactory due of the bed instability. In previous papers (Olazar et al., 1992; San José, 1991; San José et al., 1991) the ranges of the geometric factors of the conical contactor and of the contactor-particle system for stable operating condition have been established in order to become the stability.

The insertion of a draft tube in a conventional spouted bed overcomes the limitations of the spouted for improving gas-solid contact. Several advantages of using a draft tube in a conventional spouted bed are the following (Buchanan et al., 1965; Muir et al., 1990; Konduri et al., 1995; Ishikura et al., 2003): greater flexibility in the operation; lower gas flow and pressure drop; solids of any size or nature may be treated; narrower residence time distribution; better control of solid circulation; avoids maximum spoutable bed height. Consequently, solid circulation may be controlled by changing independently column diameter, stagnant bed height or particle diameter. Among the disadvantages the following are worth mentioning: lower mixing degree; complexity of design; risk of tube blockage; lower contact between gas and solids; lower heat and mass transfer; longer recirculation time.

Applications of conventional spouted beds with a draft tube cover a wide range of operations and chemical processes including: drying (Khoe and Van Brakel, 1983; Freitas and Freire, 2002; Szafran and Kmiec, 2004), combustion (Konduri et al., 1995; 1999; San José et al., 2002, 2006), pyrolysis (Stocker et al., 1989), pharmaceuticals (Littman et al., 1997) and mixing (Krambrock, 1976).

In some papers the results of the effect of non-porous draft tube in conventional spouted beds mainly focussed on: hydrodynamics (Matthew et al., 1988; Stocker et al., 1990) and particle circulation (Muir et al., 1990; Yang and Keairns, 1983; Hattori et al., 1998) have been published.

In order to widen the range of the bed stability in conical spouted beds, in this paper the bed stability of binary mixtures of different particle diameter with a non-porous draft tube of different length is analyzed in a conical spouted bed combustor.

2. Experimental

The experimental unit, Figure 1, design on a pilot scale is provided with a blower that supplies a maximum air flow rate of 300 $Nm^3\ h^{-1}$ at a pressure of 15 kPa. The flow rate is measured by means of two mass flow meters in the ranges of 50-300 and 0-100 $m^3\ h^{-1}$, with both being controlled by a computer. The accuracy of this control is 0.5% of the measured flow rate (Olazar et al., 2004; San José et al., 2005):

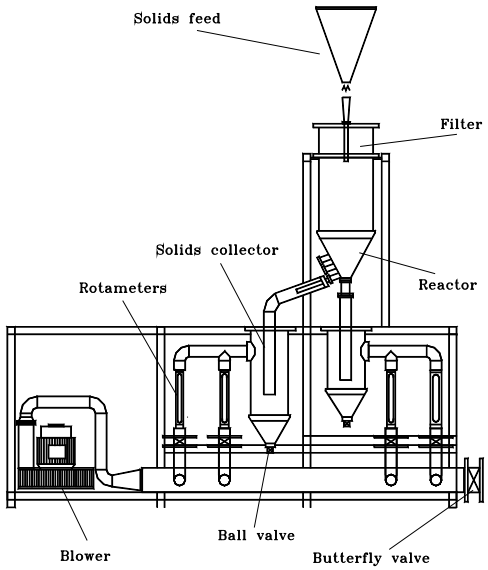

Figure 1. Diagram of the experimental equipment.

The measurement of the bed pressure drop is sent to a differential pressure transducer (Siemens Teleperm), which quantifies these measurements within the 0-100% range (Olazar et al., 2004). This transducer sends the 4-20 mA signal to a data logger (Alhborn Almeno 2290-8), which is connected to a computer where the data are registered and processed by means of the software AMR-Control. The software AMR-Control also registers and processes the air velocity data, which allows for the acquisition of continuous curves of pressure drop against air velocity.

Five conical contactors made of poly(methyl methacrylate) have been used. Figure 2 shows the geometric factors of these contactors, whose dimensions are as follows: column diameter, D_c, 0.36 m; contactor angle, γ, between 28 and 45°; height of the conical section, H_c, from 0.60 to 0.36 m; gas inlet diameter, D_o, in the range of 0.03-0.06 m. The values of the stagnant bed height, H_o, used are in the range between 0.05 and 0.35 m. Operation has been carried out at the minimum spouting velocity and at velocities 20 and 30% above this value.

The influence of the length of the device in each solid particle bed (in the same experimental conditions) has been studied by inserting centrally a draft tube in the contactor and varying the length of the draft tube from a minimum value of 0.02 m to a maximum value in which the top of the draft tube is at the same level that the upper bed surface (Erbil, 2003).

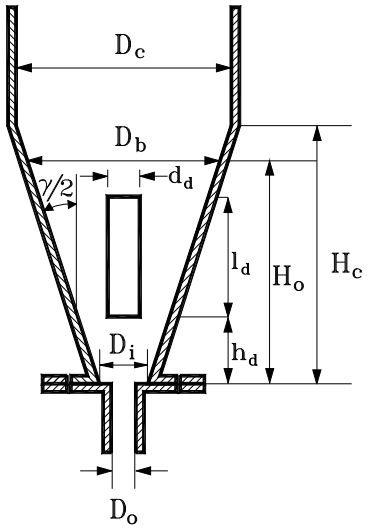

Figure 2. Geometric factors of the contactor and of the draft tube.

The draft tube, Figure 2, is a cylindrical tube made of poly(methyl methacrylate) located centrally at the bottom of the contactor. Figure 2 shows the draft tube geometries. The draft tube diameter, d_d, and height of the entrainment zone, h_d, have been determined experimentally in a previous paper (San José et al., 2007) from a viewpoint of stability of spouting and of the clogging of solid particles. The diameter of the draft tube, d_d, was varied from 0.03 m to 0.05 m. The diameter of the draft tube, d_d, was determined experimentally in a previous paper (San José et al., 2007) for a viewpoint of stability of spouting and was varied from 0.03 m to 0.05 m. The choice of the upper limit of the draft tube diameter, d_d, was made based on to the average spout diameter, (Olazar et al., 2004), which is between the gas inlet diameter, D_o, and the base diameter, D_i, and in conical spouted beds is nearer to the base diameter, D_i (Olazar et al., 2004). The entrainment zone, distance between the base of the contactor and the lower base of the device, h_d, has been determined experimentally in a previous paper (San José et al., 2007) is in the range 0.01-0.09 m. The length of the draft tube, l_d, has been varied from 0.02 m to a value calculated as $l_d = H_o - h_d$. and it is in the range 0.02-0.34 m.

The solids studied are limestone, which corresponds basically to the D group of the Geldart classification (Geldart, 1973, 1986) and their properties are set out in Table 1. Table 1 summarizes the geometric factors of the conical contactors, the dimensions of the central draft tubes and particle properties of solids studied.

Table 1. Geometric factors of the contactors and of the draft tube and particle properties

Contactor poly(methyl methacrylate)		
Column diameter	D_c (m)	0.36
Contactor angle	γ (deg)	28, 33, 36, 39, 45
Height of the conical section	H_c (m)	0.60, 0.50, 0.45, 0.42, 0.36
Gas inlet diameter	D_o (m)	0.03, 0.04, 0.05, 0.06
Stagnant bed height	H_o (m)	between 0.03 and 0.35 m
Draft tube poly(methyl methacrylate)		
Inside diameter	d_d (m)	0.03, 0.04, 0.05, 0.06
Tube length	l_d (m)	from 0.02 to 0.34
Distance of entrainment zone	h_d (m)	from 0.01 to 0.09
Particle (Limestone)		
Diameter	d_p (mm)	between 0.9 and 3.85
Density	ρ_p (kg/m^3)	2650

3. Results

In order to provide the effect of the length of the central draft tubes in conical spouted bed contactors on bed stability, a novel diagram has been proposed in this paper. In this diagram the length of the draft tube, l_d, has been plotted against the gas velocity, u.

In this diagram, Figure 3, the length of the draft tube, l_d, has been plotted against the gas velocity, u, corresponding to a system taken as an example, of contactor angle, γ= 36º, gas inlet diameter, D_o= 0.04 m, with a bed of mixtures of limestones of Sauter average diameter, $\overline{d_S}$ = 3.03 mm and stagnant bed height, H_o= 0.20 m. The draft tube dimensions are: diameter, d_d= 0.04 m, height of the entrainment zone, h_d= 0.05 m and length varied from a minimum length of l_d= 0.02 m to the maximum length of l_d= 0.15 m (corresponding to the level of the stagnant bed, $l_d = H_o - h_d$).

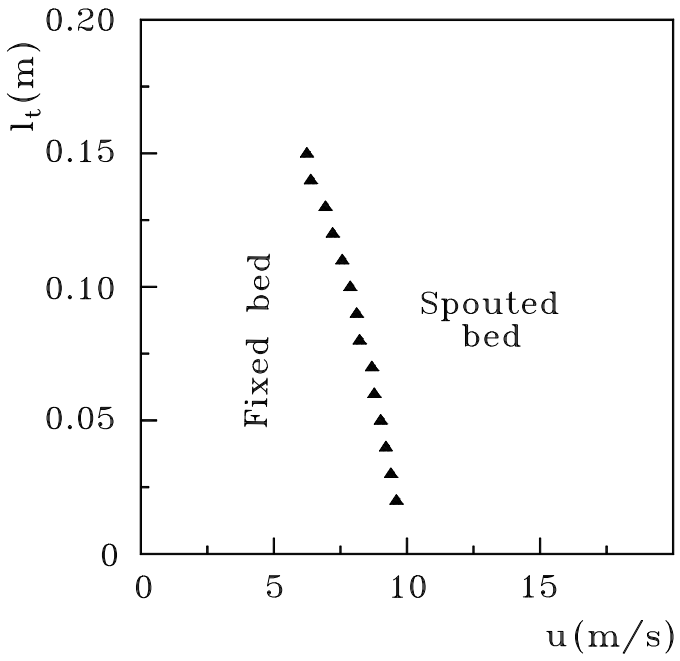

Figure 3. Operating map. System: γ= 36º, D_o= 0.04 m, beds of mixtures of limestone of Sauter average diameter $\overline{d_S}$ = 3.03 mm. Draft tube of d_d= 0.04 m and h_d= 0.05 m.

As is observed, as the gas velocity is increased, the bed passes form the fixed bed to the stable spouted bed regime. As the length of the central draft tube is increased the minimum spouting velocity decreases. Therefore, the increasing in the draft tube length enhances the stable operating conditions. Thus, with the longest draft tube the maximum range of stable operating conditions is reached.

The bed stability for binary mixtures of limestone of Sauter average diameter, $\overline{d_S}$ = 1.45 mm is plotted in Figure 4 for the same experimental conditions than in Figure 3. As it is observed as Sauter average diameter decreases the minimum spouting velocity decreases, therefore the stable operating conditions zone enlarges.

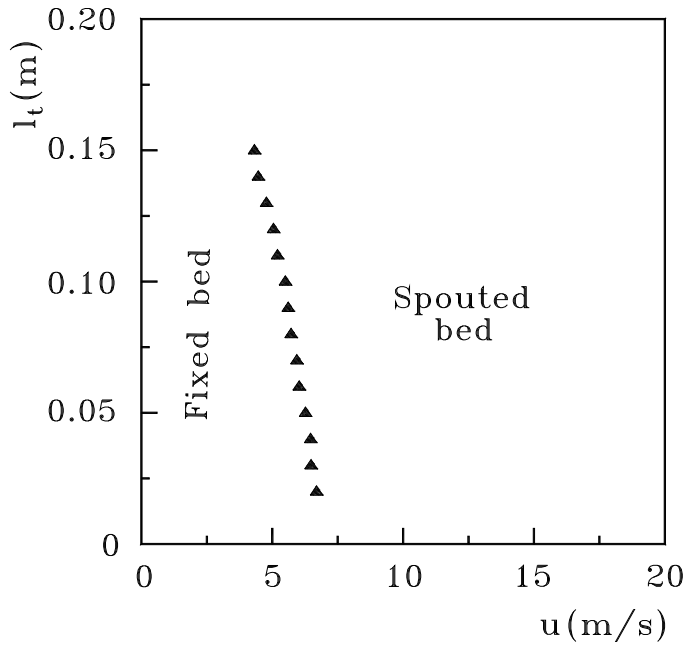

Figure 4. Operating map. System: γ= 36º, D_o= 0.04 m, beds of mixtures of limestone of Sauter average diameter $\overline{d_S}$ = 1.45 mm. Draft tube of d_d= 0.04 m and h_d= 0.05 m.

4. Conclusions

In all the experimental systems studied, the introduction of a central draft tube in the bed enlarges the range of operating conditions in conical spouted beds.

The stability of binary mixtures of different particle diameter in conical spouted beds with draft tube depends on the length of the draft tube. The increasing in the length of the draft tube gives way to a decreasing in the minimum spouting velocity, therefore an increasing in the range of operating conditions in spouting regime. It has been proven that by means of an appropriate design of the draft tube, the range of stable operating conditions of binary mixtures in conical spouted beds with a draft tube is wider than without draft tube without any instability or operation drawbacks.

Production of hydrogen by methane steam reforming coupled with CO_2 sorption

Eduardo L. G. Oliveira, Carlos A. Grande, Alirio E. Rodrigues

LSRE – Laboratory of Separation and Reaction Engineering, Faculty of Engineering, University of Porto. Porto, Portugal (arodrig@fe.up.pt)

Keyword: Sorption-enhanced reaction process, steam methane reforming, carbon dioxide, hydrogen production
Topic: Sustainable process-product development through green chemistry

1. Abstract

Hydrogen is becoming the fuel of the future. The most important technology for the production of hydrogen is methane steam reforming (SMR) (Twigg, 1989). However, there are high costs associated, both in energy and materials, as the reaction has to be carried out at high temperatures (973 K) to achieve high methane conversions.

The combination of reaction and sorption in the reactor displaces the equilibrium maintaining a high conversion at lower temperatures (~773 K) which reduces the material and energy costs of the process. The sorption of carbon dioxide is also of interest as we are able to produce hydrogen with very low (or inexistent) carbon dioxide emissions. The sorbed carbon dioxide can be sent to storage facilities.

2. Experimental

Three commercial hydrotalcite extrudates (MG30, MG50, MG70) from Sasol (Germany) were impregnated with K_2CO_3 and Cs_2CO_3 (ACS reagents) from Sigma-Aldrich. The impregnation protocol was based on literature (Nataraj, et al., 2000). Scanning Electron Microscopy (SEM) was performed on a JEOL JSM-6301F (JEOL, Japan) coupled with an Energy dispersive X-ray spectroscope (EDX) Oxford INCA Energy 350 (Oxford Instruments, UK). The surface area of the fresh sorbents was determined by N_2 adsorption at 77 K with a Coulter Omnisorp 100 CX apparatus.

The CO_2 sorption equilibrium was measured by breakthrough experiments. The feed stream comprises helium, carbon dioxide and water while helium and water were employed for sorbent regeneration. The liquid water flowrate was controlled using a HPLC pump (Merck-Hitachi, Japan) and was vaporized before entering into the column. Both CO_2 and He flowrates were controlled by independent mass flow controllers. After the column the water was condensed using an ice trap, and CO_2 concentration was measured each 10 seconds using an infrared detector (Madur, Austria). In Table 1 are reported the operating conditions of all the CO_2 sorption experiments using the MG30-K and Mg30-Cs samples.

Table 1. Experimental conditions used in the equilibrium sorption experiments

Temperature [K]	579, 676, 783
Pressure [bar]	2
P_{CO2} [bar]	0.05, 0.09, 0.19, 0.40

The SERP experiments were performed with just the catalyst and with the catalyst and the adsorbent combined in a proportion of 3:1 adsorbent/catalyst. In the experiments with combined adsorbent and catalyst a layered structure was used combining 2 layers of catalyst with a layer

of adsorbent separating them and a layer of adsorbent in the end. Each layer had half the catalyst/adsorbent and the layers were separated by a metal mesh. The experimental conditions and the mass of catalyst and sorbent used for each of the experiments performed can be seen in Table 2.

Table 2. Experimental conditions used in the SERP experiments

P [bar]	T [K]	Y_{CH4} [%]	Q_{H2O}(l) [ml/min]	Q_{CH4} [SLPM]	m_{cat} [kg]	m_{ads} [kg]
2 ± 0.05	823.15	20.6	0.9	0.147	2.053×10^{-2}	0
2 ± 0.05	773.15	20.6	0.9	0.147	1.8206×10^{-2}	5.6024×10^{-2}

The methane flowrate was started at time 0 and samples of the reactor effluent were taken. All the compositions were analyzed by gas chromatography.

3. Results

In this work, the sorption enhanced reaction process (SERP) concept was tested for SMR using a Ni/Al_2O_3 catalyst and a hydrotalcite sorbent.

3.1. Sorbent selection

The commercial hydrotalcite samples received from SASOL were impregnated with potassium and cesium (Nataraj, et al., 2000). The three pure hydrotalcite samples (MG30, MG50 and MG70) as well as the alkali-modified (with K and Cs) materials were tested to determine the material with higher capacity for CO_2 sorption in the presence of water vapor. The screening was based in a single point of CO_2 sorption equilibrium at 676 K obtained by breakthrough curves employing a stream with carbon dioxide, water vapor and helium (considered as inert gas). In all the experiments, the partial pressure of CO_2 was close to 0.40 bar and the total pressure of the system was 2 bar. The purpose of this screening was to select the two best samples, one modified with cesium and other modified with potassium to measure sorption equilibrium isotherms at three different temperatures. The screening results can be seen in Figure 1.

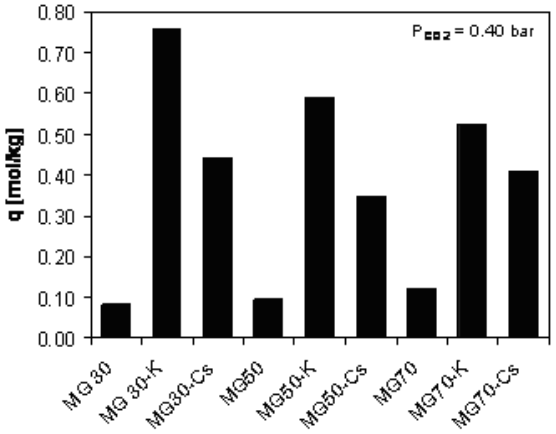

Figure 1. Comparison of the sorption capacity of CO_2 for pure and alkali-modified (Cs and K) hydrotalcites at 676 K, 2 bar total pressure, P_{CO2} of 0.40 bar in the presence of water vapor.

The pure hydrotalcite samples show a CO_2 sorption capacity lower than 0.1 mol/kg and thus cannot be used for SERP. The potassium modified sample that presented the higher sorption capacity was the MG30-K (0.76 mol/kg). In the cesium modified samples the MG70-Cs presented the highest sorption capacity followed by the MG30-Cs. The MG30-K was selected to

measure sorption equilibrium. To study the effect of Cs in the hydrotalcites, the MG30-Cs was also selected to measure sorption equilibrium.

Carbon dioxide breakthrough experiments were performed at various temperatures and CO_2 partial pressures (see Table 1). The equilibrium sorption capacity was determined and the sorption isotherms are presented in Figure 2.

In the isotherms, the capacity at 676 K is higher than at 579 K and the sorption is reversible. This "crossing" in isotherms and the reversibility cannot be explained by sorption alone (physical or chemical). One possible explanation is that together with sorption, an endothermic reaction also occurs and its conversion increases together with temperature. The bi-Langmuir model (equation 1) was selected to describe this behavior as it allows for the combination of 2 distinct sorption mechanisms. A recent work (Lee, et al., 2007) using a similar sorbent proposed a combination of chemisorption and complexation to account for the CO_2 sorption but the maximum in the sorption capacity was not reported. The bi-Langmuir parameters can be seen in Table 3.

$$q_{ads} = q_{max1}\frac{K_1(T)P}{1+K_1(T)P} + q_{max2}\frac{K_2(T)P}{1+K_2(T)P} \qquad (1)$$

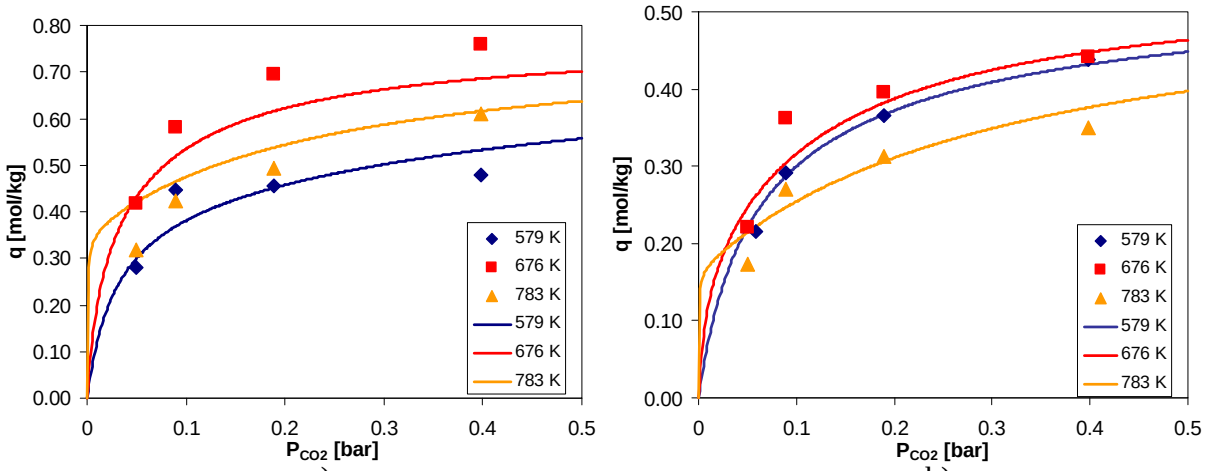

Figure 2. Sorption equilibrium isotherms of CO_2 (in the presence of water vapor) on: a)MG30-K and b) MG30-Cs hydrotalcite samples at 579, 676 and 783 K (points). Bi-Langmuir model fit (lines).

Table 3. Fitting parameters of the bi-Langmuir model for the MG30-K and MG30-Cs hydrotalcite samples (Oliveira, et al., 2008)

Parameters	MG30-K	MG30-Cs
q_{max1} [mol/kg]	0.423	0.383
k_{01} [bar^{-1}]	9.07 x10-3	1.26x10-2
(-ΔH_1) [kJ/mol]	40.0	35.9
q_{max2} [mol/kg]	0.351	0.164
k02 [bar^{-1}]	1.01 x1012	9.13x1011
(-ΔH_2) [kJ/mol]	-130.8	-127.4

3.2. SERP proof of concept

A Ni/Al_2O_3 catalyst from Degussa (Germany) was used in combination with the cesium modified hydrotalcite sample to perform the SERP proof of concept. In Figure 3 the evolution of the methane conversions in the first 500 s of operation of the SERP experiment and the traditional steam reforming are compared. Due to restrictions of the hydrotalcite material, the SERP experiment was performed at a lower temperature than the SMR experiment.

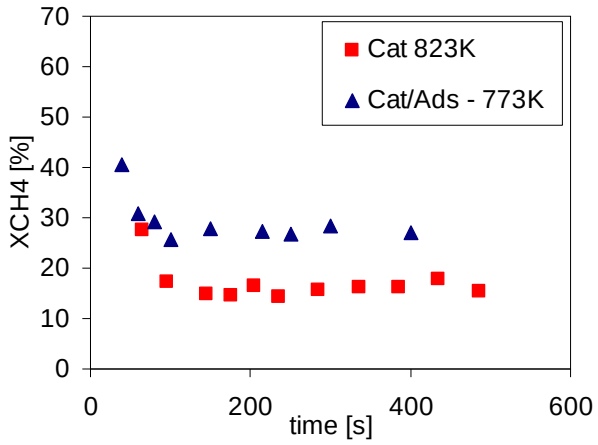

Figure 3. Methane conversion for traditional SMR and SERP (see Table 2).

The methane conversion of the traditional steam reforming was approximately 15% while in SERP we were able to achieve 27% methane conversion. As the same mass of catalyst was used in both experiments we can say that the SERP enhanced the conversion in more than 10 percentage points even though it was operating at a lower temperature. The use of lower temperatures has an impact both in the energy and material costs of hydrogen production.

In Figure 4 we can see the evolution of the compositions of the various components of the dry effluent.

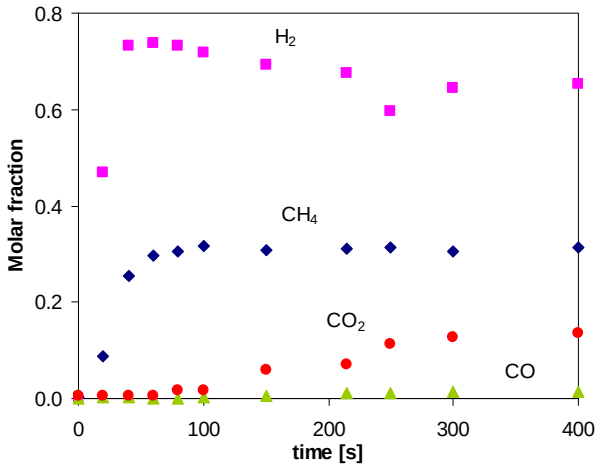

Figure 4. Dry effluent composition vs time for the SERP experiment at 773 K, 2 bar total pressure and 20% CH_4 at inlet.

The effluent stream was composed only of methane and hydrogen during the first 80 s of operation. Comparing with the traditional SMR, the results of Figure 4 indicate that fewer separation processes will be necessary after the SERP reactor. When the sorbent is saturated it is necessary to regenerate by pressure swing adsorption. During the regeneration step it is possible to recover the CO_2 for sequestration.

This proof of concept indicates that there are three main advantages of the use of SERP when compared to tradition SMR:

1. It is possible to produce hydrogen without carbon oxides, reducing the separation train after the reactor – reduction of investment and operation costs;
2. The temperature of operation can be reduced – decreasing operation and investment costs;
3. The carbon dioxide can be recovered for sequestration – reduction of the CO_2 emissions (Kyoto protocol).

4. Conclusions

Nine hydrotalcite materials were prepared and screened for carbon dioxide sorption at high temperatures [579-783] K. The MG30-K and MG30-Cs samples were selected for sorption equilibrium studies.

The sorption equilibrium isotherms showed a maximum in the sorption capacity at 676 K. The bi-Langmuir isotherm was used to describe this behavior.

The sorption enhanced reaction process proof of concept was also performed in this study. Comparing SERP with traditional steam methane reforming, the SERP was able to produce hydrogen with methane as the only impurity during 80 s. The conversion of methane of the SERP at 773 K was 27% while conversion of the traditional SMR was only 15% at 823 K, showing the advantage of the SERP.

Keywords: olefin transformation; acid catalysis; ZSM-5 zeolite; kinetic model

Topic: Catalysis and reaction engineering

Abstract

Data for the acid-catalysed transformation of propylene over four ZSM-5 zeolites with different degrees of sodium exchanged, at various temperatures and partial pressures, was analysed. This transformation is characterized by the fact that, as the temperature increased, the propene consumption rate decreased. In this work the rather complex network mechanism involved in the transformation of these light olefins was approximated by one simple kinetic model. It only details the products by the number of carbon atoms and was developed without the explicit inclusion of the step corresponding to the adsorption of the reactant molecules, altough adsorption effects are, in fact, the reason why apparent negative activation energies are obtained. Polanyi equations were used to derive quantitative relations between the ammonia adsorption energy and the activation energy. It was observed that, for the various ZSM-5 zeolites with different acidities, the model describes well the product distribution.

1 Introduction

The transformation of alkenes over acid catalysts is a very significant reaction with impact in many different applications for the chemical and petrochemical industries (O'Connor & Kojima, 1990) such as the catalytic oligomerization of light olefins, relevant in many fuel-related processes which produce hydrocarbons in the gasoline (C5 to C10) and diesel (C10 to C20) ranges (Tabak & Krambeck, 1986). These reactions are also relevant in the MTG and MTO, which convert methanol to gasoline and to olefins. The use of the ZSM-5 zeolite and other similar zeolites, to perform this reaction, was proposed in the mid 70' and 80's, in the MOGD process (Mobil olefin to gasoline and distillate) (Garwood, 1979 & 1980; Tabak, 1981 & 1985), as possible replacements for the classical phosphoric acid impregnated catalyst. This process, which produces highly branched hydrocarbons with high octane number, acquires a renovated interest with the current petroleum crises and the demand for more efficient catalysts becomes even more critical. To achieve this goal, a deep understanding of the fundamental aspects of these transformations is vital and creates a drive for the development of practical models that enable the rapid analysis of new catalytic materials and even that will allow the prediction of the catalytic behavior of these materials based on very simple characterization tests. This need is particularly

* Corresponding author. E-mail:francisco.lemos@ ist.utl.pt

important in the context of high-throughput catalyst development techniques. Aspects pertaining to the kinetics and thermodynamics of this reaction, covering different operating conditions, have been the subject of various publications (van den Berg et al., 1983; Wilshier, Smart, Western, Mole, & Behrsing, 1987; Yarlagadda, Lund, & Ruckenstein, 1990).

The simplified kinetic mechanism for this kind of reactions (Tabak & Krambeck, 1986) is initiated by a series of oligomerization steps, where linear dimers, trimers, etc, of the original olefin are produced. These newly formed molecules can undergo secondary reactions, (isomerisation, cracking, aromatization, etc.), originating a wide variety of other hydrocarbon molecules.

The objective of this paper is to initiate the mechanistic analysis of the catalytic transformation of propylene, over four ZSM-5 zeolites with different degrees of sodium exchanged, at atmospheric pressure, under different conditions of temperature and inlet concentration of the reactant. It was observed that for propene, the overall activity decreased with increasing temperature, thus presenting an apparent negative activation energy. This effect has been explained by us, as the coupling of adsorption and kinetic effects (Borges et al., 2007).

Despite the fact that the four different catalysts that were used have different acidities we can show that the same reaction network, with the same kinetic rate constants, can be applied to describe the results for all ZSM-5 zeolites, indicating that not only the underlying mechanism is the same for all catalysts, but that the transformation can be described by the same kinetics if the acid strength distribution is taken into account.

2 Experimental

Catalyst preparation

The HZSM-5 catalyst was prepared from a zeolite (ammonia form), with molar silica to alumina ratio of 30, from Zeolyst (CBV 3024G). The other three zeolites, with different acidity strength and total amount of sites, were obtained exchanging the original zeolite (designated as HZSM-5 above) with different aqueous solutions of sodium nitrate, to replace proton by sodium. This prevents the modified sites from showing Brønsted acidity, by decreasing the total amount of hydrogen obtained after the calcinations. All the exchanges were performed at room temperature varying only the concentration of the solution used and the number of exchanges that each sample was subjected to, as shown in Figure 1.

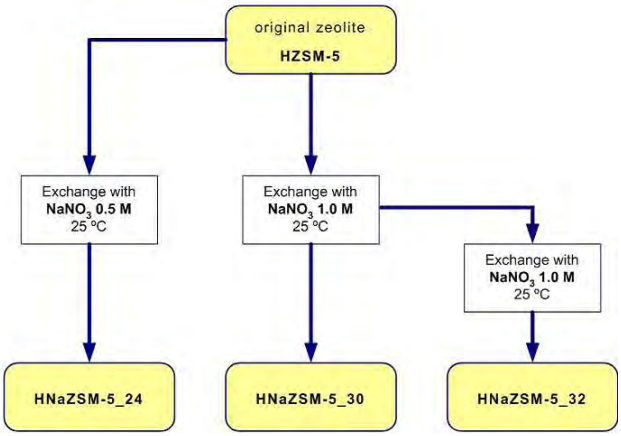

Figure 1 – Schematic of the ionic exchange paths

The new different zeolites prepared, were designated as HNaZSM-5_24, HNaZSM-5_30 and HNaZSM-5_32. The last index in their code name indicates the percentage of sodium that was exchanged, as obtained from the elemental analysis, that is, the percentage of sites exchanged with sodium in comparison to the total amount of sites in the same zeolite sample.

All zeolites were calcined at 500 ºC during 8 hours under a flow of 0.5 litres of dry air per hour and per gram of catalyst. After calcination, the zeolite was kept at room temperature in a constant and high humidity container.

Transformation of small olefins

The transformation of propene was carried out in a fixed-bed continuous flow reactor, at atmospheric pressure and within a temperature range from 300 ºC to 450 ºC. The partial pressure of the reactant was varied from 5 % to 30 %, diluted with nitrogen. Total flow of the reaction mixture was 120 ml/min. The reactant was fed for a few minutes and then the effluent stream was sampled and analysed, while reactant feeding was interrupted. During the analysis time the catalyst was kept under a flow of pure nitrogen at the working temperature. Fresh catalyst was used for each run. No deactivation with time-on-stream was detected during the experiment and no coke was detected (by thermal analysis, under air, up to 700 ºC) on the used catalyst.

External transport limitations were checked by varying the flow rate while keeping the same catalyst mass; no changes in reaction rate were observed. Internal limitations were checked, using the Weisz-Prater criterion (Froment & Bischoff, 1990). This has been reported elsewhere (Borges et al., 2007).

The analysis of the effluent was carried out with a Shimadzu GC-9A gas chromatograph equipped with a Chrompack Plot CP7515 fused silica column and a flame ionization detector. The chromatogram was integrated with a Shimadzu C-R3A integrator.

For the transformation of propene, 75 mg of each HZSM-5 catalyst (wet basis) was used.

3 Results and discussion

Kinetic model

It is assumed that the first step in the transformation of small olefins is oligomerization, leading to heavier species. These heavier species will be able to transform by a variety of processes, including β-scission, establishing a complex reaction network. In the first attempts to build the reaction network, we have only detailed products by their number of carbon atoms (no distinction between olefins and paraffins is made at this stage). Under this approach a model was developed and assumes that the reaction network occurs in pseudo-homogeneous conditions (without adsorption). This way, since only oligomerization/cracking reactions are accounted for, the reaction network can be described by the following equation:

$$C_n + C_m \underset{\leftarrow}{\overset{\rightarrow}{}} C_{n+m} \tag{1}$$

where n and $m \geq 2$ and $n+m \leq 8$. (no protolytic cracking was considered at this stage, and, thus, the formation of methane was excluded). Within this framework, the reaction network is described by just 9 different reactions. Assuming that reactions are of simple order in relation to the different species involved and that requires a total of 18 kinetic rate constants, the forward (k_i corresponding to the oligomerization) and backward (k_{-i} corresponding to the cracking) rate constants.

$$r_i = k_i \cdot p(C_n) \cdot p(C_m) - k_{-i} \cdot p(C_{n+m}) \tag{2}$$

These were assumed as obeying the Arrhenius law and Polanyi equations.

$$k_i = k_{ref,i} \cdot e^{-\frac{E_{a0,i}}{R}\left(\frac{1}{T}-\frac{1}{T_{ref}}\right)} \sum_j q_j \cdot e^{-\frac{\delta_i \cdot E_{a_j}^{NH_3}}{R \cdot T}} \tag{3}$$

where $k_{ref,i} = k_{0,i} \cdot e^{-\frac{E_{a0,i}}{R \cdot T_{ref}}}$, $k_{0,i}$ is the pre-exponential factor for reaction i, $E_{a_{0,i}}$ is the

activation energy for a specific reaction without the acidity effect, δ_i reflects the effect of the acid strength in the activation energy for a given reaction and q_j is proportional to the acid centres number with strength $E_{a_j}^{NH_3}$.

Experimental results

Values for the catalytic activity obtained for propene with the four different zeolites are shown in Figure 2.

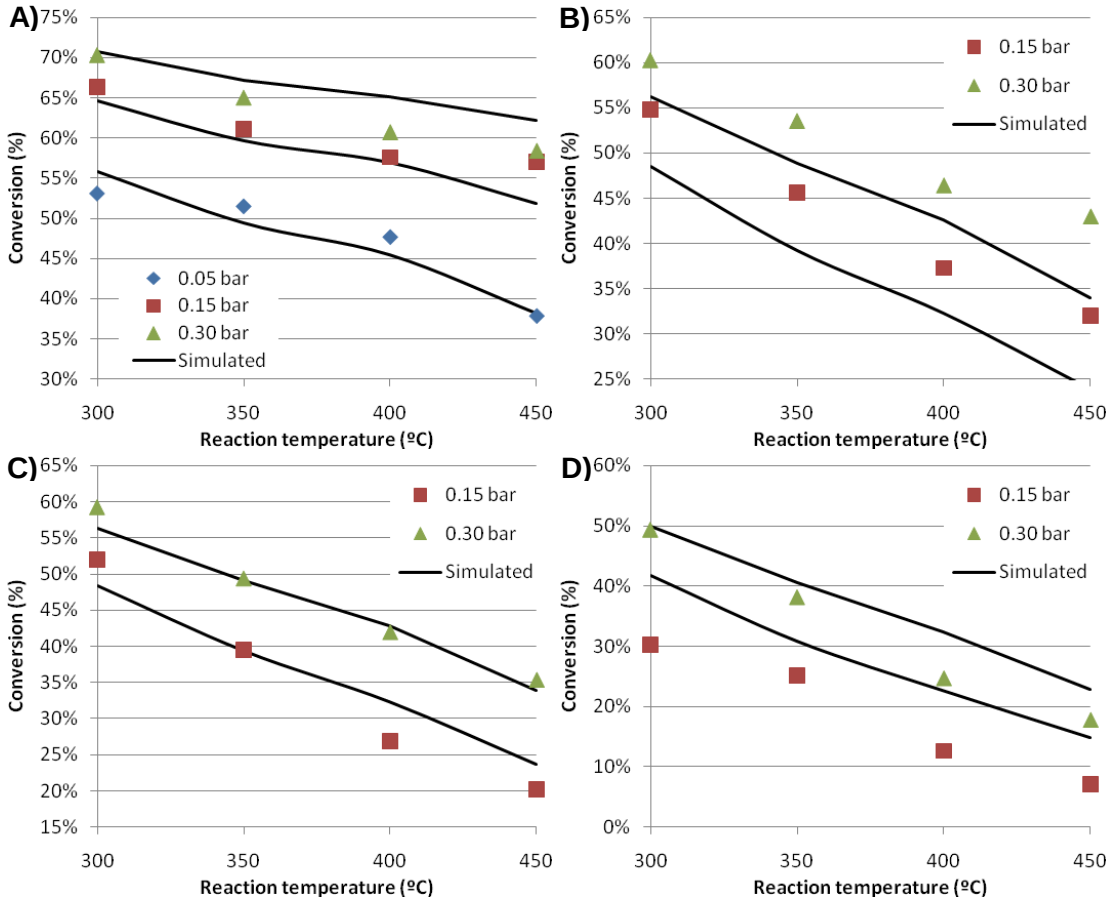

Figure 2 – Conversion of the transformation of propene with the different zeolites and model results. A) HZSM-5; B) HNaZSM-5_24; C) HNaZSM-5_30; D) HNaZSM-5_32

In the above figure is visible that conversion of propene lowers with the increase of temperature. The main products observed are olefins, resulting from oligomerization reactions, and followed by cracking; however, significant quantities of aromatic and paraffinic products are also observed, resulting from aromatization and hydrogen transfer secondary reactions (see Borges et al., 2007 for details). The increase in operating temperature produced a shifting of the products towards lighter hydrocarbons, while an increase in partial pressure had the opposite effect, as it would be expected.

The kinetic model was fitted to the experimental data using a non-linear least-squares regression technique implemented in commercial spreadsheet software (Excel). The set of experimental data used comprises all the results obtained for all the catalyst, i.e., the model will describe all the experiments with a single set of parameters, regardless of catalyst, partial pressure or temperature.

All material balances were numerically integrated using the Euler method, to obtain a computed product distribution. The sum of the squares of the residuals (difference between the experimental values and those obtained from the model) were minimized, using the Solver tool. In order to reduce correlation between the pre-exponential factors

and the activation energies, in the Arrhenius kinetic term a reference temperature was used; this temperature was the experimental temperature closest to the mean of the temperature range covered in the experiments.

The parameters obtained are shown in Table 1 and, in order to allow a simple evaluation of the quality of the fittings, the parity plot obtained and some examples of the product distributions obtained using the model for the different catalysts that were used are depicted in Figure 3.

Table 1. Parameters obtained by fitting the model, to the tests performed with the four HZSM-5 catalysts. k' is reported at 350 ºC.

Reaction network	k_{ref} mol·min^{-1} $g_{zeolite}$		E_{a0} kJ.mol^{-1}		δ	
	forward	backward	forward	backward	forward	backward
$2C_2 \rightleftarrows C_4$	1,31×10^{-1}	1,43×10^{-4}	1,18×10^{4}	1,10×10^{5}	0,00	-0,16
$C_2 + C_3 \rightleftarrows C_5$	3,31×10^{-4}	1,04×10^{-2}	-4,79×10^{4}	1,19×10^{5}	0,01	0,45
$C_2 + C_4 \rightleftarrows C_6$	1,36×10^{-1}	7,64×10^{-4}	5,35×10^{4}	1,05×10^{5}	0,14	-0,08
$C_2 + C_5 \rightleftarrows C_7$	2,15×10^{-2}	1,22×10^{-3}	2,85×10^{2}	1,67×10^{4}	0,01	0,03
$C_2 + C_6 \rightleftarrows C_8$	1,37×10^{-2}	4,77×10^{-3}	2,48×10^{4}	5,06×10^{4}	0,05	0,78
$2C_3 \rightleftarrows C_6$	9,66×10^{-7}	3,34×10^{-2}	-7,95×10^{3}	4,85×10^{4}	0,00	0,41
$C_3 + C_4 \rightleftarrows C_7$	1,09×10^{-3}	4,78×10^{-2}	9,53×10^{4}	5,36×10^{4}	0,01	0,37
$C_3 + C_5 \rightleftarrows C_8$	3,17×10^{-3}	1,04×10^{-2}	5,69×10^{4}	1,47×10^{3}	0,00	0,34
$2C_4 \rightleftarrows C_8$	1,43×10^{-3}	2,04×10^{-2}	8,73×10^{4}	4,32×10^{4}	0,00	0,30

As it can be seen from table 1, some of the apparent activation energies are negative because this model does not explicitly take adsorption into account,as it would be expected from the results presented before (Borges et al., 2007).

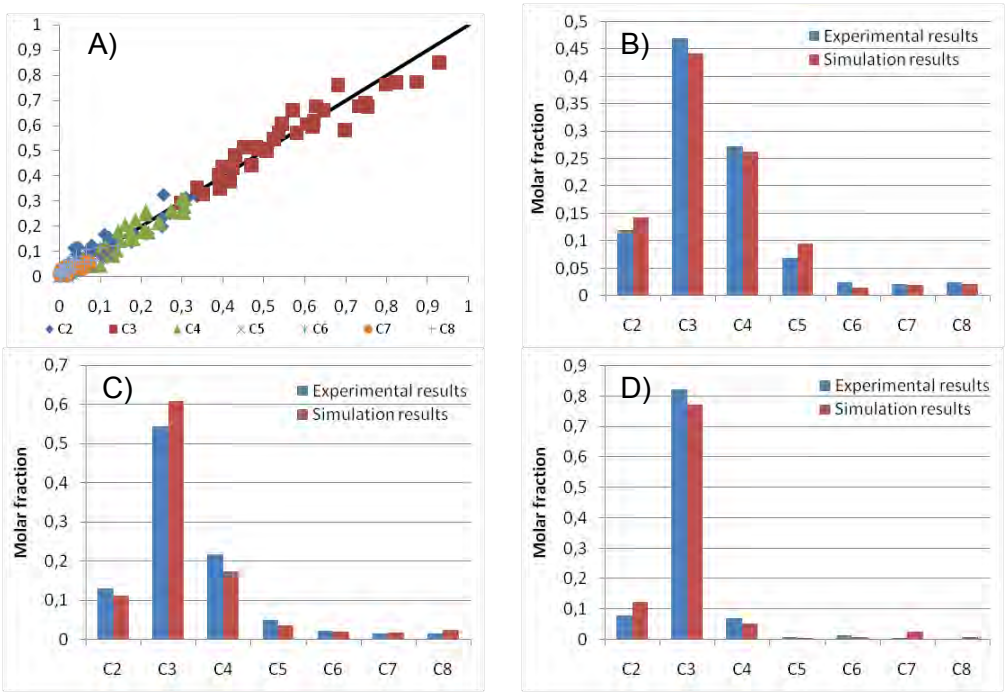

Figure 3 – A) Parity plot. B) Product distribution obtained for the transformation of propylene at 5 kPa and 300ºC for catalyst HZSM-5 and predicted by the Model. C) Product distribution obtained for the transformation of propylene at 15 kPa and 350ºC for the less sodium exchanged HZSM-5 catalyst and predicted by the Model. D) Product distribution obtained for the transformation of propylene at 30 kPa and 450ºC for the most sodium exchanged HZSM-5 catalyst and predicted by the Model

4 Conclusions

Although the model used was relatively simple, it is able to provide a generally acceptable description of the activity and distribution of products for the experiments under analysis.

It is very important to note, that, although the number of parameters is relatively high, only one set of parameters is used to describe all the available experimental data, covering not only all the temperatures and partial pressures used in this study, but also all the catalyst tested. This result opens the way for the development of universal kinetic models that may be applied to any HZSM-5 catalyst, or even to any mixture of HZSM-5 catalysts, for a given reactant.

CARBON DIOXIDE REFORMING OF METHANE OVER NI/γ-Al_2O_3 IN FLUIDIZED-BED REACTOR

José A. Pacífico[1*], Ana, C. Cabral[1], Nelson, M.L. Filho[1], Augusto, Knoechelmann[1], César, A.M. Abreu[1]

[1] UFPE – Chemical Engineering Department, Centre of Technology and Geo-Science Federal University of Pernambuco, Av. Prof. Artur de Sá, S/N, 50670–901 Recife-PE, Brazil.

Keywords: Methane reforming, nickel catalysts, fluidized bed reactor
Topic:Multi-scale and/or multi-disciplinary approach to process-product.

Abstract: To establish operational relations for the catalytic carbon dioxide reforming of methane into syngas, a one-dimensional Kunii-Levenspiel heterogeneous model for the fluidized bed reactor was developed. Effects of reaction parameters as temperature, and pressure on the dry reforming reaction were analyzed in terms of conversion, reagent and product concentrations. The fluidized-bed reactor presented the following dimensions: height of the reactor H_t = 1,180 mm, internal diameter D_{int} = 38 mm, particle diameter d_p = 70-85 μm, minimum fluidization velocity U_{mf} = 0.0011 m/s, superficial velocity U_o = 0.0191 m/s, mass of catalyst m_{cat} = 300 g, and the catalyst 4.98 wt% Ni/γ-Al_2O_3. The reactions were evaluated at 1023K, 1073K, and 1123K respectively, and under atmospheric pressure. Under these conditions and employing a Langmuir-Hinshelwood kinetic model, for 1073 K to 1123 K a methane conversion of 85,62 to 97.89% was obtained.

1. Introduction

Conventional fixed-bed steam methane reformers have some disadvantages, such as low heat transfer rates, diffusional resistance in catalyst pores and large temperature gradients. In addition, steam methane reforming, a highly endothermic process, is affected by the efficiency of the heat input into the reformer. The carbon dioxide reforming of methane may be presented as an alternative process, mainly when employed in a fluidized bed reactor. Improved heat transfer, catalyst uniformity, and the virtual elimination of diffusion limitations are the major advantages of when this reactor is employed (Chen, Honda and Zhang, 2004; Bradford and vannice, 1996; Souza, Aranda and Schmal, 2002). The catalyst particles in a fluidized bed has to be in a proper range, and they have to withstand the mechanical environment. Catalyst particles with a mean diameter in the range of 70 to 85 μm were employed and the thermal uniformity of the fluidized-bed was obtained at a flow rate three times the minimum fluidization velocity.

2. Experimental

The column was built in stainless steel, it has a diameter of 38 mm and a height of 1.180 mm (Figure 1). The bed pressure drops were measured with a differential

pressure transducer . The experimental fluidynamic data were obtained relating the pressure drop in the bed with the superficial velocity.

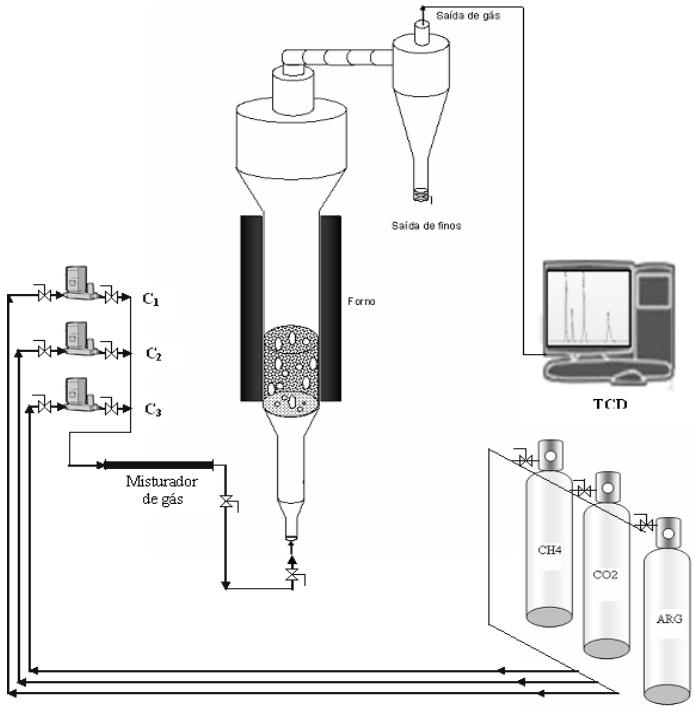

Figure 1. The Schematic representation of fluidized bed reactor

2. Results and Discussion

For evaluation of the process the main reaction considered were:

$$CO_2 + H_2 \leftrightarrow CO + H_2O \quad \Delta H_{298} = 41 kJ/mol \tag{1}$$

$$2CO \leftrightarrow CO_2 + C \ \Delta H_{298} = -172 kJ/mol \tag{2}$$

$$CH_4 \leftrightarrow C + 2H_2 \ \ \Delta H_{298} = 75 kJ/mol \tag{3}$$

Considering the reaction steps the following rate equations were proposed:

$$r_{CH_4} = \frac{k_1 K_{CH_4} C_{CH_4}}{1 + K_{CH_4} C_{CH_4}} \qquad \text{(step I)} \tag{4}$$

$$r_{CO_2} = k_2 \left(C_{H_2} C_{CO_2} - \frac{C_{CO} C_{H_2O}}{K_{eq}} \right) \quad \text{(step II)} \tag{5}$$

$$r_{CO_2} = k_3 C_{CO_2} \quad \text{(step III)} \tag{6}$$

The values of the kinetic parameters of the reaction steps obtained from the optimization procedures and the value of the equilibrium constant of the reverse water gas-shift reaction, are expressed in function of the operating temperature (Pacífico, Abreu, Santos and Lima Filho, 2008).

$$k_1 = 3{,}58 \times 10^9 \times \exp(-248.547 / RT) \tag{7}$$

$$k_2 = 1{,}07 \times 10^{13} \times \exp(-350.080 / RT) \tag{8}$$

$$k_3 = 1{,}16 \times 10^5 \times \exp(-115.860 / RT) \tag{9}$$

$$K_{CH_4} = 1{,}39 \times 10^{-11} \times \exp(167.320 / RT) \tag{10}$$

$$\begin{aligned} lnK_{eWRGS}(T) &:= 5.1377 + 0.2596 x ln(3.3540 x 10^{-3} xT) - \\ & 7.7989 x 10^{-4} xT + 2.2653 x 10^{-7} xT^2 - 2.9724 x 10^{-11} xT^3 - \\ & 4932.0430 xT^{-1} \end{aligned} \tag{11}$$

The solution of the mass balances, from the kinetic laws obtained from the experimental evaluation of steps 4, 5, and 6 of the reaction, and the temperature and the pressure employed, simulations were considered which produced the profiles presented in Figures 2. 3 and 4 in mass base..

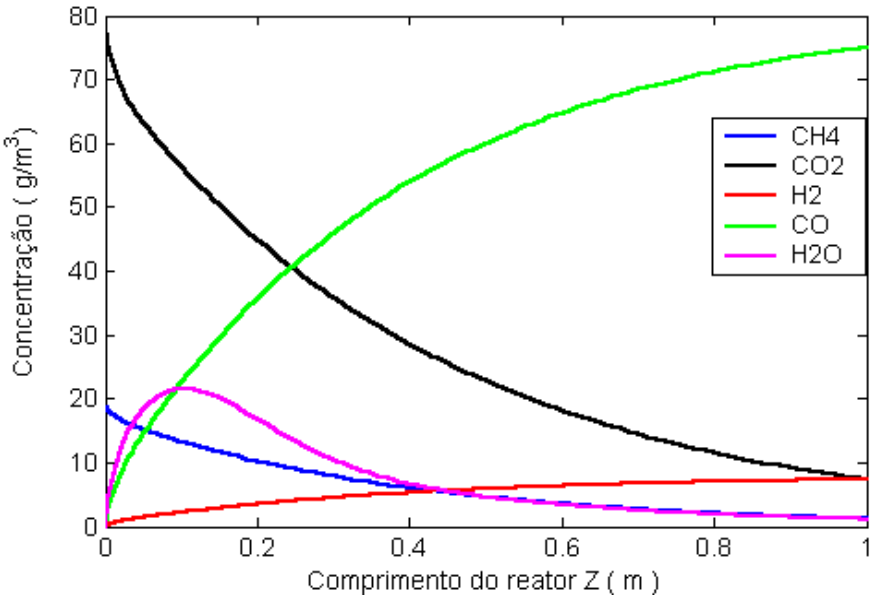

Figure 2. Schematic Profiles of reagents conversion and products.

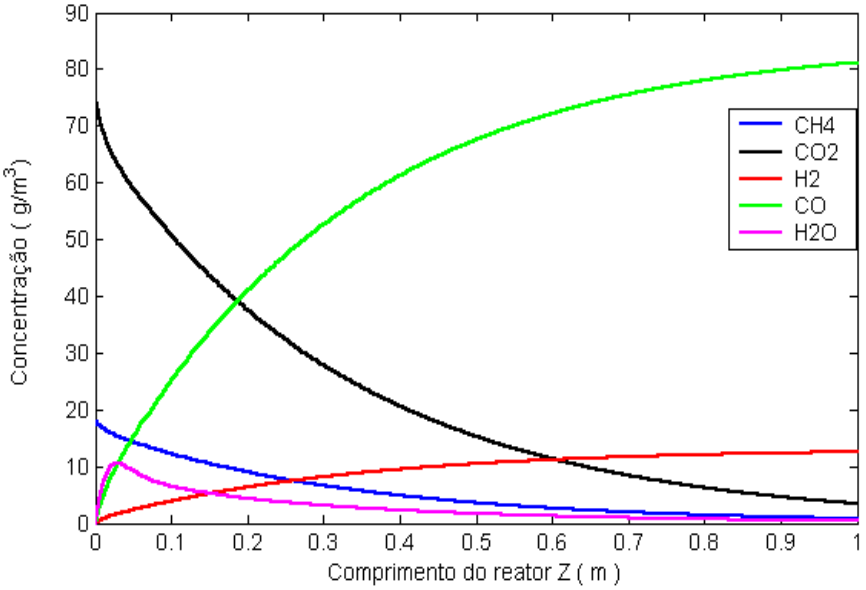

Figure 3. Schematic Profiles of reagents conversion and products.

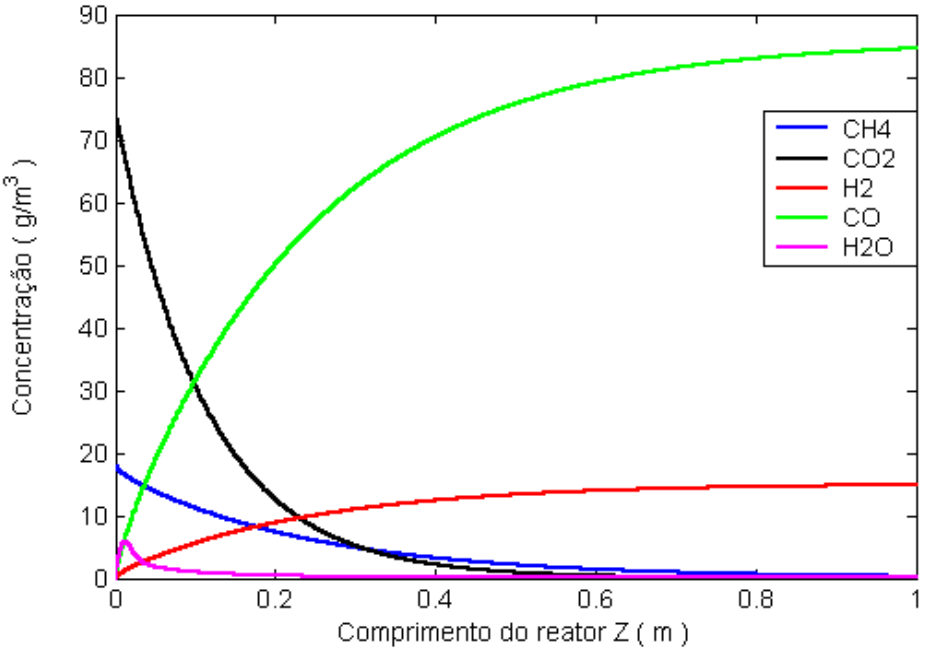

Figure 4. Schematic Profiles of reagents conversion and products.

3. Conclusions

From modeling and the simulation of the reforming process the concentration profiles of CH_4, CO_2, CO, and H_2O along of the fluidized-bed reactor were obtained. The curves in Figures 2, 3, and 4 indicate that, as the temparature of carbon dioxide reform of methane in the the fluidized bed reactor is maintained at a high level, water production via reverse water gas shift diminishes (Edward and Maitra,1995; Yaw and Amin 2005). So, the temperature increase

indicated a higher hydrogen and carbon monoxide production and less coke, as the Boudouard reaction is exothermic and at high temperatures it shifts to the left in the direction of carbon monoxide production.

Keywords: Ethylene polymerisation, Polymeric supports, Spherical Polyethylene, Hydroxypolystyrene, polystyrene-b-polyisoprene
Topic: Multi-scale and/or multi-disciplinary approach to process-product innovation.

Abstract

The industrial use of metallocene/methylaluminoxane catalytic systems and late transition metal catalysts requires the use of supports to improve the operational conditions, catalyst stability and directly get polyethylene with spherical morphology. However, the presence of residues of the inorganic support at the end of the polymerisation reaction gives rise to some inconvenients and contamination problems. Therefore, important efforts are being nowadays employed in the replacement of inorganic supports ($MgCl_2$, Al_2O_3, SiO_2) by organic supports. The latter are mainly based on polymers like polystyrene. In this work, linear hydroxypolystyrene (PSOH), polystyrene-block-isoprene copolymer (PS-b-PI) and plurihydroxy-functionalised PS-b-PI (PSPI-OH_n) were tested as supports for ethylene polymerisation. The ability of these various polymers when dissolved in a selective solvent to self assemble and form micelles was investigated first by Light Scattering techniques. Then, the capacity of these polymer micelles to act as active supports towards MAO-activated MeDIP(2,6-iPrPh_2FeCl_2) catalyst was analysed through ethylene polymerisation tests and morphology studies of the obtained polyethylene.
The most promising results were obtained for the PS-b-PI copolymer in heptane, which enabled the obtention of Polyethylene with spherical morphology and higher densities than polyethylene obtained in homogeneous conditions.

1 Introduction

Various routes have been investigated to support metallocenes onto organic particles and a special interest has been focused in polystyrene-bound polymerisation precatalysts. This derives from the idea that the catalytic species reside within a mobile hydrocarbon-rich matrix providing a polymerisation microenvironment that more closely resembles to a homogeneous solution polymerisation. Moreover, polystyrene supports are very versatile materials in terms of the incorporation of functional groups, enabling the development of numerous routes to anchor metallocene and/or postmetallocene systems on these organic supports. Therefore, polystyrene-based polymers are largely the most popular organic polymeric supports.

Hong et al. [1] carried out the ethylene copolymerisation using metallocene catalysts encapsulated in gel-type polystyrene-co-divinylbenzene beads. The zirconocene is introduced in the polystyrene-co-divinylbenzene particles by a simple swelling-shrinking process carried out in the presence of the solvent. The polyethylene synthesized particles using this supported catalytic system replicate the polystyrene-co-divinylbenzene particles.

Klapper and co-workers [2] describe the synthesis of polystyrene supports with polyethylene oxide (PEO) and polypropylene oxide (PPO) functionalities. These functional groups containing electronegative oxygen atoms enable to anchor the MAO-metallocene catalytic

complex by electrostatic (non-covalent) interactions with the oxygen atoms.

Bouilhac et al. [3] synthesized star shape polystyrene supports having –O-CH_3 or –OH functionalities at the end of the chain and new polystyrene functionalised microgels containing benzoic acid or benzophenone functionalities [4]. Over this functionalised supports, they added an alkylaluminum to generate the MAO like activating species in situ. At the end, the iron catalyst is anchored on the activator-support complex. The polyethylene synthesized with these new supports presents a spherical morphology and activities may vary from 100 to 1020 KgPE/ (molFe.h.bar). More recently, Bouilhac et al. [5] have developed another strategy based on the self-assembly of end-capped PS and PS-based block copolymers that spontaneously form well defined micelles in a selective solvent [6] which is another important feature for the use of these polymers as organic supports.

On this basis, linear hydroxypolystyrene (PSOH), polystyrene-block-isoprene copolymer (PSPI) and plurihydroxy-functionalised PSPI (PSPI-OH_n) are tested, in this work, as supports for ethylene polymerisation.

2 Materials and Methods

Reagents:
PS, PS-OH and PS-b-PI (PS=37 wt %; PI=63 wt %) were synthesised at LCPO (Université de Bordeaux I). The correponding molecular weights are: Mp=7840, Mn=7240, Mw=7520; Mp=5040, Mn=4860, Mw=5030 and Mp=49000, Mn=37000, Mw=44400. The iron catalyst [MeDIP(2,6-iPrPh_2FeCl_2)] was also synthesised at LCPO (Université de Bordeaux I) according to literature. Trimethylaluminium (2M solution in heptane) and Methylaluminoxane (10% w/v in toluene) were purchased from Aldrich and were used without further treatments. Heptane and toluene were purified according to standard procedures.

Light Scattering Studies of Polymer Solutions in toluene or heptane:
The desired amount of polymer was dried under vacuum during 3-4 hours. The polymer was then solubilized/dispersed in 10 ml of purified toluene or heptane. The light scattering measurements were carried out in a Malvern (Zetasizer 3000 HSA) apparatus.

Polymerisation Tests:
First, the polymeric support was dispersed in the solvent, then MAO or TMA and the catalyst were added. Polymerisations were performed in a modified schlenk (with an adapted cell for light scattering measurements) allowing “in-situ” light scattering studies. The polymerisation reactions were carried out in the following conditions: n (Fe)= $0,8*10^{-6}$ mol; Pethylene=1 bar, T=30 ºC; t= 1 h.

Characterisation of Obtained PE:
The polyethylene images were obtained in Scanning Electronic Microscope JEOL JSM 2500.

3 Results and Discussion

3.1 Light Scattering Studies

3.1.1 Hydroxy-polystyrene (PSOH) polymer

Light scattering measurements were performed to check the formation of micelles/aggregates of PS based polymers when in toluene solution. As expected, when polystyrene is dissolved in toluene, no agregation is observed all over the whole range of concentrations studied indicating that polystyrene is present in the form of single chains in the solvent. The situation changes with PSOH polymer, as shown in Figure 1a). Although at low PSOH concentrations (equal or inferior to 10 g/l), no formation of aggregates/micelles is

observed, aggregates are detected for higher PSOH concentrations (20, 50, 100 g/l). The presence of –OH group induces the self assembling of the polymer chains in toluene. The possible structure of the PSOH micelles (spherical shaped) is illustrated in Figure 1b). The core of the micelles is formed by the –OH groups whereas PS chains will constitute the corona.

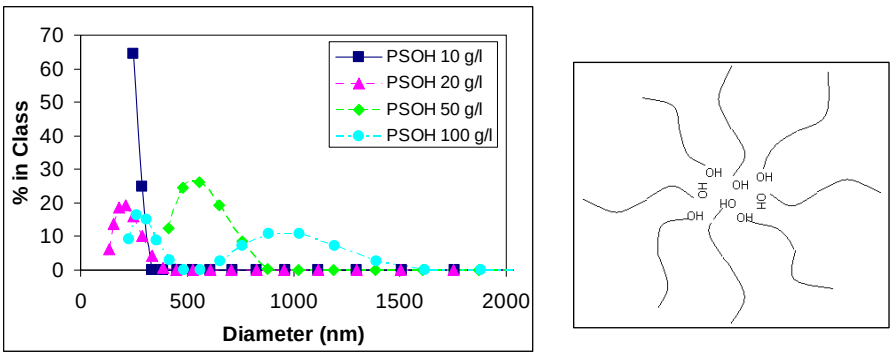

Figure 1a)- Light Scattering of PSOH polymer in toluene and b) Aggregates formed.

The ability of PSOH to form micelles after MAO addition was then investigated. Light scattering results after the addition of MAO over a 10 g/l solution of PSOH are presented in Figure 2. Initially, at this concentration (10 g/l), the PSOH solution in toluene does not form aggregates. However, the addition of MAO to the solution of PSOH leads to the formation of aggregates at lower PSOH concentrations (3 g/l). The diameter of the PSOH/MAO aggregates is around 1000 nm. However, in a solution containing only commercial MAO, the presence of well defined aggregates with cc. 750 nm diameter is also observed. We assume that in PSOH/MAO systems, MAO molecules are in the center of the aggregates, as illustrated in Figure 2b).

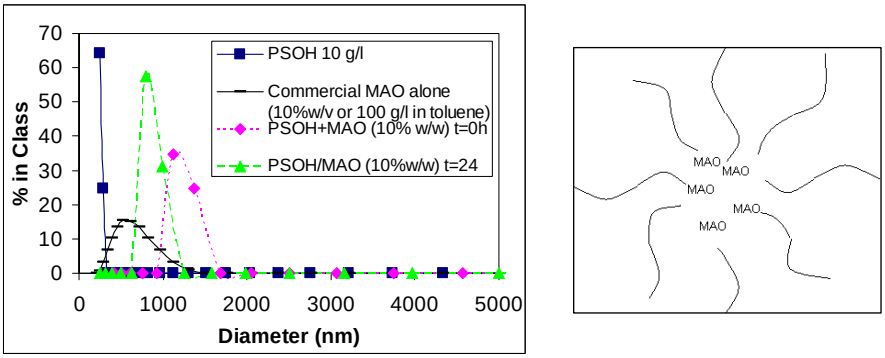

Figure 2a)- Light Scattering of PSOH+MAO polymer in toluene and b) Aggregates formed.

3.1.2 Polyisoprene-b-polystyrene (PS-b-PI) block copolymers

The PS-b-PI in heptane solutions form well defined micelles, with sizes ranging between 200 and 250 nm (in average). Once formed, the micelles are stable and do not change significantly neither with the dilution of the solution nor with time. It is known that the size of the formed aggregates/micelles depends both on the molar mass of the block copolymer and on the relative amount of the isoprene and styrene units [7]. This fact may in part explain why the size of the micelles with this PS-b-PI block copolymer is larger in this case than the one observed by Borsali and co-workers (between 50 and 60 nm).[6] Although both PS-b-PI present quite similar molar masses, the relative lengths of the two blocks are quite different. While the block copolymer used in Ref [6] shows a polystyrene block larger than the polyisoprene block (DP_{PS}=290 and DP_{PI}=110). In our case the situation is reversed; the length of the polyisoprene (PI) block is larger than the polystyrene (PS) block (DP_{PS}=239 and DP_{PI}=280) and a large corona may be expected- Figure 3b).

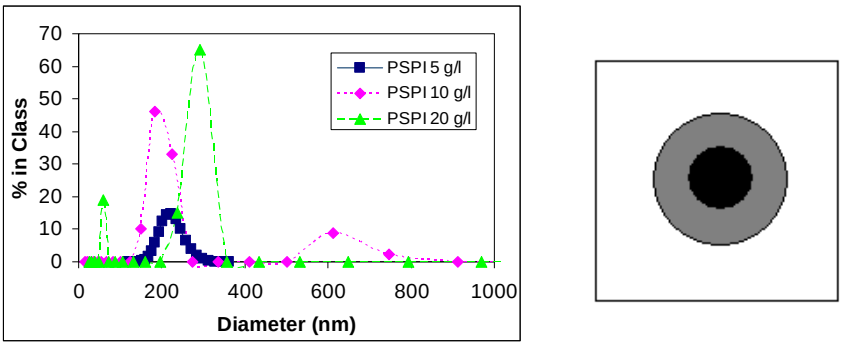

Figure 3a)- Light Scattering of PSPI polymer in heptane and b) Micelles formed (PS Core and PI Shell).

When toluene is used as solvent, both PS and PI blocks are soluble. Therefore, very small objects corresponding to single PS-b-PI chains of lower molecular mass are formed.

In order to anchor the MAO cocatalyst on the PS-b-PI support, functional groups containing oxygen atoms were introduced in the PSPI chains (PI- moieties) via epoxydation and hydrolysis reaction. Two Modified polymers containing OH groups, with two degrees of functionalisation (5 % and 30 %) were obtained and characterised by ^{1}H-NMR and FT-IR. The spectra of these modified polymers confirms the presence of –OH groups.

The behaviour of both modified PS-b-PI copolymers [PSPI-$(OH)_n$] in toluene and heptane was studied. For the PS-b-PI with 5 % of –OH groups, no important changes were observed comparing to the non-modified PS-b-PI. However, for the PS-b-PI with 30 % of –OH groups, some significant changes were observed due to the presence of -OH groups. As both PS and PI-OH blocks are not soluble in heptane, this copolymer becomes insoluble and precipitation of the polymer occurs. Light scattering studies confirm, in fact, the destabilisation of the micelles observed for the non-modified PS-b-PI. By exchanging the solvent from heptane to toluene, the solubility of the two blocks in the PSPI-$(OH)_n$ copolymer is changed. The PS block that is not soluble in heptane is easily solubilized in toluene. However, the PI-OH block (with high extent of functionalisation) will probably remain insoluble in toluene. This way, the formation of soluble PSPI-OH micelles is expected. In fact, Light Scattering studies on modified PSPI (30 % -OH groups) in toluene showed the formation of some micelles with approximately 200 nm diameter and some aggregation tendence. In this case, micelles have a PI-OH core and a PS shell.

The situations observed for the four different systems examined by light scattering are briefly resumed in Table 1.

Table 1- Light Scattering and solubility studies carried out for the PSPI-based polymers.

Polymer	Heptane	Toluene
Non-Modified PSPI	PI block: soluble PS block: not soluble *Formation of micelles* *(PS Core; PI Shell)* 	PI block: soluble PS block: soluble *Single PSPI Chains.* *No Micelles* Modified PSPI (PSPI-OH_n)	PI-OH block: not soluble PS block: not soluble *Destabilization of micelles, precipitation of the polymer* 	PI-OH block: not soluble PS block: soluble *Aggregation depending on the % of –OH groups inserted* *(PS Shell; PI-OH_n core)* 
Note: Average diameter of the micelles: 200-250 nm determined by Light Scattering.

Only the two systems which showed the formation of micelles and/or aggregates (PS-b-PI in heptane and PS-b-PI-OH in toluene) were kept to be evaluated in polymerisation tests.

3.2 Polymerisation Tests and Characterisation of the Synthesized PE

3.2.1 Hydroxypolystyrene (PSOH) in toluene

The morphology of the polyethylene synthesized with the PSOH/MAO catalytic systems is shown in Table 2. The obtention of polyethylene in the form of aggregates of spherical particles is clearly observed. In agreement with this morphology, an increase in the PE density as compared to homogeneous conditions is also observed.

Table 2- Morphology of the polyethylene obtained with PSOH/MAO catalytic systems

Co-Catalyst	Polymerisation Activity KgPE/(molFe.h.bar)	PE Photographs obtained by SEM (Scanning Electronic Microscopy)	Density PE (g/l)
Commercial MAO	3960		157
PSOH/MAO 20% w/w	2720		252

Note: Al/Fe=400; V(toluene)= 50 ml; n(Fe)= $0,8*10^{-6}$ mol; T=30ºC; t=1h; Pet=1 bar;

3.2.1 Polyisoprene-polystyrene (PSPI) in heptane

Polymerisation tests were conducted using the PS-b-PI polymer as support in heptane. Besides the obtention of polyethylene with well defined spherical micelles quite good polymerisation activities are attained – See Table 3.

Table 3- Polymerisation activities and morphologies of the polyethylene obtained with PS-b-PI/TMA catalytic systems.

Support/ Co-catalyst System	Al/Fe	Polymerisation Activity KgPE/(molFe.h.bar)	PE Photographs obtained by SEM (Scanning Electronic Microscopy)
TMA	2000	1678	PSPI/TMA m(PSPI)/m(TMA)=0,054	1000	391	PSPI/TMA m(PSPI)/m(TMA)=0,026	2000	975	PSPI/TMA m(PSPI)/m(TMA)=0,05	2000	1461	
Note: n(Fe)=$0,8*10^{-6}$ mol; V(heptane)=50 ml; T=30ºC, Pet=1 bar.

3.2.2 Plurihydroxy Polyisoprene-polystyrene PSPI(OH)$_n$ in toluene

The (PS-b-PI(OH)n) polymer in toluene was also tested as support in ethylene polymerisation. Although quite acceptable polymerisation activities are achieved, in the range from 600 to 1400 KgPE/(molFe.h.bar), the formation of micelles observed by light scattering was not reflected in the polymer morphology.

4 Conclusions

Concerning the behaviour of hydroxy-polystyrene (PSOH) copolymers in toluene, we may conclude that the –OH groups already yield the formation of polymer aggregates in toluene relatively to non modified polystyrene (PS). However the formation of aggregates was observed only for high PSOH concentrations (above 20 g/l). Nevertheless, the addition of MAO over a PSOH solution in toluene allows the obtention of aggregates with sizes in the order of 1000 nm at lower PSOH concentrations – around 3-5 g/l. The ethylene polymerisation activities do not decrease significantly in the presence of PSOH/MAO cocatalysts in comparison to homogeneous MAO polymerisation values. Moreover, the obtained polyethylene shows spherical particles for high PSOH/MAO ratios which are not visible in PE obtained in homogeneous conditions (MAO alone as cocatalyst).

The polyisoprene-polystyrene (PS-b-PI) block copolymers gave very promising results when used as supports for ethylene polymerisation in heptane. Well defined micellar systems of PS-b-PI with sizes around 200-250 nm are formed in heptane. Moreover, the polymerisation activities in heptane (in the order of 900-1000 KgPE/(molFe.h.bar) are quite acceptable if compared with the corresponding activities in homogeneous conditions (around 1600 KgPE/(molFe.h.bar)). The formation of spherical PE may be tentatively attributed to the catalyst system heterogenisation around the micelles through the electrostactic interaction between the free double bonds of the PI block of the micelle and the cationic active species (formed by the reaction of the cocatalyst with the metal catalyst). A quite different behaviour is observed for the same PSPI block copolymers in toluene. In this case, no stable micelles are formed.

Through the introduction of functional protected groups containing oxygen in the PSPI chain, it was aimed to anchor more efficiently MAO or TMA by electrostatic interactions (that are expected to be stronger than with the single double bonds). However the presence of free –OH groups in the PSPI chain reflected negatively both in polymerisation activities and in polyethylene morphology. In fact, when using heptane, the presence of –OH groups in PSPI(OH)$_n$ chains leads to the insolubility of the two block copolymers and therefore inhibits the self assembling of PSPI(OH)$_n$ chains. When using toluene as solvent, the self assembling of PSPI chains is slightly favoured and aggregates with insoluble PI-OH block in the core and PS soluble block in the corona are expected to be formed. Nevertheless, no improvement of polymer morphology was achieved in this case. The obtained activities are although quite acceptable.

Abstract

Pultrusion is a continuous process used for manufacturing constant cross section composite materials. In this process, fibers are continuously pulled and impregnated in a resin bath before entering in a heated die, where occurs an exothermic cure reaction. Normally the die is heated by electrical heaters coupled on its outer surface. The known of cure kinetic is relevant to improve process parameters as heat flux and pulling velocity. It was observed that the most usual heat configuration used in the present literature can be improved by changing the geometry of heaters. In this paper, it was used a CFD package (Ansys CFX 11.0™) to simulate a volume finite mesh of a die with a I beam cavity. The strategy adopted was to minimize the superficial area of heaters in order to reduce the energy consumption. The results were compared with results from the literatute and showed that the proposed heat configuration is a more efficient way to conduce the pultrusion process in terms of energy.

1 Introduction

Polymer composites are materials consisted by a cure reaction of thermosetting or thermoplastic resin associated with reinforcement. These materials can be manufactured by several industrial processes as rtm, filament widing, hand lay-up and pultrusion. Among these technologies, pultrusion stands out because of its ability to combine a high production rate with high quality of produced parts. In pultrusion, fibers are continuously pulled and impregnated in a resin tank before entering into a heated die, where occurs an exothermic cure reaction. The die may be heated by electrical heaters, strip heaters, hot oil or by steam, although electrical heaters are the most common (Coelho and Calado, 2001). Outside the die, the composite part is pulled by a continuous pulling system and then a cut-off saw cuts the part into a desired length. In Fig. 1 is represented a scheme of a pultrusion equipment:

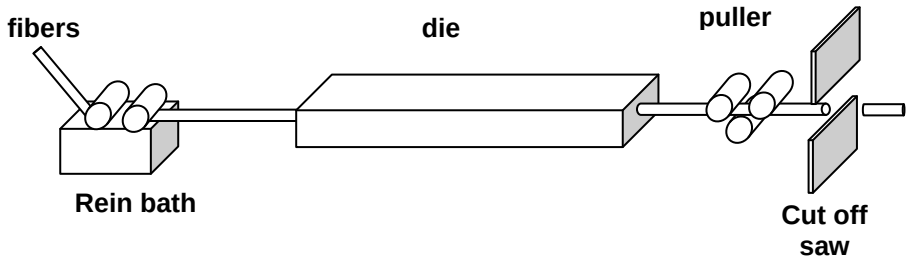

Figure 1. A simplyfied diagram of pultrusion process.

* Corresponding author. Tel +55 21 2562-8345. E-mail:evaristo@peq.coppe.ufrj.br

The heat flux provided by die must be sufficient to promote the polymerization reaction of thermosetting matrix. Besides, the cure process of composite should be uniform and enough to reach good properties of final product. Variables, such as die temperature, pulling speed, pulling force, internal pressure and resin cure kinetics control the composite process during the pultrusion. Among these variables, the die temperature (the temperature imposed on the die wall) is the most relevant one for obtaining a part with uniform and excellent mechanical properties (Pagano *et al.* 1996).

Han *et al.* (1986) studied the pultrusion process to solve the mathematical model by finite difference method. Moschiar *et al.* (1996) also solved the pultrusion model using finite difference and the viscosity, temperature and degree of cure profiles were studied. A good agreement between simulated and experimental results was obtained in low pulling velocities of the process. Liu and Hillier (1999) studied the pultrusion process simulating a composite of geometry like I beam using a vinyl resin/glass fiber system and also achieved a good agreement between results. Other paper using the same geometry was proposed by Liu XL. (2001), however, in order to study the temperature and degree of cure profiles, he proposed a heating configuration to improve the cure of product and consequently to obtain a part with homogeneous cure. The FE packages are appropriate to model irregular shapes in three-dimensions and a variety of boundary conditions and material properties can be defined easily. Jianhua *et al.* considered the simulation of three heaters on the top and three on the bottom of the die wall. Srinivasagupta *et al.* (2003) affirmed that the number of heating zones is variable, but three are found to be sufficient in practice. These authors (Jianhua *et al*, 2001, Srinivasagupta *et al.,*2003) have used this heater arrangement to model the pultrusion process of composites with different dimensions and properties. However, no attention was given to the effects of heater arrangement changes on the necessary thermal energy and composite quality.

In the present investigation, a numerical procedure based on CFD technique for the three-dimensional simulation of pultrusion process of a I beam composite was developed. The heater arrangement on the die wall and its influence on the energy consumption were studied here and compared with results from Liu XL. (2001). The suggestion of a heating configuration to reduce the energy consumption in the pultrusion process is the main objective of this work.

2 Mathematical Model

The mathematical model of the steady state pultrusion process is composed by the energy balance and the kinetic cure reaction. These equations can be written, respectively, as:

$$\rho_c \; C_C\left(u_i \nabla T\right) = k_c \nabla^2 T + c_{in}(1-\phi)\left(-\Delta H\right) R_a \tag{1}$$

$$u_z \frac{d\alpha}{dt} = R_a = \left(A e^{\left(\frac{-Ea}{RT}\right)} \right) (1-\alpha)^n \tag{2}$$

where T is temperature, u velocity vector, C_c specific heat of the composite, k_c thermal conductivity of the composite, ($-\Delta H$) total heat generated, ρ_c the density of the composite, R_a resin reaction rate, Φ fiber volume fraction, c_{in} resin initial concentration, α degree of cure, A frequency factor, E activation energy, and $m + n$ reaction order.

The fiber-resin system was assumed to be epoxy resin and glass fiber. The physical properties of the composite were calculated by the following equations:

$$\rho_c = \phi_r \rho_r + \phi_f \rho_f \tag{3}$$

$$\rho_c Cp_c = \rho_r \phi_r Cp_r + \rho_f \phi_f Cp_f \quad (4)$$

$$\frac{1}{k_c} = \phi_r \frac{1}{k_r} + \phi_f \frac{1}{k_f} \quad (5)$$

where the subscripts r, f and c represent resin, fiber and composite respectively.

In this work, the degree of cure was assumed to be zero *($\alpha = 0$)* before the fiber-resin system entering into the die, and the inlet temperature was considered as 298 K. In order to compare our results with the results presented by Liu X.L (2001), the same physical parameters and kinetic parameters were here considered, shown in Table 1.

Table 1. Physical and Kinetic Parameters

Fiber fraction ***(Φ)***	0.72
Density of the resin ***(ρ_r)***	1100 (kg/m^3)
Density of the fiber ***(ρ_f)***	2560 (kg/m^3)
Thermal conductivity of the resin ***(k_r)***	0.169 (J/m.s)
Thermal conductivity of the fiber ***(k_f)***	1.04 (J/m.s)
Thermal capacity of the resin ***(Cp_r)***	1640 (J/kg.K)
Thermal capacity of the fiber ***(Cp_f)***	640 (J/kg.K)
Initial temperature ***(T_0)***	300 K
Initial concentration of resin ***(c_{in})***	1100 (kg/m^3)
Frequency Factor ***(A)***	1.869x10^6 (s^{-1})
Activation Energy ***(E_{a1})***	71.688x10^3 (J/mol)
Order of reaction ***(n+m)***	2
Universal constant of gases ***(R)***	1.98 (cal/mol. K)
Heat generated ***(ΔH)***	398 (J/g)

For the numerical solution, it was used a CFD-type model. Computational Fluid Dynamics (CFD) is a computer tool for simulating the behavior of systems involving fluid flow, heat transfer, and other related physical processes. Fluid flow equations can be solved over a region of interest with specified conditions on the boundary of that region. The numerical method on which ANSYS CFX 11.0© is based is known as the finite volume technique. In this technique, the region of interest is divided into small sub-regions, called control volumes. The equations are discretized and solved iteratively for each control volume. In this work, a mesh with 34590 nodes and 37690 elements were suficient to integrate with fidelity the system equations.

3 Results and Discussion

According to the reported literature [2-4], the heat flux at the final stage of the cure reaction can be decreased due to the fact that the heat generated by the cure reaction inside the die can provide suficient energy to cure the material at this stage. Hence, the temperature may assume different values along the die length and it may be reduced at the final stage of the cure reaction. The procedure here was based on the simulation of pultrusion process by several times, assuming different values of heat rate at each heater, until finding a minimum value of energy consumption to totally cure the material. Assuming this fact, our methodology was to decrease the superficial area of heaters in order to minimize the spent heat flux along the die length. We believe that the typicial heater configuration suggested by Liu X.L. (2001), Fig. 2, can be configurated in a more efficient way in order to avoid energy loss during the process.

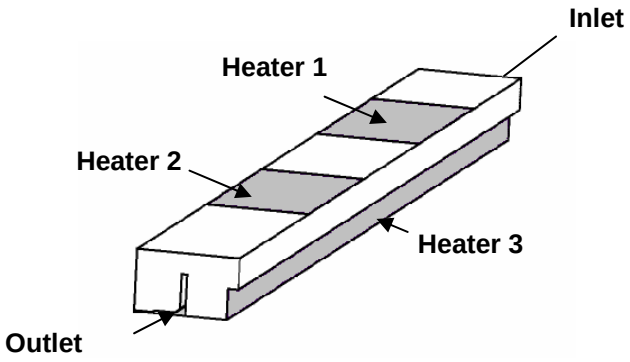

Figure 2 – Typical heating configuration for pultrusion die of composite I beam.

The proposed heat configuration was a tooling pultrusion die consisted of internal heaters inside an insulated die, as shown in Fig. 3. The distance between each heater was set to be 0,2 m. It was assumed the dimensions of 0.002 m×0.002 m×0.06 m.

Considering this heat configuration, simulated temperature and cure profiles along the beam are shown in Figures 4 and 5, and temperature profiles at three points of the beam are presented in Figure 6. It should be pointed out that the proposed configuration was able to cure the material in a more efficient way. This efficiency is characterized by approximately a 20 % reduction of the energy consumption in comparison with the heat strategy used by Liu X.L. (2001). According to the proposed configuration, the necessary power of heaters to cure the material was 7.3 kW.

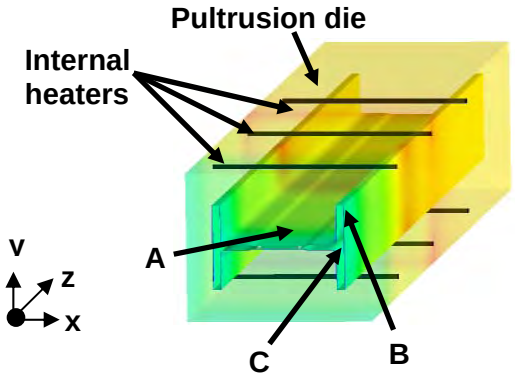

Figure 3 – Internal heating configuration.

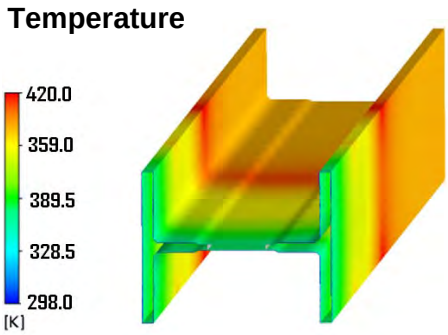

Figure 4 – Composite temperature.

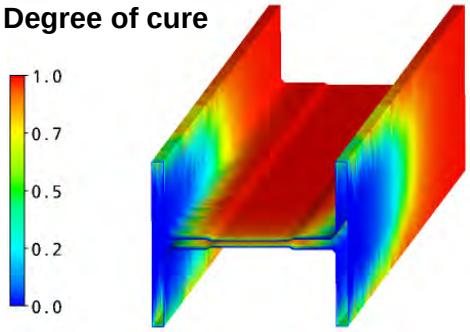

Figure 5 – Degree of cure of the composite.

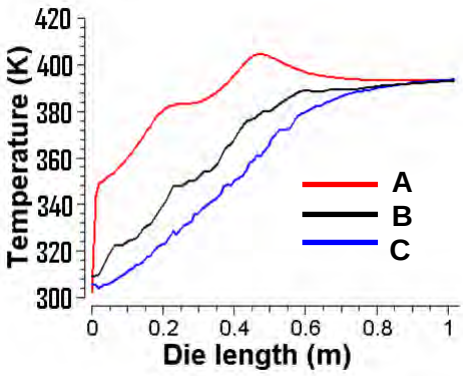

Figure 6 – Temperature profile.

As seen in Fig. 5, the composite part was totally cured at the exit of composite. In Fig. 6 it is possible to see the temperature distribution in funtion of pulling direction at three diferent points. The final temperature of the conjunct was around 400 K reaching a maximum value of 410 K.

4 Conclusions

Through intensive computer simulations, were verified that smaller energy consumption can be obtained with the suggested heat strategy in pultrusion process. This economy was verified by the reduction of the surface area of the heaters causing a significant decrease of the energy consumption. This internal heat configuration appears to be a good alternative to improve global thermal efficiency of the process. The following conclusions can be drawn from the results presented in this paper:

1. The temperature profile depends strongly upon the heat configuration of the die. Heaters with small transversal area must be primarily assumed to simulate the process in order to provide a adequate temperature distribution along the die length. According to the results, heaters with wide transversal area may spend excessive thermal energy to cure the resin.

2. The results suggest new studies about heater arrangements of the pultrusion process. Each particular case must be examined, taking account the variables and the geometry of the desired composite to be obtained.

Keywords: hydrogel, poly(acrylic acid), microparticles, hydrophobicity/hydrophilicity, inverse-emulsion polymerization, textiles, swelling behaviour.

Topic: Advancing the chemical engineering fundamentals.

Abstract

In this work we wish to report the synthesis of polymeric microparticles based on a hydrogel made of Poly(Acrylic Acid) (PAA). They were prepared by inverse-emulsion polymerization. This material is intended to be used in textile industry in order to improve confortability.

The polymerization conditions and their effects on the morphology (analyzed by Scanning Electron Microscope (SEM)), structure (analysed by Attenuated Total Reflectance - Fourier Transform Infrared (ATR-FTIR)) were determined.

The swelling and water adsorption behavior of the PAA microparticles before and after his incorporation in the textiles (cotton) were evaluated. The morphology of the polymeric microparticles after the incorporation, in the textiles was also assessed.

1 Introduction

Polymeric hydrogels are three-dimensioned networks obtained either by chemical bonds and/or physical forces. They are able to absorb high quantities of water without dissolving. Recently, the interest in the development of hydrogels has increased considerably due to their intrinsic properties. (Hoffman, J., 1999; Can, H., 2003) The polymer particles prepared in this work have been produced by inverse-emulsion polymerization (Lim, D., 2002).

The hydrogel properties are directly dependent on the amount of water that the hydrogel can imbibe into his molecular matrix which is referred as the degree of swelling (Devine, D., 2005).

During human history, the functions of textiles were, for long time, important not only from cultural and technologic development aspects but also from the fashion and comfort aspects. Although their variety was dependent on the available of natural fibres (Schuster, K., 2006). These natural fibres could be either hydrophobic or hydrophilic, being these aspects the main reason for specific selections. However, nowadays the specificity of the textile fibres properties, and the features that are possible to incorporate in those materials, are the main goal for their success.

The hydrogels proposed in this work are referred to be incorporated into the textile fibbers in order to enhance the hydrophilic/hydrophobic character, and, in this way, to improve the comfortability.

Here we report the synthesis of polymeric microparticles based on a hydrogel – PAA, crosslinked with N,N'-Methylene Bisacrylamide.

2 Experimental Results

Synthesis Procedure

The PAA microparticles were prepared by inverse-emulsion polymerization, and the final structure of the polymer is represented in the Figure 1. The polymerization occurs under inert atmosphere (N_2), at 75ºC for 2h. The mixture components were stirred with mechanical stirring during the reaction time.

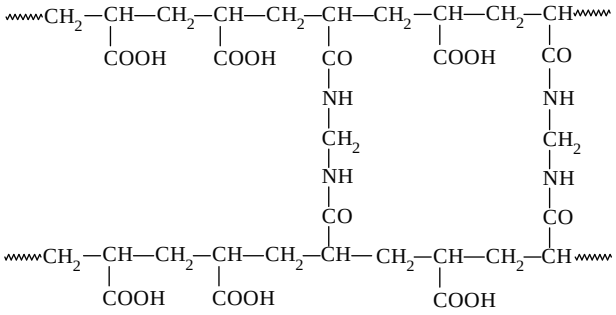

Figure 1 – Structure of the PAA polymer particles produced.

The scale up of the production was carried out for 250mL, 500mL and 1L reactional systems with success and good yields were observed (70-95%).

The size and morphology of the polymeric microparticles have been optimized by the manipulation of critical reaction factors, such as: the organic and aqueous solutions homogeneity phases; the addition time of the monomer and initiator; the cleaning time of the oxygen in the reactional atmosphere with N_2; and the isolation and cleaning of the solid polymer.

ATR-FTIR

The prepared hydrogel was characterized by ATR-FTIR analysis.

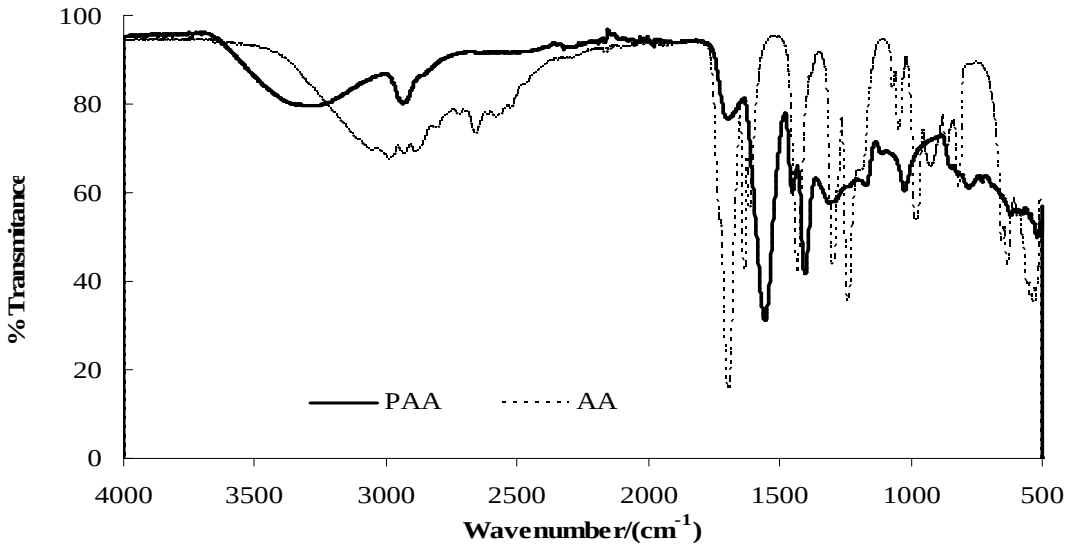

Figure 2 – FTIR spectrum of the prepared polymer (PAA) and of the monomer (AA) used to prepare the polymer.

In the polymer and monomer spectrums (see Figure 2), it is observed the presence of the characteristic COO^- bands (symetrical and assymetrical stretching bands) at 1715cm^{-1}, 1443cm^{-1} and 1408cm^{-1}; Due absence in the polymer spectrum of the characteristic band (1633 -1630cm^{-1}) that belong to the double bands, confirms the polymerization success; The

presence in the polymer spectrum of the amide (N-H linkage) characteristic band at 1699cm^{-1} confirm the crosslinking reaction of the acrylic acid with the N,N'-methylene bisacrylamide.

Swelling Behaviour

The swelling behaviour corresponds to the increase in the volume or changing in the shape of an area or surface. This property was evaluated in the PAA polymer particles and in the textiles fibres after hydrogel incorporation. This test is important to assess the capacity of the polymer to swell, in the presence of water.

The degree of swelling was calculated by evaluating the mass differences, which considers the initial mass as the dry weight of the polymer and end as the mass of polymer after the swelling, using the following equation:

$$\% \text{ swelling} = [(\text{final weight} - \text{initial weight}) / \text{initial weight}] \times 100 \quad (1)$$

Experimentally, for PAA swelling evaluation, two samples of 500mg of dried polymer, were weighted (initial weight), and then dispersed in 50mL of deionized water for 15 minutes, at room temperature (20±1ºC). The excess of water was removed and the samples were weighted (final weight). By the equation (1), it is possible to determine the swelling percentage.

The results obtained for the swelling of the polymeric particles in deionized water are presented in the Table 1. It is possible to verify that the material is an hydrogel with very high and fast swelling capacity. This result is a direct consequence of the very small particles (see SEM results), that possess very high surface areas.

Table 1 – Experimental results for the swelling percentage the PAA in deionized water.

Medium used for promote the polymer swelling	% Swelling
Deionized water (pH~ 5-6)	4512.4 ± 23.5

For the case of the textiles, the swelling capacity was determined after 12 hours of contact with the medium. The dry and wet weight were determined and related by the same equation (1), and the results are referred in the Table 2.

Table 2 – % swelling of the various cotton textiles samples with different treatments.

Sample	% Swelling
Cotton Standard	178.9 ± 4.4
Cotton + PCM + PAA	167.4 ± 3.8
Cotton +PCM + Conditionator	115.0 ± 4.9
Cotton + PCM	127.2 ± 5.3

The cotton fibbers are hydrophilic by nature, but some specific treatments to those fibbers decrease significantly that swelling behaviour. In the case has been incorporated in the textile fibbers PCM's (Phase Change Materials) refered by Su, J., and its colaborators (Su, J., 2006) as materials with capacity to store thermal energy, that could be released over a

defined temperature range, while itself changes phase.

In this case, the textiles swelling decreases from around 179% to around 127%, when they are treated with PCM. The refered decreasing is more significant when the final material is also treated with the conditionator. To counteract the hydrophobic behaviour, PAA hydrogel particles were incorporated in the textile fibbers, at the same time that PCM was incorporated. This incorporation permit to increase the swelling behaviour of the textiles (167%), to values close to the values obtained to the cotton sample without treatment (179%).

Water adsorption behavior

In this study it is important to know what the behaviour of the PAA regarding the ability to adsorb liquids from its surface.

The water adsorption capacity of the polymer particles was availed during 24h at room temperature (T=20±1ºC), putting the samples in contact with a atmosphere with a saturated solution of $CuSO_4.5H_2O$. The dry and wet weight of the samples were determined, along the time and related by the follow relation:

$$\% \text{ Water adsorption} = [(\text{final weight} - \text{initial weight}) / \text{initial weight}] \times 100 \quad (2)$$

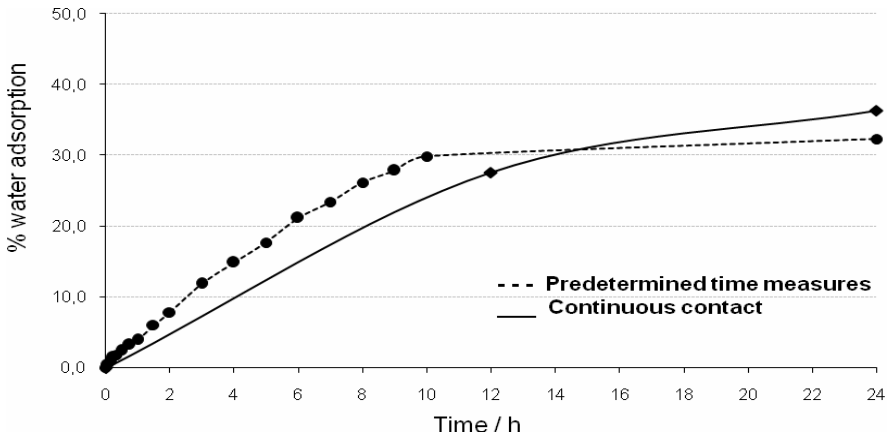

Figure 3 - Water adsorption capacity of the PAA polymer particles.

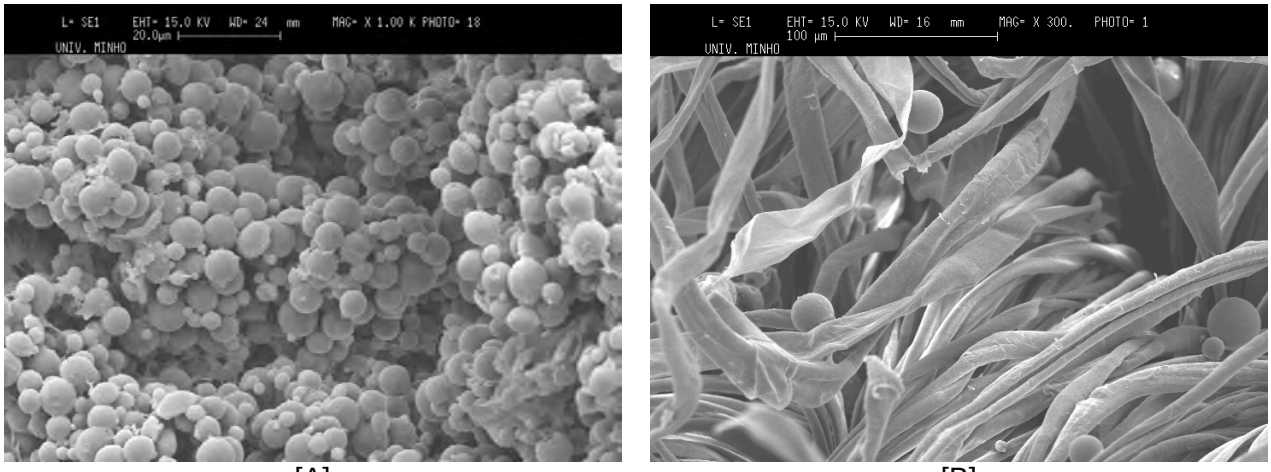
The results obtained in this test (Figure 3), reveal that the polymer prepared (PAA) is an hydrogel, because it has capacity to adsorb more than 30% of water in his surface for an saturated atmosphere.

SEM

By scanning electron microscope (SEM) analysis it is possible to verify the morphology of the polymeric material.

The Figure 4 – [A] suggest that the prepared material has spherical shape and small sizes (≤10μm). In the Figure 4 – [B] it is possible to verify that the hydrogel microparticles, after the incorporation in the textiles, keep their morphology and they are perfectly attached to the textile fibres.



[A] [B]

Figure 4 – SEM images of the PAA microparticles [A] and of the PAA microparticles incorporated in the textiles fibers [B].

3 Conclusions

The PAA hydrogel were efficiently prepared by inverse emulsion polymerization with good yields (about 70-90%). These materials are morphologically spherical and have small sizes (≤10µm). As expect the PAA hydrogel behave as a superabsorbent, because they swell over than 4500%. The hydrogel keep his swelling capacity after the incorporation in the textiles.

This work allows us to conclude that the incorporation of these microparticles in the textiles fibbers increases their swelling properties.

Keywords: Titanium dioxide, Sol-gel, Photocatalysis, Clofibric acid, Pharmaceuticals
Topic: Environmental engineering & management

Abstract

In this paper different titanium dioxide (TiO_2) powders are used as photocatalysts in the liquid phase heterogeneous photodecomposition of clofibric acid, a current lipid regulator drug. The preparation of the TiO_2 powders was made following an acid-catalyzed sol-gel method starting from titanium isopropoxide. It is described how temperature can be used to control surface and morphological properties of the material. Extensive characterization of the materials by spectroscopic, microscopic and calorimetric techniques is given. The performance of TiO_2 catalysts under visible light activation is quantified in terms of kinetic rate constant and total organic carbon removal. The photo-activity is found to increase with calcination temperature up to 673K and to decline afterwards. This behavior is explained in terms of morphological and structural changes associated with the thermal treatment. The photochemical and photocatalytic oxidation is shown to follow a pseudo-first order kinetic rate law, with 4-chlorophenol, isobutyric acid, hydroquinone, benzoquinone and 4-chlorocatechol being the main detected intermediates.

1 Introduction

Treatment systems for water and air based in semiconductor heterogeneous photocatalysis represent an area of major technical importance in our days (Fujishima et al., 2000). However the implementation of such systems in an efficient way requires very efficient photocatalysts. Titanium dioxide (TiO_2) is the most popular semiconductor material in photocatalytic applications, mainly due to its strong oxidizing power, high chemical stability and relative inexpensiveness. TiO_2 exists in different crystalline forms such as anatase, rutile and brookite. It has been long recognized and recently reviewed that TiO_2 photocatalytic efficiency is related to surface and structural properties of the semiconductor such as crystal structure, surface area, particle size distribution, porosity, band gap and surface hydroxyl density (Carp et al., 2004). In addition, resistance to mechanical stress may be important in industrial applications.
Although TiO_2 is readily available from commercial sources and is quite inexpensive, synthesizing the material can be advantageous when there is a need to control several of the above mentioned surface and structural properties. Liquid phase, sol-gel synthesis is very used to produce thin films, powders and membranes. This technique advantages include ease of processing, control over the composition, purity and homogeneity of the final materials. This method involves formation of a TiO_2 sol or gel, or precipitation by hydrolysis and condensation of titanium alkoxides (a common starting material). The synthesis is followed by a thermal treatment to remove the organic part and to induce the crystallization of TiO_2.

* Corresponding author. Tel + 351-22-5081645. E-mail:jlfaria@fe.up.pt

The physical-chemical properties of the so obtained semiconductor are found to be directly related to preparation parameters such as type of Ti(IV)-alkoxide precursor, solvent, aging time and calcination temperature (Hsiang and Lin, 2006).
In the present work, we produced TiO_2 nanocrystalline powders from Ti(IV) isopropoxide by an acid catalyzed sol-gel method. We used the calcination temperature to induce the appropriate changes on several properties including crystal structure, phase composition, surface area and particle size. We tested the materials in the visible photocatalytic oxidation of clofibric acid (2-(*p*-chlorophenoxy)-2-methylpropionic acid).
Clofibric acid is the active metabolite of several fibrate drugs prescribed to reduce blood cholesterol levels. These drugs act to lower elevated serum lipids by reducing the very low density lipoprotein fraction that is rich in triglycerides. It is also classified as a plant growth regulator (antiauxin) pesticide (Emblidge and DeLorenzo, 2006). Pharmaceuticals are a class of emerging environmental contaminants that are extensively and increasingly being used in human and veterinary medicine. A considerable percentage of these compounds are excreted unchanged through urine and feces, or as metabolites entering the waste water streams. If they are not biodegraded or eliminated in sewage treatment plants they may enter the aquatic environment and eventually reach drinking water. Clofibric acid is resistant to degradation, having an estimated persistence in the environment of 21 years. We describe the photocatalytic degradation kinetics of clofibric acid along with the identification of the reaction intermediates. A correlation between morphological, crystalline and spectroscopic properties of the synthesized TiO_2 materials and its ability for the degradation of this organic pollutant is attempted.

2 Experimental

TiO_2 was prepared by a modified acid-catalyzed sol-gel method as described in the following. An ethanol solution 0.5M in $Ti(OC_3H_7)_4$ was stirred for 30 minutes and acidified with 0.8% v/v nitric acid. The solution was loosely covered and kept stirring until the homogeneous gel formed. The gel was aged in air for one week. The resulting xerogel was ground into a fine powder and dried at room temperature. The powder was divided in several batches and thermally treated (calcination) at different temperatures (from 573 to 973K) in a nitrogen flow for 2 hours. Catalysts were labeled as TX, where X is the calcination temperature. Catalysts were characterized by thermogravimetric (TG) and differential scanning calorimetry (DSC) analysis, N_2 adsorption-desorption, powder X-ray diffraction (XRD), X-ray photoelectron spectroscopy (XPS), atomic force microscopy (AFM), diffuse reflection infrared Fourier transformed (DRIFT) spectroscopy and UV-Vis diffuse reflectance spectroscopy.
The photocatalytic activity of the prepared materials was evaluated following clofibric acid degradation in aqueous solution under visible irradiation. The experiments were carried out in a glass immersion photochemical reactor charged with 250 ml of suspension. The reactor was equipped with a Heraeus TQ 150 medium-pressure mercury vapor lamp (the UV line at 254 nm was filtered by a DURAN 50® glass jacket, excitation being carried out by the more intense lines at λ_{exc} of 366, 436 and 546 nm) which was located axially and held in a quartz immersion tube. In a typical experiment, the initial clofibric acid concentration and the amount of suspended TiO_2 were set at 8.33×10^{-5} M (~18 mg l^{-1}) and 1 g l^{-1}, respectively. An oxygen/argon stream (20% *vol.* of oxygen) was continuously supplied to the reactor. Reactions took place under natural pH conditions (pH~4.2). Before turning on the illumination, the suspensions were saturated with the gas mixture and magnetically stirred for 30 minutes. Then, the suspensions were irradiated at constant stirring speed. Samples were withdrawn regularly from the reactor and centrifuged for separation of any suspended solid, prior to analysis.
The clean transparent solution was then analyzed by HPLC using a Hitachi Elite LaChrom liquid chromatograph equipped with an L-2450 diode array detector. The stationary phase consisted in a YMC-Pack ODS-AQ endcapped column (250 mm × 4.6 mm, 5μm particles) working at room temperature. The mobile phase was a mixture of a 20 mM NaH_2PO_4/H_3PO_4 (pH=2.8) buffer solution and acetonitrile with a gradient concentration at a flow rate of

1 ml min^{-1}. Total organic carbon (TOC) measurements were performed in a Shimadzu TOC-5000 analyzer.

3 Results and Discussion

3.1 Catalysts characterization

Nanocrystalline TiO_2 was obtained by hydrolysis starting from titanium isopropoxide. In acidified ethanol solution the alkoxide is hydrolyzed and then condensation of the polymeric chains takes place. This acid catalyzed hydrolysis prevents premature TiO_2 precipitation. The resulting xerogel was treated thermally under nitrogen flow.

The mass loss and heat release from xerogel samples during calcination was followed by thermal analysis. As shown in Fig. 1a, DTG curve of TiO_2 xerogel presents one intense band at 373K and a broad band centered around 553K. The corresponding peaks could be observed in DSC profiles (Fig. 1b). The former can be attributed to the evaporation of remained ethanol and adsorbed water, which corresponds to an endothermic process. The second band is ascribed to the exothermal crystallization of the amorphous gel to anatase form. The glass transition point can be observed at around 650K, ascribed to the inflection of the DSC curve at this temperature. The strong and well-defined exothermic peak centered at 800K corresponds to the anatase to rutile phase transition.

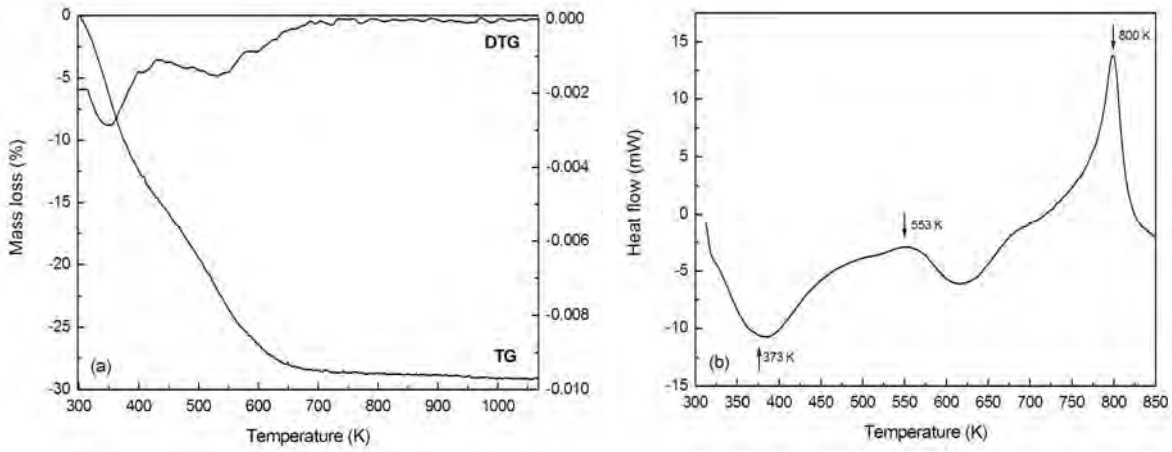

Figure 1. Xerogel evolution during calcination process: (a) TG/DTG and (b) DSC profiles.

The crystal phase of TiO_2 was studied by powder X-ray diffraction. At temperatures below 723K only anatase phase was detected. Anatase to rutile transformation was found to occur between 723 and 773K, thus, at temperatures above 723K, and to a certain point, there is a mixture of anatase and rutile phases. At 973K only the rutile phase was observed. Crystallite size and phase composition obtained by XRD are listed in Table 1.

Table 1. Anatase (d_A) and rutile (d_R) crystallite dimensions, surface area (S), anatase content (x_A), absorption edge (AE) and band gap energy (E_g) of the TiO_2 samples obtained at different calcination temperatures.

Catalyst	d_A (nm)	d_R (nm)	S (m^2 g^{-1})	x_A (%)	AE (nm)	Eg (eV)
T573	5.7	-	134	100	389	3.19
T673	8.5	-	107	100	391	3.17
T723	10	-	84	100	403	3.08
T773	14	20	26	69	410	3.03
T823	23	24	13	38	412	3.01
T873	37	39	3	5	413	3.00
T973	-	39	3	0	413	3.00

The crystallite sizes of both anatase and rutile forms increased with calcination temperature. The TiO_2 surface area was determined by nitrogen adsorption isotherms at 77K. Results show that higher the temperature, lower the surface area. Catalysts obtained at the lowest temperature (T573) exhibited a surface area of 134 m^2 g^{-1}. As the temperature increases, the surface area gradually decreases, reaching 3 m^2 g^{-1} at temperatures higher than 873K. This increase is paralleled by an increase in the crystallite dimensions. The anatase to rutile transformation was confirmed by the change on the DR UV-vis spectra of the solids (Fig. 2). On decreasing the calcination temperature, the absorption edge moved towards shorter wavelengths (blue shift), which corresponded to an increase in the band gap energy.

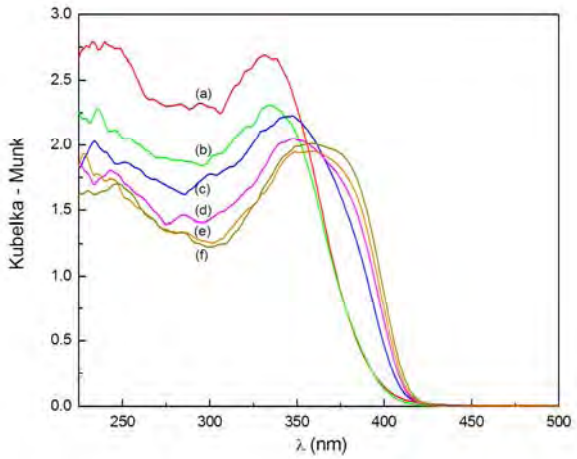

Figure 2. Diffuse reflectance UV-vis spectra of the catalysts: (a) T573, (b) T673, (c) T773, (d) T823, (e) T873, and (f) T973.

The 335 nm characteristic band of anatase disappears progressively as temperature increases. The absorption edges and the calculated band gap energies for each catalyst are given in Table 1. For samples T673 (pure anatase) and T973 (pure rutile) the measured band gap energies were 3.17 and 3.00 eV, respectively, in agreement with 3.20 and 3.02 eV referred in the literature (Carp et. al, 2004).

3.2 Phtotocatalytic degradation of clofibric acid

In order to explore the photo-efficiency of the prepared materials, we tested TiO_2 nanocrystalline catalysts in the photocatalytic oxidation of clofibric acid aqueous solutions under visible irradiation. First, we conducted the neat photochemical reaction, without any catalyst, to have a comparison standard. Both, photochemical and photocatalytic degradation of clofibric acid followed a pseudo-first order kinetic model. Kinetic rate constants (k_{app}) are listed in Table 2.

Table 2. Pseudo-first order apparent kinetic rate constants (k_{app}), clofibric acid conversion after 30 minutes of irradiation ($\chi_{30\ min}$) and total organic carbon removal at the end of 4 hours of irradiation ($\chi_{TOC,4h}$).

Catalyst	k_{app} (min^{-1})	$\chi_{30\ min}$ (%)	$\chi_{TOC,\ 4h}$ (%)
T573	8.03×10^{-2}	91.0	76.1
T673	1.11×10^{-1}	97.4	79.4
T723	7.50×10^{-2}	88.2	72.9
T773	4.76×10^{-2}	74.2	64.5
T823	2.76×10^{-2}	59.3	51.1
T873	2.14×10^{-2}	50.5	40.5
T973	1.02×10^{-2}	27.9	20.0
Blank*	3.62×10^{-3}	14.6	2.6

* no catalyst

The degradation was faster with T673 (k_{app} of 1.11×10^{-1} min^{-1}) even when compared with pure photochemical reaction (3.62×10^{-3} min^{-1}). For this catalyst, close to complete clofibric acid removal was achieved after only 30 minutes of irradiation. Catalysts obtained at higher temperatures resulted on progressively lower kinetic rate constants. Catalyst T973, constituted by pure rutile crystals, showed a k_{app} of 1.02×10^{-2} min^{-1}, close to one order of magnitude lower than the pure anatase catalyst (T673).

The main reaction intermediates detected by HPLC analysis were found to be 4-chlorophenol, isobutyric acid, hydroquinone, benzoquinone and 4-chlorocatechol. Figure 3 shows the concentration profiles of clofibric acid and reaction intermediates for photocatalytic experiments using T673 and T973. The difference in performance between the two catalysts is evident. With T673 there is an abrupt abatement on clofibric acid concentration and it is completely removed very early. The concentration of the main intermediates initially rises and then decreases until complete disappearance after 4 hr of irradiation (Fig.3a). With T973 the rate of removal is much slower. At the end of the irradiation run (4 hr) there was still a considerable amount of the initial compound and reaction intermediates in solution (Fig. 3b). The most important intermediate was 4-chlorophenol, the others being detected at lower concentrations.

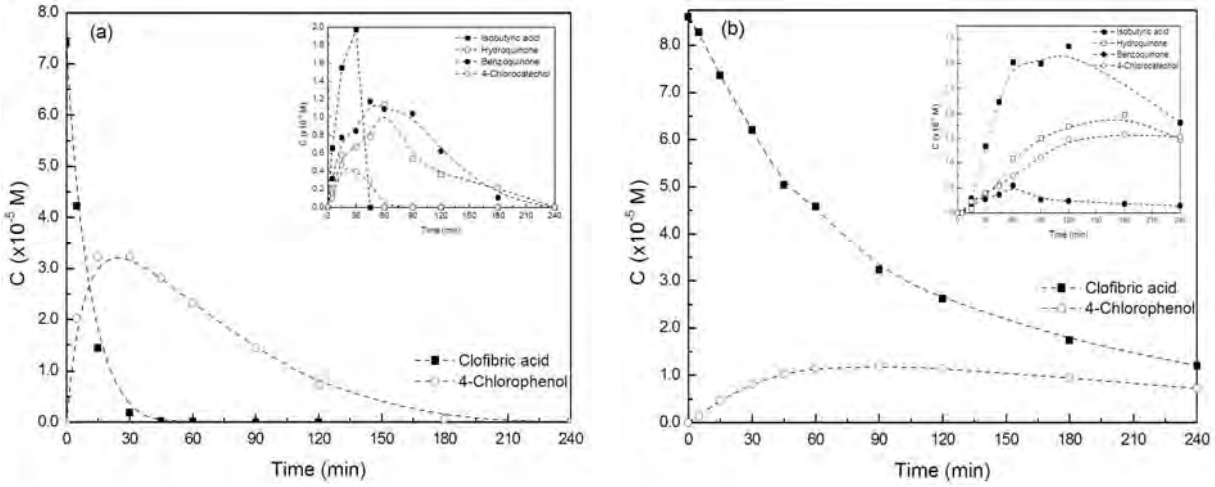

Figure 3. Concentration profiles of clofibric acid and reaction intermediates during the photocatalytic reaction using T673 (a) and T973 (b) catalysts.

Total organic carbon (TOC) analysis provided valuable information about the efficiency of the photo-assisted processes. At the end of the photodegradation runs (4 hr of irradiation) it was observed a merely 2.6% decrease in TOC for reaction without catalyst while for reaction in the presence of T673 the observed TOC removal was 79.4%. The fraction of non-mineralized organics probably corresponds to aliphatic acids, such as lactic, acetic, formic, maleic, oxalic and others resulting from the aromatic ring opening, not detected by HPLC in these experimental conditions. A possible degradation pathway is presented on Fig. 4.

From the presented results it is obvious that the photocatalytic performance depends on the structure and morphology of the TiO_2 powder induced by the final thermal treatment. The 573K treatment leads to the material with the highest surface area, mainly composed of anatase. In XRD measurements (not shown) was possible to observe some peak broadening indicating that the crystallization process was not complete. It is known that amorphous titania has low photocatalytic activity due to a high electron-hole recombination rate and this is in agreement with the observed poor performance of this material.

As the calcination temperature increases up to 673K the performance also increases and T673 is the most active photocatalyst for degradation of clofibric acid. As we increased the calcination temperature a progressive loss in photocatalytic efficiency was observed. The T973 photocatalyst was the less active of all series.

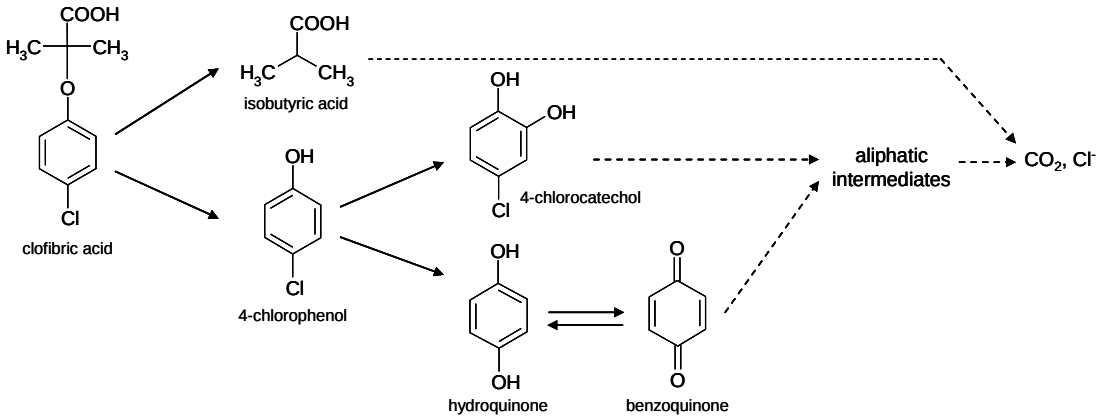

Figure 4. Simplified degradation pathway for the photocatalytic degradation of clofibric acid.

The observed decline in photoefficiency is explained in terms of phase transformation from anatase to rutile. In addition, there is an increase in crystallite size which also contributes to a more efficient electron-hole recombination. Finally, the surface area of the catalyst is also drastically reduced (Table 1) which leads to a lower surface to volume ratio, which is critical in heterogeneous catalysis.

4 Conclusions

The nitric acid catalyzed sol-gel method, using titanium(IV) isopropoxide as precursor leads to the formation of nanocrystalline TiO_2. The control of the calcination temperature in the thermal treatment step, in the range of 573-973K, allowed the production of materials with distinct physical-chemical properties such as crystal phase composition, crystallite dimensions and specific surface area. Pure anatase TiO_2 obtained at 673K produced the best catalyst: complete removal of clofibric acid and its main reaction intermediates (4-chlorophenol, isobutric acid, hydroquinone, benzoquinone and 4-chlorocatechol) after four hours of irradiation. Pure rutile produced at 973K revealed to be a rather inefficient catalyst.
At 573K there is a fraction of titania that is still not crystallized reducing the photo-efficiency of this material. Higher calcination temperature promotes phase transition from anatase to rutile and simultaneously the increase in crystallite and particle dimensions, with the corresponding decrease in surface area, leading to a loss on the activity of the photocatalysts.
From this study, it is clear that the composition of the TiO_2 powders (anatase to rutile ratio) greatly affects the photocatalytic performance. Having the catalytic system well characterized is essential to develop efficient TiO_2-assisted photocatalysis for the mineralization of persistent pharmaceutical compounds in wastewaters.

Keywords: Catalytic cracking; n-decane; Acid zeolites; Activity; Selectivity; Deactivation
Topic: Advancing the chemical and biological engineering fundamentals

Abstract
In this work, n-decane cracking, taken as a model reaction, was carried out at 350°C over various protonic zeolites (H-Y, H-β, H-ZSM-5 and H-MCM-22) with similar silica-to-alumina ratio (Si/Al~15). The initial catalytic activity depends on both the size of the pore apertures and the pore architecture (channels or cages). On the other hand, the selectivity only depends on the size of the pore apertures: the smaller the pore apertures, the higher the selectivity towards light products (C_3 and C_4). Finally, although all the zeolites undergo deactivation by coke formation, this deactivation is more important for large pore zeolites (H-Y, H-β) than for medium pore size zeolites (H-ZSM-5, H-MCM-22).

1. Introduction
With the declining of petroleum resources, combined with its increased demand and the social and political instability of the petroleum exporter countries, it is imperative to develop economical and energy-efficient processes for the sustainable production of transportation fuels and chemicals [1]. In this way, it can be possible to continue to ensure the global economical development and the improvement of standards of living.

The Fisher-Tropsch (FT) synthesis is an attractive route to produce not only high-quality liquid fuels and lubricants but also valuable materials for petrochemical industry, such as premium naphtha and α-olefins [2]. This industrial process uses alternative sources to petroleum, such as coal, natural gas and biomass via conversion of syngas (mixture of CO and H_2) and produces mostly straight chain paraffins, ranging from C_1 to C_{50} [1, 2]. Another advantage of this process is the almost inexistence of aromatic and sulphur compounds in the final products [2].

The FT products can then be fed in fluid catalytic cracking (FCC) units to produce high-octane gasoline (with high content of isoparaffins) and light olefins, which are valuable materials for petrochemistry. FCC is, in fact, one of the most frequent petroleum-refining processes because it allows to obtain crucial products: mainly gasoline, but also, diesel and light olefins (notably propene) [3].

In this context, n-decane cracking, taken as a model reaction, was carried out at 350°C over various protonic zeolites: H-Y and H-ZSM-5, which form the active phase of FCC catalysts, but also H-β and H-MCM-22, which are used in other commercial processes.

The objective of the present work was to determine the influence of the zeolite pore topology (apertures size and architecture) on the catalysts activity, stability and selectivity, using samples with the same silica-to-alumina bulk ratio (Si/Al~15).

2. Experimental

2.1 Catalysts preparation

The H-Y (CBV 720) and H-ZSM-5 (SM 27) zeolites were purchased from Zeolyst International and AlSi-penta respectively. The H-β zeolite was synthesized in the "*Laboratoire des Matériaux Minéraux*, UMR 7016, Mulhouse, France''. The H-MCM-22 zeolite was prepared in our laboratory, following the procedure reported in reference [4].

2.2 Characterization of zeolite samples

The elementary analysis of silicium and aluminium, which allowed to estimate the bulk Si/Al ratios were done by Inductively Coupled Plasma - Optical Emission Spectrometer (ICP-OES) on a Optima 2000 DV equipment.

The zeolite crystallite sizes were estimated by a high resolution scanning electron microscopy, on a Philips CM 120 microscope.

Nitrogen adsorption measurements were performed at -196°C on a Micromeritics ASAP 2000 apparatus. The microporous volumes were estimated by the t-plot method, using the Harkins and Jura standard isotherm. Before measurement, the samples were out gassed under vacuum for 12 h at 350°C.

The acidity of the samples was measured by adsorption of pyridine and subsequent desorption at increasing temperature (150-450°C), followed by IR spectroscopy, on a ThermoNicolet - Nexus spectrometer. The experimental procedure is reported elsewhere [5]. The amounts of pyridine retained over Brönsted and Lewis acid sites were calculated from the areas of the IR bands at 1545 and 1455 cm^{-1}, respectively, using the extinction coefficients previously determined [6].

The carbon content of the used samples was measured by total burning at 1020°C under helium and oxygen on a Thermoquest NA2100 analyser.

The sample nomenclature and main chemical characteristics are summarized in Table 1.

Table 1: Characterization of zeolite samples

Samples	Bulk Si/Al ratio	Crystallites size (µm)	Pore volume (cm^3/g)		Acidity (µmol/g)			
					Brönsted		Lewis	
			Micro	Meso	Total	Strong	Total	Strong
H-Y	13.3	0.5	0.317	0.190	271	13	101	26
H-β	10.6	1.5	0.212	0.039	398	73	504	345
H-MCM-22	16.8	<< 1	0.218	0.292	651	55	76	63
H-ZSM-5	10.8	1.0	0.158	0.027	1161	459	27	16

2.3 Catalytic experiments

The catalytic tests were performed in a tubular Pyrex fixed-bed continuous-flow reactor, at 350°C and atmospheric pressure. The n-decane (Fluka, 98%), fed to the reactor system using a syringe pump, was diluted with dry nitrogen to achieve a partial pressure of 0.13 atm ($p_{nitrogen}/p_{n\text{-}decane}$= 7). Prior to the catalytic experiments, the zeolite samples were activated, *in situ*, for 12 h at 450°C, in dry air (60 mL/min). The deactivation profile was obtained by accumulating samples of the reactor effluent for different values of time on stream (TOS): 1, 2, 5, 10, 30 and 60 minutes. Different contact time values were obtained by varying the mass of catalyst (10 – 300 mg) and maintaining the n-decane flow constant (2.92 g/h). The reaction effluent was analysed using a VARIAN 3400 chromatograph equipped with a 100 m PONA CP-Sil CB capillary column and a flame ionization detector.

3. Results and discussion

3.1 Initial activity

Figure 1 shows the evolution of the initial n-decane conversion (1 min reaction) as a function of the contact time τ (taken as the reciprocal of the weight hourly space velocity WHSV), for the different zeolite samples.

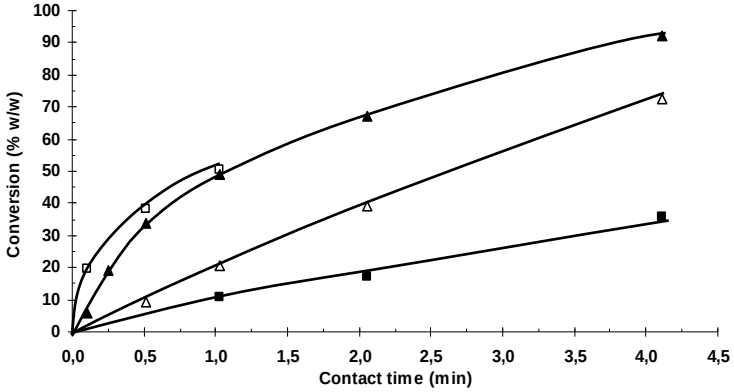

Figure 1: Initial conversion vs. contact time for the different zeolite samples: (■) H-Y, (Δ) H-MCM-22, (▲) H-ZSM-5, (□) H-β

The values of the initial activity of the different catalysts (slope of the tangent of the activity curves in Figure 1 for $\tau = 0$) are reported in Table 2. H-β is the most active catalyst, followed by H-ZSM-5, H-MCM-22 and H-Y. Moreover, Table 1 shows that the concentrations in protonic sites, which are the active sites for catalytic cracking, differ greatly from one zeolite to another: they vary from 1161 µmol g^{-1} in the H-ZSM-5 sample to 271 µmol g^{-1} in the H-Y sample. Therefore turn-over frequency (TOF) values were estimated by dividing the activity values by the total number of protonic acid sites (Table 2), although this calculation implies that all the acid sites have the same activity (hence the same strength). A very high TOF value (2032 h^{-1}) was obtained for H- β, which is 7.7, 12 and 16 times more active than H-ZSM-5, H-Y and H-MCM-22, respectively.

Table 2: Initial activity and TOF for the different zeolite samples

Zeolites	Initial activity (mmol.g^{-1}.h^{-1})	TOF (h^{-1})
H-Y	45	167
H-β	809	2032
H-MCM-22	81	125
H-ZSM-5	307	264

Observing the values reported in the Table 2, one can see that the zeolite structure influences strongly the activity of zeolite samples. These values suggest that the main criterion is not the size of the pore apertures: the large pore H- β zeolite is much more active than H-ZSM-5, which is a medium pore size zeolite, but H-ZSM-5 is more active than H-Y. Therefore, the catalytic activity could depend firstly on the pores architecture (presence of channels or cages): the catalysts exhibiting channel systems, such as H-β and H-ZSM-5 samples, are more active than the zeolites presenting supercages pore structures (H-Y). This could be due to a slower diffusion of n-decane molecules in the channels, which signifies a greater residence time inside of zeolite structure, favouring their adsorption over acid sites, and, subsequently, their cracking in smaller ones. In the case of zeolites presenting supercages, the diffusion of n-decane molecules is much faster and their adsorption less plausible, because residence time is too low.

The channels size also plays an important role because it influences strongly the diffusion velocity inside of the structure. If comparing H-β (large channels) and H-ZSM-5 (medium

channels), one can see that the first one presents a TOF value much higher than the second one (7.7 times).

3.2 Initial selectivity

Whatever the zeolite sample, at least 97% (%wt) of identified products result (directly or indirectly) from the cracking of n-decane and only 3% are aromatic compounds and isomers.

The cracking products distributions (at 10 % of n-decane conversion) obtained after 1 minute of reaction over the different zeolite samples are reported in Figure 2. Similar product distributions are obtained for both large pore zeolite samples (H-Y and H-β): C_4 alkanes and alkenes are the main reaction products, followed by C_5, C_6 and C_3. This suggests that the product distribution depends on the size of the pore apertures, but not on the pore architecture.

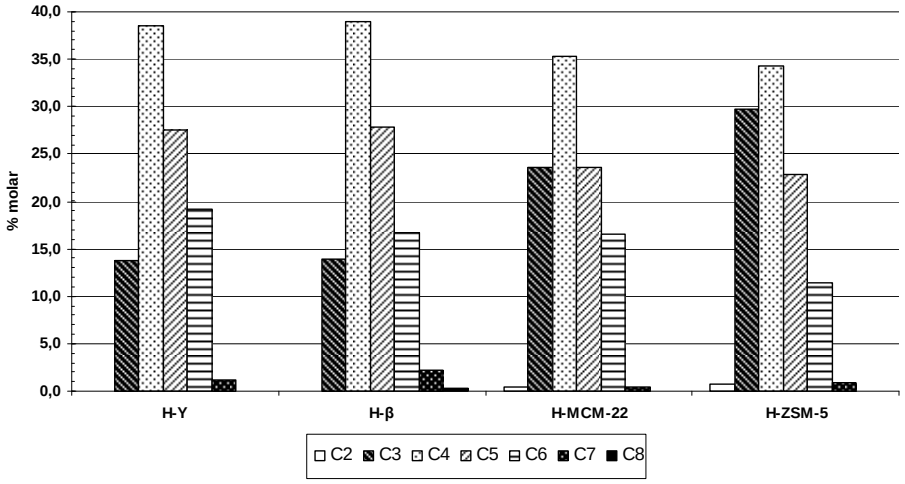

Figure 2: Initial cracking product distribution obtained over the different zeolites for 10% of conversion

On the other hand, the product distributions obtained over H-ZSM-5 and H-MCM-22 suggest that the acid sites concentration (or density) strongly influences the selectivity of the n-decane transformation. The very high C_4/C_6 ratio obtained for H-ZSM-5, associated with the large amount of C_3 products, shows that secondary cracking of the C_6 products (mainly hexenes) happens in a large scale over H-ZSM-5. This could be due to the slow diffusion of these compounds in the narrow channels of this zeolite, which would favour their cracking in smaller products. Nevertheless, the distribution found for the H-MCM-22 sample is not the one expected, it is intermediate between those obtained over large pore zeolites (H-Y and H-β) and over H-ZSM-5. This result cannot be explained by the size of the pore apertures of H-MCM-22 zeolite, which is smaller than that of H-ZSM-5 (hence should lead to an enhanced formation of C_3 products compared to H-ZSM-5). Therefore, the acid sites concentration (and density) could be an explanation: the higher the concentration, the higher the probability of secondary cracking reactions. In this case, the probability for secondary cracking reactions would vary in the following order: H-ZSM-5 >> H-MCM-22 > H-β > H-Y.

3.3 Zeolites deactivation

Figure 3 shows the evolution of n-decane conversion as a function of time-on-stream (TOS), for a contact time value of 1 minute, over the different zeolite samples.

All zeolite samples suffer deactivation, which is more evident during the first 10 minutes of reaction. The extent of the deactivation depends very much on the zeolite structure: it is faster and stronger over the large pore zeolites (H-Y and H-β) and more limited over H-ZSM-5. H-MCM-22 presents, once again, an intermediate behaviour, that could be related to the coexistence of large internal cages and narrow 10-MR pores in its structure [7]. The same order was found for the carbon content (%C, Table 3), indicating that deactivation is due to the formation of bulky polyaromatic compounds (“coke”), which is known to be favoured over large pore zeolites.

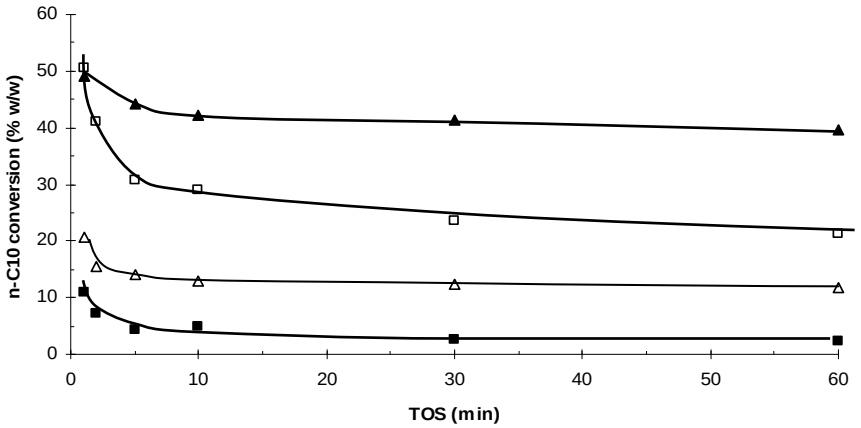

Figure 3: Deactivation profiles for 1.0 min of contact time for the different zeolite samples: (■) H-Y, (Δ) H-MCM-22, (▲) H-ZSM-5, (□) H-β

Table 3 shows that the toxicity of coke depends on the zeolite. For example, H-Y lost nearly 80 % of its initial activity when 2.2 wt% of carbon were deposited, whereas the formation of 3.3 wt% of coke over the H-β zeolite leads to a 57 % reduction of its catalytic activity. This variation in toxicity could be related to the concentration of protonic sites: this concentration is very low over H-Y, which could explain that a low amount of coke could be sufficient to poison (hence deactivate) the most part of its acid sites.

Table 3: Residual activity and carbon content for the different zeolite samples

Zeolites	Residual activity (%) [(1)]	Carbon Content (% wt) [(2)]
H-Y	22	2.2
H-β	43	3.3
H-MCM-22	59	3.5
H-ZSM-5	88	1.0

[(1)] – Ratio of the activities determined after 60 min and 1 min of reaction
[(2)] – For 10% of n-decane conversion and after 60 min of reaction

Catalytic experiments for TOS longer than 60 minutes were also performed with H-MCM-22 and H-ZSM-5 samples, for the same value of the contact time (1 min). After 4 hours, the zeolite samples presented approximately the same activity obtained after 1 hour. This fact can be explained by a slowdown in coke formation after the first 10 minutes of reaction, as suggested by the evolution of the n-decane conversion (Figure 3).

This hypothesis is in agreement with the evolution of the paraffin to olefin (P/O) ratio with TOS (Table 4). If only primary cracking of n-decane molecules happened, one would obtain the same quantity of paraffins and olefins (P/O = 1). However, when the secondary cracking of olefins (mainly hexenes) takes place, two other olefins are produced, reducing the paraffins/olefins ratio. On the other hand, olefins molecules can undergo several reactions (hydrogen transfer, oligomerisation, etc.) leading to the coke formation and to an increase of the P/O value.

Table 4: Parafins/Olefins* ratios at 10% conversion for fresh and coked zeolites samples

TOS (min)	H-Y	H-β	H-MCM-22	H-ZSM-5
1	2.3	2.0	1.6	0.85
60	1.2	1.2	0.95	0.87

* Calculated only for C_4, C_5 and C_6 compounds

The values in Table 4 clearly indicate that these reactions are very important over the fresh H-Y and H-β zeolites and very limited over H-ZSM-5 zeolite, which is consistent with the coke contents (Table 3). Moreover, the decrease of the P/O value, when TOS increases, suggests that coke formation mainly occurs during the first minutes of reaction.

Finally, deactivation has a limited effect on the product distributions obtained over H-Y, H-β and H-ZSM-5 zeolites. This is not the case of H-MCM-22: increase of the C_3 and C_4 products at the expense of C_5 and C_6. This particular behaviour could be related to the presence of two different pore systems in H-MCM-22, which would not be affected in the same way by coke formation. Indeed, it has been previously shown that coking mainly occurs in the large supercages [8]. Therefore, it can be suggested that the evolution with TOS of the product distribution is due to the progressive deactivation of the active sites located in the supercages, which causes an increase of the relative contribution of the active sites located in the sinusoidal channels. The shape of these channels, which are narrow and tortuous, would favour the desorption (hence the formation) of the lighter C_3 and C_4 products.

4. Conclusions

The initial catalytic activity depends on both the size of the pore apertures and the pore architecture. The presence of channels is the main criterion to achieve a very high activity level, but the size their apertures also plays an important role. The following catalytic activity order can be proposed: H-β >> H-ZSM-5 > H-Y > H-MCM22.

On the other hand, the selectivity depends on the size of the pore apertures: the smaller the pore apertures (ZSM-5 and MCM-22), the higher the selectivity towards light products (C_3 and C_4). Nevertheless the acid sites concentration can also influences the selectivity of the n-decane transformation.

Finally, although all the zeolites undergo deactivation by coke formation, this deactivation is more important for large pore zeolites (Y, β) than for medium pore size zeolites (ZSM-5, MCM-22).

Abstract

A numerical optimization method, previously applied to a large cogeneration plant has been adapted for a small-scale unit delivering 100 kWe of electricity and 0.5 kg/s of saturated steam. The unit is based on a micro gas-turbine and includes an internal pre-heater (typical of these types of small-scale units) and the usual HRSG (Heat Recuperator Steam Generator). Despite difficulties in obtaining data for some of the components cost-equations, the preliminary results indicate that the optimal compressor pressure ratio is about half of the usual value in large installations, while the turbine inlet temperature remains virtually unchanged. The method is being adapted to a micro-scale cogeneration unit (<6 kWe), for single household applications, that involves different components including an IC engine and a novel two-step heat recuperator. This methodology is invaluable in the undergoing design and construction of this micro-cogeneration prototype which is part of this project.

1 Introduction

Cogeneration or Combined Heat and Power (CHP), is the simultaneous production of thermal and electric energies. It is a major option to achieve primary energy savings, avoid grid network losses and reduce GHGs emissions. It has been worldwide implemented in large scale installations (>1 MWe) but the use of microcogeneration units (<50 kWe), for domestic or small commercial buildings, is still at an incipient level. This scenario will change rapidly, triggered by rocketing fuel prices, climate change awareness and government support mechanisms (Onovwiona and Ugursal, 2006; DL n.º 363/2007; Directive 2004/8/EC).

The development of a new technology must take into account the socio-economic aspects, thus providing a realistic way to evaluate the production and operation costs of these systems. The economic aspects are important, namely for the final consumer.

Thus far, numerical methods of optimization have been used for the thermo and economic optimizations of large systems. The aim of these procedures is to minimize the total costs including those related with the thermodynamic inefficiencies (Silva et al., 2003). However, applications of these methodologies to small-scale installations cannot be found in the literature.

In the present project, a multidisciplinary team has been adapting a thermoeconomic optimization method, which gave good results with multi-megawatt cogeneration systems (Silva et al., 2003), to small-scale (<1 MWe) and micro-scale cogeneration units (<50 kWe).

* Corresponding author. Tel + 351-253-510344. E-mail: lmartins@dem.uminho.pt

Different technologies are available for cogeneration systems, and the choice depends on, among other factors, the size of the unit and the required power to heat ratio. A small scale cogeneration plant based on a gas turbine has been studied (Martins et al., 2008) and the optimization tool is now being used in the design of a micro-scale cogeneration prototype.

2 Small-scale Gas Turbine Cogeneration Plant

In a still recent past the gas-turbine engines available as prime movers for electricity generation were only large industrial or expensive aeroderivative models typically with powers in the order of tens of megawatts. In recent years, however, this type of engines has undergone major improvements both in efficiency and cost reductions. Nowadays, several inexpensive models are available in the range of 30 to 250 kWe, with electrical efficiencies already exceeding 30%, thanks to the use of a basic air-compressor associated to an internal air pre-heater.

Gas turbine engines offer significant advantages over Diesel or IC engines, particularly when Natural Gas is used as fuel. Working with high levels of excess air, they do not need a cooling system, the emission of pollutants and noise are lower and, in cogeneration mode, total efficiencies of up to 90% are feasible, with the further advantage of flexible heat production through the possible use of post-combustion.

With the current market trends toward Distributed Generation, and the increased substitution of boilers with NG powered cogeneration units for CO_2 emissions reduction, small-scale gas turbine units are the ideal solution for energy systems located in urban areas.

2.1 Plant description

A small-scale cogeneration plant that delivers 100 kW of electricity and 0.05 kg/s of saturated steam has been simulated (Martins et al., 2008). This system is constituted by a compressor, a combustion chamber, a gas turbine, a pre-heater that uses the burnt gases thermal energy to heat the air before entering the combustion chamber, and an exhaust heat recuperator to generate steam.

2.2 Mathematical Model and Numerical Solution

In general, for micro-cogeneration systems, two different optimization criteria can be considered: on the one hand the maximization of the annual cash flow and on the other hand the minimization of the generation cost of the plant (Valdés et al., 2003). The main objective of this study is to minimize the annual cost of the micro-cogeneration system. A mathematical model has been developed to simulate this cost analysis.

In engineering economics, the unit of time intervals for such purpose is usually taken as one year (Zhang et al., 2004). The energy system produces in unit time the desired amounts of products. The total cost per year includes the fuel cost, the initial investment (initial cost) and the operation and maintenance cost. The monetary balance equation for unit time can be applied to the complete system, as well as to its components, in the following general form:

$$C_t = \left(P \rightarrow A, i_e, n\right) C_i + C_{tf} + C_{om} \tag{1}$$

where C_{tf} is the total cost of the fuel (€/year), C_i the initial investment (initial cost), ($P \rightarrow A, i_e, n$) the capital recovery factor, n the system economic life (years) and C_{om} the operation and maintenance cost per year (€/year). The initial investment (C_i) for a micro-cogeneration system consists of purchasing costs of j components, C_j.

The initial investment is distributed over years equally. The capital recovery factor (*CRF*) is used to determine the equal amounts of n cash transactions for an investment and can be expressed as:

$$CRF = \left(P \rightarrow A, i_e, n\right) = \frac{i_e\left[\left(1+i_e\right)\right]^n}{\left[\left(1+i_e\right)\right]^n - 1} \quad (2)$$

where A is called annuity, a series of equal amount cash transactions, P is the present value of the initial cost, i_e is the effective rate of return, and n is years of operation. Effective rate of return is imposed by the owner of funds who makes these funds available for the investment. For thermoeconomic optimization the effective rate of return can be approximated as: nominal rate of return (i.e interest rate) minus inflation rate plus owners' risk factor and correction for the method of compounding (Gogus, 2005).

The fuel cost rate is an important parameter. It can be expressed as the product of the price of unit energy with the input energy rate. The total fuel cost is determined as:

$$C_{tf} = C_f\left(\frac{\bar{W}}{\eta}\right) \times h \quad (3)$$

where C_f is the fuel cost per kWh (€/year), $\bar{W}$ the mean annual output power of the plant (kW), h the system working hours per annual system operation period (h/year), and η the thermal efficiency. The rate of operation and maintenance cost per year was assumed equal to 6% of the equal amount of initial investment per year:

$$C_{om} = 0.06\left(P \rightarrow A, i_e, n\right) C_i \quad (4)$$

Thus, the objective function can be formulated as a minimization of the total annual cost of operation for the micro-cogeneration system, when the components are analyzed separately:

$$\min C_t = 1.06 \sum_j C_{ij}\ CRF + C_{tf} \quad (5)$$

To complete the mathematical model, the equations that describe the purchase cost of the main components of the micro-cogeneration system, must be known. Despite difficulties in obtaining data for these components cost-equations, the authors have adapted some coefficients of the mathematical model used for cogeneration systems (Silva et al., 2003). In addition to these cost equations, a set of nonlinear inequality constraints must be imposed by the operability of the system, taking into account safety considerations, legal regulations, among others.

This system defines a nonlinear optimization problem with constraints, where the pressure ratio of the compressor (P_2/P_1), the isentropic efficiencies of the air compressor and the gas turbine (η_c, η_t, respectively) and the temperatures of the combustion gases at the gas turbine inlet (T_3) and at the outlet of the gas chamber (T_4), are the decision variables.

This optimization problem has been solved by a direct method, the Box method (Rao, 1996). This method, implemented in Fortran, is similar to the simplex method used for linear programming. In previous works, this method shows to be efficient (Silva et al., 2003). Two subroutines must be supplied by the user: one to compute the objective function for any given set of independent variables, and the second one where the upper and lower bounds on the independent variables and the constraints are specified. The method assumes that an initial feasible point, that satisfies all the constraints, is available.

2.3 Some Results

The system delivers a 100kW of electricity, for a combined supply of 0.05 kg/s of saturated steam at 9.8 bar. The fuel is natural gas with LHV (Lower Heating Value) equal to 45100 kJ/kg.

When the optimization method reaches the convergence, the optimal values for the decision variables and costs are obtained. All the temperature and pressure values for the streams in the optimal design of the micro-cogeneration plant are also obtained (see Figure 1).

The preliminary results indicate that the optimal compressor pressure ratio is about half of the usual value in large installations, while the turbine inlet temperature remains virtually unchanged (Martins et al., 2008).

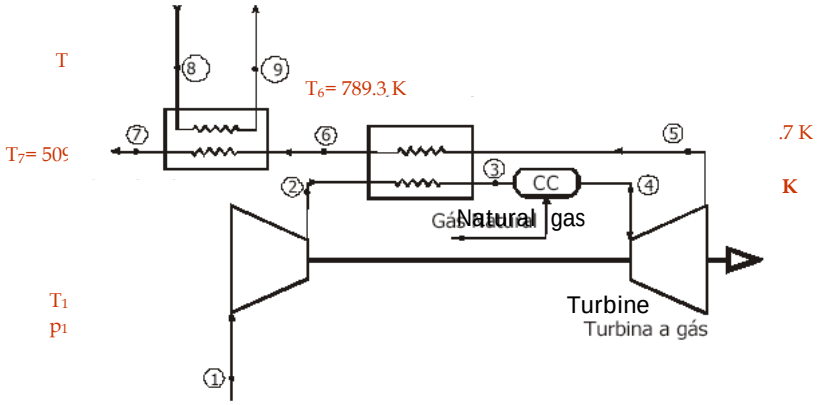

Figure 1. Temperature and pressure values for the streams in the optimal design of the micro-cogeneration plant.

3 Development of a Micro-scale Cogeneration Prototype

The micro-cogeneration prototype that is being designed and constructed (<6 kWe), is aimed at the single household market and is based on a commercial IC engine-generator, complemented with a heat recuperating system. The system layout is shown in Figure 2.

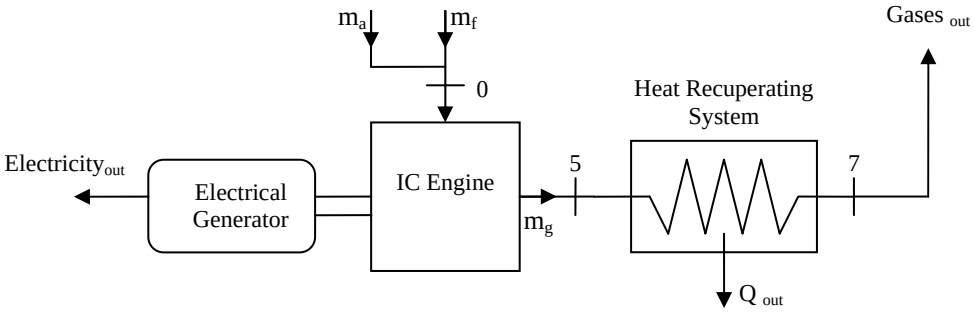

Figure 2. Micro-cogeneration system layout

3.1 Design and Construction

The main component is the Spark Ignition Internal Combustion engine, a single-cylinder with 390 cc capacity, undergoing a four-stroke thermodynamic cycle. It is currently running on gasoline as fuel which is evaporated and fed into the incoming air via a carburettor. The engine powers a 3-Phase synchronous electric generator rated at 6.5 kVA and 50 Hz.

The unit will be converted to Natural Gas and it is expected that, depending on the optimized operating conditions and other engine modifications, the unit will deliver an electric power in the range of 3 to 5 kWe. The conversion to NG will involve the substitution of the carburettor with a proper gas-injector.

The incoming air passes through a filter and is premixed with the NG via the gas injector, immediately upstream of the cylinder inlet valve (point 0). After the 4-stroke cycle the high-

temperature burnt-gases leave the engine through the exhaust valve (point 5). For the sake of simplicity, the intermediate thermodynamic states (1 to 4) are not presented in Figure 2.

With an Internal Combustion Engine there are two possible sources for recovered heat: the high temperature exhaust gases and, as the thermodynamic cycle is non-adiabatic, the engine cooling system. In this work and for the first stage of the prototype development, only the energy associated to the exhaust gases will be taken into account. Thus, the main innovation will be the exhaust gases heat recuperating system, which consists on a series of two counter flow gas-water heat-exchangers (Figure 3). The first one is a direct-heat exchanger where the incoming hot gases are mixed with cold water and as a result the two outgoing streams (water and saturated gases) will leave at approximately the same temperature (T_{W2}=T_6). In the process, a portion of the inlet water evaporates and the exhaust gases become saturated before flowing into the second heat-exchanger for further cooling and partial condensing, with the gases exiting at a low temperature (T_7).

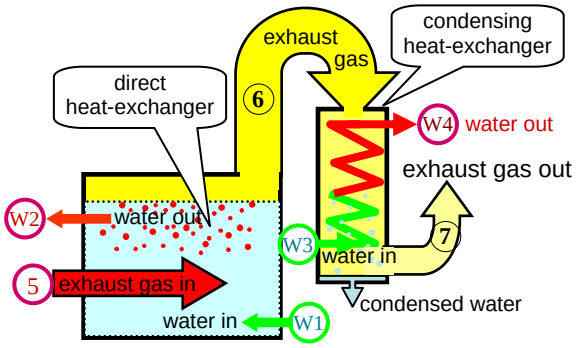

Figure 3. Heat recuperating system.

This novel thermal system and engine cycle analysis has been implemented in Excel in order to study its efficiency. It has been demonstrated that this layout leads to a lower exhaust gas temperature, i.e. to a higher global efficiency by comparison with traditional heat recuperators (Teixeira, 2007).

3.2 Thermoeconomical Optimization Model

At the moment, this optimization tool is being applied to the new microcogeneration system in order to improve design and to study the economical viability of the project.

The expressions and parameters used for obtaining the purchase costs are presented bellow (Table 1). They are based upon available literature for heat exchangers and other components (e.g Haslego and Polley, 2002; Honda, 2007) with the constants tuned for the Spanish and Portuguese market. All the costs are in Euros. As for the equations describing the physical energy system, they are based on the analysis previously done by Teixeira (2007) and are not presented here. The r_v is the engine volumetric ratio with reference value is 8.0, typical of commercial small engines running on gasoline, P_{mec} the engine nominal mechanical power (kW), T_{max} the temperature (K), η_G is the generator efficiency and thr reference equal to 0.825, P_{elect} the nominal electrical power (kW), $\dot{m}_g$ the exhaust gases mass flow rate (kg/s), and A_{HE2} the heat transfer area (m^2) of the cooling heat exchanger.

The decision variables selected for the optimization are the engine volumetric ratio (r_v), the combustion equivalence ratio (ϕ), the temperature of the gases after combustion (T_{max}) and the generator efficiency (η_G). The imposed operational conditions for the unit are 3.5 kW of electricity and 5.5 kW of thermal power.

Table 1 Purchase costs equations for the main components

Component	**Purchase cost equation**
Internal Combustion Engine	$C_{Eng} = 805\left(P_{mec}\right)^{0.5}\left(\frac{r_v}{8}\right)^{0.62}\left(\frac{T_{\max}}{2300}\right)^{7.42}$
Electric Generator	$C_G = 327\left(P_{elect}\right)^{0.7}\left(\frac{0.175}{1-\eta_G}\right)$
Direct Heat-exchanger	$C_{HE1} = 4280\dot{m}_g^{0.37}$
Second Heat-exchanger (condensing)	$C_{HE2} = 800A_{HE2}^{0.46}$

4 Conclusions

After good results with a 5 MW plant and small-scale 100 kW cogeneration unit, both centred on gas-turbine technology, it is expected that the optimization methodology herein presented will be a redoubtable guidance tool in the design of the domestic-scale cogeneration prototype, by allowing the research team to define the optimal values for design variables such as engine volumetric-ratio, excess air, maximum combustion temperature and in the sizing of the heat recuperating system. These objectives will be accomplished, provided that realistic cost-equations and a good thermodynamic model are used as inputs to the computational model.

Topic: Sustainable process-product development through green chemistry

Abstract

An important issue in process design is related to which tools (indicators) should be used to include environmental concerns on the analysis and synthesis steps. According to Cano-Ruiz and McRae (1998) environmental indicators have been developed based on several concepts: minimization of the more concerning pollutants in the emissions, minimization of generated total waste mass, minimization of contributions to specific problems and minimization of an aggregated indicator. The environmental assessment based on the total mass of waste generated is not sufficiently enlightening since it does not consider the characteristics of the different substances emitted. The environmental assessment based on specific indicators is very restrictive and does not allow for the consideration of various aspects of the environmental impacts. The consideration of different environmental impacts is the best way to evaluate the environmental performance of a process.

This paper proposes a methodology to develop and determine a global (aggregated) potential environmental impact indicator based on the Guinée model (2002). In this model the impact categories were chosen considering a base list proposed by SETAC (*the Society of Environmental Toxicology and Chemistry*). To determine the global environmental indicator one should consider the baseline category impacts suggested by Guinée (2002) and select those that apply to the case in study. Since for the category human toxicity there aren't internationally accepted impact indicators it is suggested to use the ones that are more suitable for the case in study including the use of other models like the IChemE (2007). Then it follows characterization and normalization steps and finally, the establishment of weights to obtain an aggregated indicator. The normalization can be done using the mean value of the indicators values for all the compounds in each category as suggested by the WAR methodology (Cabezas et al., 1999). The application of this methodology implies the establishment of the scope (time and space). The environmental performance evaluation should be compatible with the information available since it can be interesting to perform a cradle to grave, a cradle to gate, a gate to grave or a gate to gate assessment. The energy environmental impacts should always be taken in consideration. This methodology was applied to the HDA process (Douglas, 1988) in a gate to gate approach considering energy environmental impacts, to select the best topologies by sorting.

1 Introduction

The consideration of the different environmental impacts can be used to evaluate the environmental performance of a process. There are several methodologies to evaluate the potential environmental impacts (Cabezas et al., 1999, IChemE, Janeiro/2007). These methodologies imply the scope definition, space and time, and the choice of a set of impact categories, its characterization, normalization and the selection of weights to obtain a global indicator. To calculate the global potential environment impact it is necessary to use a

weighted sum of the normalized impacts of the several impact categories and for that reason it is necessary to establish weights, that show the importance of each impact category. This is usually done using a panel, or weights developed by others whether by value judgement or with some scientific base.

The environmental performance evaluation should be compatible with the information available since it can be interesting to perform a cradle to grave, a cradle to gate, a gate to grave or a gate to gate assessment. An indicator based in a cradle to grave procedure allows for a very complete analysis, although it may become very difficult to calculate since the information available in the conceptual design step is limited and uncertain. For that reason it seems more logic and interesting to perform a gate to gate approach, considering the process and including its energy requirements impacts. As a time basis one can consider a year of operation.

The methodologies mentioned below were chosen since they calculate or allow the determination of a global indicator, taking into consideration the several environmental impacts and represent an acceptable trade-off between objectivity and simplicity. The determination of a global indicator is very useful to compare different topologies and for optimization purposes, since it easily allows the definition of an environmental objective function.

- WAR methodology (*Waste Reduction*) developed by Cabezas et al. (1999) and Young and Cabezas (1999), initially based on Heijungs et al. (1992), and considering eight impact categories: global warming potential, ozone depletion potential, photochemical oxidation potential , acidification, human toxicity potential by ingestion, human toxicity potential by exposure both dermal and inhalation, aquatic toxicity potential and terrestrial toxicity potential.
- IChemE methodology (IChemE, Janeiro/2007) that considers the following environmental compartments: air (impact categories: acidification, global warming, stratospheric ozone depletion, human health – carcinogenic effects and photochemical ozone (smog) formation), water (impact categories: aquatic acidification, aquatic oxygen demand, ecotoxicity to aquatic life and eutrophication) and soil (impact categories: total hazardous solid waste disposal).

2 Environmental assessment

In order to develop a methodology to calculate a global potential environmental indicator it is necessary to define the impact categories that should be included considering the Guinée model (2002) and the process studied, namely the predicted emissions.

In the Guinée model (2002) the environmental impact categories were chosen taking into consideration the basic list developed by the SETAC group (*the Society of Environmental Toxicology and Chemistry*) concerning the impact assessment. It is a problem-oriented approach, because it is driven by environmental problems (the mid-point of the cause-effect chain), rather than by damage (end-point of the chain). The impact categories chosen belong to the first group, namely the baseline impact categories for which there is a characterization method available in the literature (Guinée, 2002). The impact categories considered are: depletion of abiotic resources, impacts of land use, climate change, stratospheric ozone depletion, human toxicity, ecotoxicity, photo-oxidant formation, acidification and eutrophication. For global warming there are impact factors internationally accepted but for human toxicity there aren't. So for the impact category human toxicity it may be more important to use a characterization more specific for the process considered (ex.: in a process where carcinogenic chemicals are emitted it is more suitable to use the IChemE impact category: human health – carcinogenic effects).

Since it is important to obtain a global indicator for environmental impacts it is necessary to proceed to the normalization, in this case adopting the WAR strategy (Young and Cabezas, 1999) , namely dividing each chemical indicator by the mean value of the indicators values for all the compounds in each category. According to the ISO14042 normalisation is to calculate the magnitude of an indicator towards a reference information. The reference information can be related to a community (country, continent, world), a person or other system, for a given period of time. A goal to be achieved can also be a reference information. Although the normalisation within each category, using the mean value of the indicators values for all the compounds in each category, allows for an analysis more independent of space and time referentials, in the case of the design and optimisation of chemical processes it can have some advantages, specially if that reference information do not exist (more importance of regional and local impact categories).

If there isn't a local defined to the production unit, we may consider that all the impact categories have the same importance, so the weight given to each category will be 1. The sensitivity analysis can be replaced by the application of an end point approach like Eco-indicator 99 or the EPS system (Guinée, 2002).

2.1 Case study

As case study was selected a well documented process, namely the non catalytic hydrodealkylation of toluene to benzene (HDA). To this process several topologies with different options of mass and heat conservation can be established. The raw-material streams are toluene and hydrogen with 3% of methane at 3.964X10^6 Pa and 303.2 K, normally used and referred by Qiu et al. (2000), Luyben et al. (1999) and Douglas (1988). The benzene stream product should be of high purity.
The main reactions are:

$$C_7H_8 + H_2 \rightarrow C_6H_6 + CH_4 \quad (6)$$

$$2C_6H_6 \Leftrightarrow C_{12}H_{10} + H_2 \quad (7)$$

2.2 Topologies for environmental evaluation

There were 21 topologies available for environmental evaluation. For each topology a set of simulations were performed (using PRO/II as simulator) according to a statistical design plan. The next figure shows the flowsheet of one of those topologies.

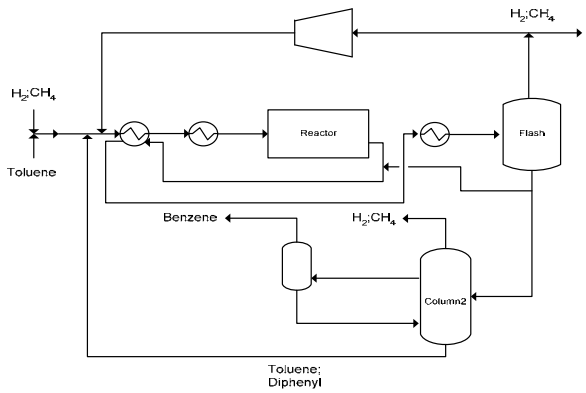

Figure 1 Topology CrTBRe

2.3 Application to the case study

When applying the methodology proposed to calculate the value of the global potential environmental impact indicator we concluded that some impact categories are empty and others were not selected. The impacts of land use weren't considered because the study performed didn't included any detailed project information like the necessary area and the local of implantation of the unit. Ecotoxicity was not considered because it presented very low values to the chemicals of the case study, so its impacts wouldn't be significant. The category stratospheric ozone depletion is an empty category since there aren't chemicals emitted that contribute to this impact category. Also from the Guinée model (2002) the category human toxicity wasn't considered because it was replaced by a more suitable impact category, namely the human health – carcinogenic effects from the IChemE model, since in this process carcinogenic chemicals (benzene) will be emitted. In the IChemE model and for the above mentioned impact category the factors are calculated using occupational exposure limits set by the *UK Health and Safety Executive*.

Table 1 shows the impact categories, the models and the indicators used. The chemicals emitted or necessary by the process that contributed to each impact category are also indicated.

In the reference document on best available techniques, Integrated Pollution Prevention and Control- IPPC, to this type of industry (European_Commission, February 2003) is stated that for this process (HDA) there aren't significant emissions to water or soil, so they weren't considered. It was also considered that there are no direct emissions; the existing emissions are fugitive or emissions related to the use of subproduct streams as fuel and in this last case complete combustion was considered. To estimate the fugitive emissions emission factors were used. The emissions to air are mainly due to fugitive emissions, use of subproduct streams as fuel and use of energy. The environment impacts due to the use of energy (compressor, reboilers and furnace) were calculated by doing the inventory of the related production emissions and considering the selected impact categories.

Table 1 Impact categories, models and indicators

Scale	**Impact categories and models**	**Reference chemical**	**Emitted or necessary chemicals**
Global	Climate change (Guinée model)	CO_2	CO_2 CH_4
Global Regional Local	Depletion of abiotic resources (Guinée model)	antimony	Fuel
Regional Local	Acidification (Guinée model)	SO_2	NO_x SO_2
Local	Eutrophication (Guinée model)	PO_4^{3-}	NO_x
	Photo-oxidant formation (Guinée model)	ethylene	C_6H_6; CH_4 C_7H_8; SO_2
	Human health – carcinogenic effects (IChemE model)	benzene	C_6H_6

3 Results

For each topology and set of simulations the mean value of the global potential environment impact (GPEI) was calculated and the results distribution analysed (the range of responses was divided in 10 intervals and the percentage of results falling in the first interval was calculated for each topology). The average values were used to rank the topologies (Table 2).

Table 2 Topology ranking according to GPEI mean value

Topology	GPEIx10^{-5}	Percentage of results falling in the first interval
Ae	7.1	100%
As	8.5	100%
Es	14.2	100%
Ee	17.3	100%
GrTBe	20.3	100%
GrTBe5	34.3	83%
GrTB	40.3	63%
GrTBe4	43.9	67%
Ce	85.4	0%
ErTB	107.5	33%
ErTBe3	108.4	33%
ErTBe4	112.0	33%
CRe	127.5	75%
ErTBe2	130.7	33%
CrTBR	163.5	33%
GrTBe3	170.6	0%
DrTB	184.3	40%
CsR	201.7	67%
GrTBe2	226.4	0%
ErTBe	240.0	0%
CrTBRe	286.6	0%

Since the normalisation was done within each category the values to the global potential environmental indicator are high.

From table 2 it is possible to conclude that the topology Ae presents the best average value. Topologies As, Ae, Es, Ee and GrTBe are the most promising since they present the best average values and simultaneously have a percentage of results falling in the first interval of the response distribution equal to 100%.

.

4 Conclusions

The methodology proposed to calculate the global potential environmental impact can be used to rank a set of different topologies allowing for the selection of the more promising ones. The way it was developed considers the specific characteristics of the process under studied, taking into account the emissions and chemicals released. For the impact categories that don't have internationally accepted factors this methodology proposes the selection of the more suitable indicators in order to calculate a more process specific value for the global potential environmental indicator.

ENVIRONMENTAL PERFOMANCE OF THE WINE INDUSTRY. OPPORTUNITIES FOR UPTAKE CLEANER PRODUCTION

Rosa A. Rodriguez[1*], Carlos Palacios[1], Stella M. Udaquiola[1]
[(1)]Instituto de Ingeniería Química -Facultad de Ingeniería -Universidad Nacional de San Juan
Libertador 1109 (O) CEP 5400, San Juan, Argentina

Keywords: winery, environment, water, energy, water vapour, wastewater, infrastructure.
Topic: Sustainable process-product development through green chemistry

Abstract

The wine industry is one of the main industries in San Juan, Argentina. The majority of the large firms still consider the environmental issues as a cost driver. As a result of this consideration firms do not use more resources for environmental technologies. On the other hand, the more important impacts associated with wine making are: energy and water consumption, solid wastes generation and gaseous emission.This work presents an environmental diagnosis of winery industry, taking into account the main aspects and the collected data. The evaluation was carried out applying the Schaltegger and Sturm´s definition. This diagnosis originates the necessity to propose the opportunities for uptake of Cleaner Production to wineries in San Juan. In this work, these opportunities are proposed using Cleaner Production Assessment. They are focused in each unit operation, stage process and services and utilities.

1. Introduction

The United Nations Environment Program defined Cleaner Production (CP) as “the continuous application of an integrated, preventative environmental strategy to processes, products and services to increase eco-efficiency and reduce risks to humans and the environment”.

The term Eco-efficiency (EE) is used in different ways and other terms are used overlapping with these meanings, like environmental cost-effectiveness and environmental productivity.

Starting point for the formal definition of EE is the general definition of WBCSD (World Business Council for Sustainable Development, 1992): "To provide goods and services to a competitive price that satisfies the human necessities and the life quality, at time that reduces the environmental impact and the use intensity of resources progressively along the cycle of life, until a compatible level with the dear carrying capacity of the planet." Schaltegger and Sturm (1989), describing EE as a ratio between two elements: environmental impact, to be reduced, and value of production, to be increased.

The connection between CP and EE varies according different bibliographies. Howgrave-Graham and van Berkel (2007) say: “CP is most commonly understood as positive economic benefits arising from efficient use of materials and energy. EE is concerned with positive environmental benefits from economic efficiency”. For Pagan and Prasad (2007), CP and EE are similar concepts. However, for van Berkel (2002), the CP and EE are complimentary. EE focus on the strategic side of business (value creation) and Cleaner Production on the operational side of business (production).

This work presents the results of EE evaluation (applying the Schaltegger and Sturm´s definition) and the opportunities for uptake of CP (using Cleaner Production Assessment) for the wine industry. This industry is one of the main industries in San Juan, Argentina. The wine making process varies greatly between sites, winemakers, quality and style of wine. The vinification process can be divided into unit operations. Every unit operation was drafted as a block and by connecting all the individual unit operations in the form of diagram.

2. Environmental Perfomance of Wine Production

The EE is suited to the industrial world, because its practical approach makes it possible to balance environmental and economic benefits in an integrated way. The concept represents one of the most tangible paths to sustainability for economic players. Its objectives are to reduce the consumption of resources, as well as the impact on nature, while maintaining or enhancing the value of the manufactured product (producing an equivalent amount, or even more). The EE indicators (EEIs) are the tools used for condensing information and assisting with decision making. In order to describe the initial situation of the winery, different intensity indicators defined by Industry and Environment Council, (Murcia, Spain, 2002) were calculated. The data were gathered of eight wineries located in San Juan, Argentina. Table 1 shows each EE indicators definitions. The obtained results are plotted in figures 2 to 7.

Table 1: Quantities used for the EEIs.

Title	Symbol	Units
Specific consumption of Electrical Energy	Es	Kwh/ product ton
Specific consumption of water	Ws	m^3/ product ton
Specific consumption of additives	As	ton/ product ton
Specific quantity of generated wastewater	WWs	m^3/ product ton
Specific quantity of generated solid wastes	Ss	ton/ product ton
Specific consumption of combustible	Cs	ton/ product ton

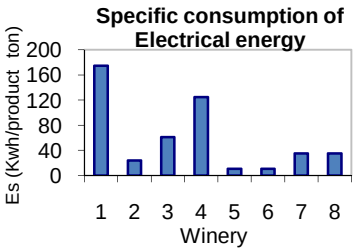

Figure 2*:* Specific consumption of electrical energy for different winery.

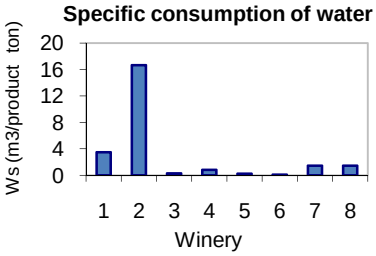

Figure 3: Specific consumption of water for different winery.

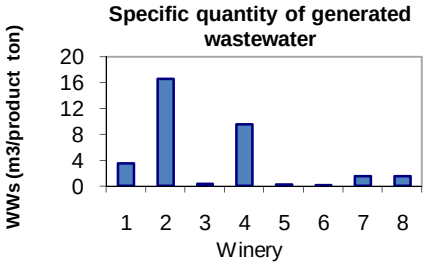

Figure 4: Specific quantity of generated wastewater for different winery.

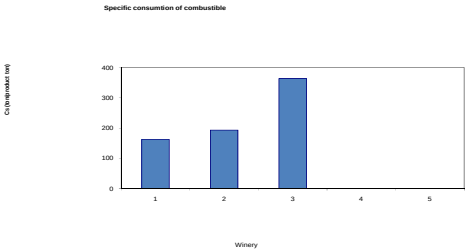

Figure 5: Specific consumption of aditives for different winery.

3. Discussion

The wine industry has the ability to manage some of environmental issues and potentially reduce the extent of their impacts. The more important impacts associated with wine making are: energy and water consumption, solid wastes generation and gaseous emission. These topics are analyzed in this section and the environmental evaluation results are discussed.

Energy consumption: In order to evaluate this consumption, Es was calculated. The wineries 1 and 4 present the highest values. Generally, this consumption in wine production is high. Refrigeration has been estimated to account for 50-70% of used total energy (Broadbridge, 1994). The frigorific energy consumption is produced especially during different process

operations such as pre-fermentative maceration, must cooling for clarifying, fermentation, cold burling, cold stabilization, bottles rinsing and pasteurization. Other power uses include pumping, heating water, cooling cellars, operating machinery, running compressed air systems along with standard business uses such as lighting, air conditioning and running office equipment. In large wineries, pumping can account for around 20% of energy use (Hislop, 1995). Heating, cooling and filtration operations require movement of large volumes of liquid, often utilising several pumps in different stages.

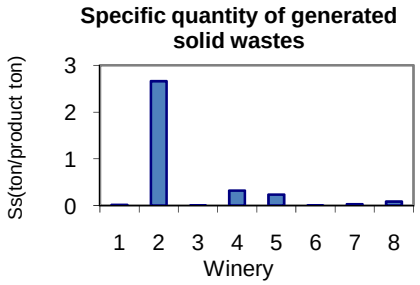

Figure 6: Specific quantity of generated solid wastes for different winery.

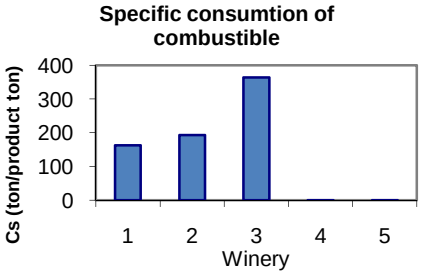

Figure 7: Specific consumption of combustible for different winery.

Water consumption and wastewater generation: Comparing the calculated Ws and WWs values, the highest were observed for winery 2. Water is mainly used in cleaning tasks, disinfection, heat exchange, winery work areas, barrels, process water associated with filtration, ion exchange, sterilizing bottles and cooling system. Solid components in effluent streams arise from tanks, solids settled in tanks and filter media, which may be flushed into treatment systems during cleaning. Spilt and waste juice and wine also add to the wastewater system. Wastewater from wineries is characterized by high biological oxygen demand (BOD), salinity and sodicity from contamination with caustic, mild acids and sometimes biocides (Chapman, et al. 2001). The amount of water used at a winery can easily be associated with design and management of the system rather than tonnes of grapes processed. Calcium tartrate and other residues may also remain once a tank is emptied. Caustic soda (NaOH) is commonly used to remove calcium and potassium residues leading to high sodium ions in wastewater, resulting in sodicity and salinity problems (Chapman, et al. 2001). Following initial tank cleaning using caustic, acidic rinses are used to remove alkaline residues. These chemicals can pose problems in managing wastewater.
Modern production systems generally use more water; 2-5 litres per litre of wine compared to 0.5 litres of water per litre of wine previously. Increased technology and processing methods may be partially responsible; however, given the increasing size of the industry and related increasing demand for water resources, there is a limit on potential water and wastewater resources.
Solid wastes: In order to evaluate the generated solid wastes, Ss was calculated. The winery 2 presents the highest value. Solid wastes generated directly from wine production include marc, filter earth solids from barrels and tanks (lees) and barrels. Grape marc is generated from initial crushing and pressing stages of wine making and is made up of skins, seeds and stalks of grapes. Pressing is performed to remove solids following crushing operations (white wine) or fermentation (red wine). At different stages through the wine making process varied filtration methods are used to remove solid particles. Diatomaceous earth filtering is used to remove tartaric acid crystals and other solid particles from wine. Safety issues are also associated with diatomaceous earth use and disposal due to the risks associated with exposure to fine dust particles if diatomaceous earth dries out. According the higher Ss, winery 2 shows the higher As, also. As was calculated taking into account the quantities of all additives: bentonite, diatomaceous earth, tartaric acid, activated carbon, SO_2, etc.
Gaseous emissions: The main gaseous emission in the wine industry comes from the sulphication and fermentation processes as well as from the boilers. The first process

mentioned emits SO_2. The fermentation process produces CO_2.The boilers are used to provide hot water and steam. If clean fuels are used, the emissions will mainly contain water vapor and CO_2. If other kind of fuels (not the cleaner ones) are burnt, besides the above mentioned pollutants, NO_x, SO_x, among others will be emitted. Although, the emission of gases has not been evaluated, the specific consumption of combustible and the additive are calculated. Considering the first indicator, the winery 3 shows the highest value. Taking into account the specific additive consumption, the winery 2 shows the higher value. During the gaseous substances addition, there are emissions, decreasing the working atmosphere quality. In this case, safety issues are also associated with it. Other aspect to consider is the corrosion by the sulphuric acid; the lost SO_2 react with the air humidity producing this acid.

4. Opportunities for uptake of Cleaner Production

Taking into account the previously exposed diagnosis, the opportunities for uptake of CP were determined. For that, the Cleaner Production Assessment was applied to wineries in San Juan. The cleaner alternatives was proposed, analysing each stage of winery and identifying the environmental impact modifications and possible impediment or restriction for each stage of the wine making process and services-utilities. Tables 2 and 3 detail the current practices and the substitute alternatives identified, to carry out each unit operation of the wine making process and services-utilities respectively.

5. Conclusion

The wine industry is facing serious challenges comprised of internally driven factors, such as rising costs of production due to carry out environmental practice. The majority of the large firms still consider the environmental issues as a cost driver. As a result of this consideration firms do not use more resources for environmental technologies. According to the indications, the firms use more resources for end-of-pipe technologies than the other environmental technologies. However, in this moment, a Program of Cleaner Production is implemented for this industry in San Juan, offering different economic opportunities. In this study, an environmental diagnosis of winery industry was carried out, taking into account the main aspects and the collected data. A great results variation was observed. The winery 2 presented the highest indicators values almost in all analyzed cases. Generally, the high indicators values result of bad management of process or effluents, inadequate technical equipment or planning. The previously exposed diagnosis originated the necessity to propose the opportunities for uptake of CP to wineries in San Juan. These opportunities were focused in each unit operation, stage process and services and utilities.

REDUCING THE POLLUTION OF LEATHER MANUFACTURING PROCESS

Viorica Deselnicu*, F. Platon, L. Albu, M. Crudu
Leather and Footwear Research Institute, 93 Ion Minulescu Street, 031215, Bucharest
Romania

Keywords: tanning, wet white leather, free chrome leather
Topic: Sustainable process-product development through green chemistry

Abstract

Even the optimization of common chromium tannage, and combined tannage with chromium and other tanning materials have led to outstanding results related to the lowered pollution level in effluents and sludge, the problem has not been solved wholly. The single solution for this problem is finding out an environmentally friendly alternative to chromium tannage. This work also is within the above line, aiming to obtain wet-white leather by an organic tanning process.

1 Introduction

Chromium III salts are used extensively in the tanning process. Approximately 90% of the leather manufactured around the word is tanned using chromium III. It has been used in the leather industry for almost 100 years, primarily because it remains the most efficient and versatile tanning agent available; it is also relatively cheap. Due to toxicity of chromium III, which can convert to chromium VI with higher toxicity, tanners around the word are often place under pressure to reduce the chromium content of their effluent discharges and the resulting sluges. (1)

While much of the chromium used in the tannery may be recycled or reused or removed from waste streams on-site by precipitation as insoluble chromium III hydroxide, a small amount may be discharged to the sewage treatment works. This chromium will be disposed of with the waste sluge from the treatment works and this is one of the main disposal routes by which waste chromium leaves the tanning industry.

By the term „tannage" we understand an additional grind-like interlinking of the skin's collagen network, which results in stabilization against heat and micro-organisms and production of a material which remains supple after drying, retaining the flexibility of the fiber structure. Chrome tannage is quite obviously particularly suited to obtaining these desirable new properties in the hide material. These can be no other explanation for the 70-80% share held by this method in the main tannage of leather produced around the world and the resulting international Cr tanning agent consumption of approx. 400000 tons per annum (2). If we look at alternatives to chrome tannage, quite irrespectively of the question of actual ecological benefits to be drawn from using a different method, it is necessary to consider the extent to which a comparable tanning effect and the achievement of the required characteristics are possible at all on basis of the existing natural circumstances. To permit optimum stabilization of the hide material by the tannage process, it is necessary for the tanning agent to penetrate into the interior of the fibrils to cross-link the polypeptide chains. A stable bond is formed with the hide in the case of tanning with reactive organic substances as a result of reaction with the reactive groups in the collagen. The fact that the shrinkage temperature of leather tanned in this way hardly, in contrast to chrome tannage, exceeds the 800C mark is an indicative of stabilizing effect. The extent to which this type of tanning system can assert itself on a broad basis in the future in the field of pre-tannage or intermediate stabilization due to ecological and economic advantages remains to be seen. One class of syntans that has found application in high stability organic tanning (2) is resins

* Viorica Deselnicu, Tel. +4021-323.52.80, viorica.deselnicu@icpi.ro

(melamine resins, phenol resins, etc.). This resin can react with collagen under typical post tanning conditions, when their expected effect is to fill the fiber structure selectively, but they have little effect on raising the shrinkage temperature, either singly or as part of a combination tannage. A practical option is to use pre-polymer with defined particle size, which are incompletely cross linked and then to complete the polymerization reaction in situ using a cross linking agent. In general, this does not work, yielding only moderate shrinkage temperatures. The critical factor that controls the shrinkage temperature is the particle size of depending on the temperature of the solution. this is because the particles are aggregates of smaller particles; the distribution of particle sizes depends on exactly how the resin was polymerized.

2 The basic procedure

In the framework of this paper the tannage is performed in situ by making use of two pre-polymers, one based on a dialdehyde and the other on a diphenol, in the pickling bath. Having bound in hide the above two materials, the pH is risen up to 4.6 – 4.8 by sodium hydrogen carbonate or magnesium oxide. During this time a tanning resin is made within the leather that increases the hydrothermal resistance of leather, resulting in a shrinkage temperature of 70 – 720C. The obtained leather is white and resistant to the mechanical operations. The wet white leather may be subsequently processed with chromium or only with vegetable and synthetic tanning agents according to the finished leather type to be obtained.

The process is capable of fitting into the current process flow and use existing equipment. The following flow chart, comparing „normal" practice with „wet-white" production indicates that this can be achieved.

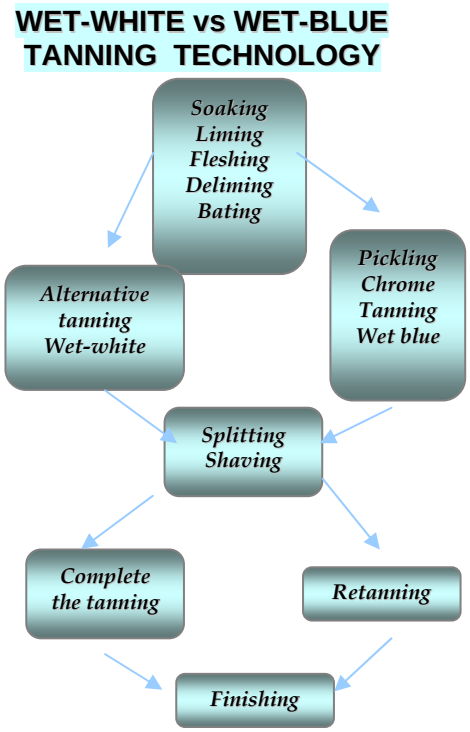

Figure 1. Flow Chart

* Viorica Deselnicu, Tel. +4021-323.52.80, viorica.deselnicu@icpi.ro

The wet-white stock can be tanned with low chrome, vegetable tannins, aldehyde, acrylic/ Zirconium, aldehyde / Aluminum. The variety of leathers produced using „wet-white" stock has adequately demonstrated the versatility of the material.

This procedure was developed for shoe upper leather from bovine hides. This allows good quality, metal-free shoe for garment and upholstery leathers to be produced with no problem.

3. The effect on leather quality

The quality of the crust leathers was directly comparable with those from standard procedures.

Taking the type of tannage into account there are no obvious problems shown in chemical analysis results. If any major differences are to show it is more likely to be highlighted by physical properties. But with appropriate process optimization, these differences would be minimized.

Table 1. Chemical analysis and physical test of leathers

Test	Chrome tanned leather	Wet white tanned leather

Obs: All results related to 0% moisture

4 The environmental impact

4.1 The environmental impact of shavings

One of the main benefits hoped for as a result of this type of wet-white process lies in the elimination of chrome shavings, which occur at a quantity of approx. 5-10% of the hide weight as a permanent by-product of the chrome main tannage process (in the whole of the Single European Market to approximately 100 000 tons per annum is produced) (2). For the wet-white shavings produced as a result of organic tanning, in contrast, according to studies

* Viorica Deselnicu, Tel. +4021-323.52.80, viorica.deselnicu@icpi.ro

not only the recovery of protein hydrolyzed, but also use for fertilizers and for gelatin, glue and other industrial products.
The comparative chemical composition of shavings from wet blue stock vs. wet white stock is given as Table 2.

Special attention is drawn to the digestibility of the shavings. This figure is often as key value for degradation as well as for utilization.

Table 2. Chemical composition of shavings

Test	Wet blue shavings	Wet white shavings
Moisture,%	59.0	67.06
Ash,%	16.6	0.6
Cr_2O_3,%	5.24	2.35
Extractible fat and grease%	1.2	5.6
Total Nitrogen,%	12.7	15.13
Hide substance,%	78.12	85.01
Cr, mg/Kg	4.2	2.1
pH	3.5	6.0
Digestibility, %	52	65

4.2 The environmental impact of effluents

Legal requirements relating to the chrome content of tannery effluent also cause problems in the chrome tannage process. The high chloride, sulfate and chromium concentrations play a decisive role her. The advantage of the new process is that, besides reducing the salt load of the effluent (about 50% of the total sulfate load arises during tanning), the ash content of a skin is reduced from Also, in the next step, the chrome uptake was improved and the volume of sludge was reduced.

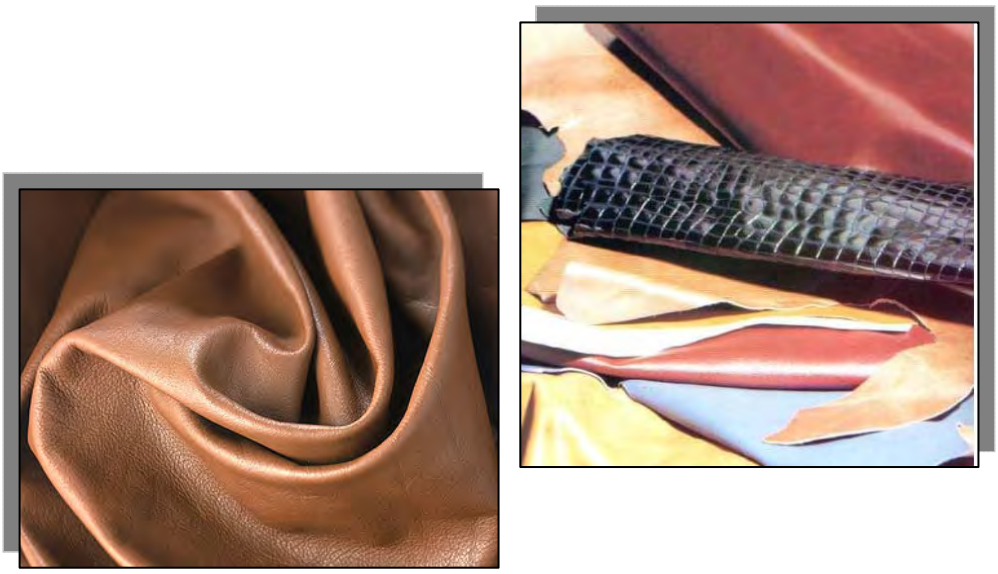
5. Feasibility and financial viability

As wet-white stabilization can be carried out with equipment that is already available, no further machine or drum investment will required. The process costs can be estimated, but no significant increase of costs are anticipated. When fully optimized savings due to improved auxiliary exhaustion and reduced disposal costs can be expected.

The objective of the EU chemical policy is to ensure a high level of protection of human health and the environment for both present and future generations, while ensuring the efficient functioning of the chemical industry. Another important objective is to encourage the substitution of dangerous chemicals by less harmful alternatives.

The actual making of the leather is a multi-step, time consuming process involving the use of a variety of materials.

* Viorica Deselnicu, Tel. +4021-323.52.80, viorica.deselnicu@icpi.ro



6. Conclusion

The wet-white leathers obtained have a white shade and a shrinkage temperature of 70-720C. It can be mechanically processed in the same way as wet blue leather. By after treating this tannage with chromium, the shrinkage temperature can be increased over 1000C; with synthetic or vegetable replacement tannins, the shrinkage temperature can be increased to 90-950C. This allows well –quality, metal-free shoe, garment and upholstery leathers to be produced with no problem.

The salt content of the effluent considerably reduced, pickling being eliminated. In piling and storing, care must be taken to ensure that the skin do not starts to dry. Owing to their low salt content, the water content and thus the weight of the skin is slightly reduce. Subsequent tanning is better as the actual tan extracts can diffuse into the hide more easily and than form a more stable bond with collagen in the inter fibril spaces.

This new „wet white" procedure does not claim to be a replacement for chrome, vegetable or other tannages, but an alternative. It is a pretannge which can subsequently be tanned with chromium, vegetable or synthetic tanning agents. The advantage of this is that the shavings arising are metal free and, therefore, a valuable by-product. Like untanned solid waste, they can be recycled and used as a starting material for gelatin, fertilizer, glue and other industrial products.

While it is true that from a manufacturing point "wet-white" production will fit into current tannery practice, it is also true that an „overnight" switch cannot be made. Machine handling, sorting and grading characteristics, although acceptable, are different and require that operators gain a familiarity with the material. At the same time the effort required to adjust tanning / retanning processes to produce acceptable leather should not be overlooked.

1. SUMMARY

Leather industry has to cope nowadays with major environmental problems because of the polluting processes (a World Bank report has placed the leather industry in the ninth place when considering the environmental impact). Therefore, increasing the environmental efficiency in the leather sector is the major aim of leather, auxiliary materials and equipment manufacturers.

To achieve this, a new concept has arisen that is trying to join new processing rules leading to the harmonization of economic performance of the manufacturing units with the human and environmental protection criteria.

An environmental efficient process has to minimize the raw materials being used, meet the users' requirements, and minimize the emissions (polluting byproducts, wastes, refuses).

The current hide processing can be only thought to be controlled environmentally aggressive, inclining to be limited environmentally aggressive.

The wish of bringing the current hide processing up to the environmentally admitted level has required some decisions to be made on the implementation of new environmentally friendly processes and materials, and this work is in line with this.

The original contribution of this work in solving the above problems has involved the use of solid titanium wastes (cuttings) resulting from the process of obtaining highly pure titanium (ingots) in the preparation of new tanning compounds intended to increase the environmental efficiency of the leather sector.

2. KEY WORDS

Solid titanium wastes, reclaiming, environmentally friendly tanning agents

3. INTRODUCTION

Leather is perhaps the first material being processed chemically by the man (as yearly as 8000 years B.C. – leather was obtained by fat tannage) [1].

Leather belongs to our life; daily we are coming into contact with leather objects making our life more comfortable. Art, traditions, culture, and science have been employing over time leather and parchment [2].

Leather manufacture involves the processing of hides (byproducts of meat industry) into finished leather (a steady material) that can be used in making a large range of products.

Because of the specific tannery processes (use a raw material of organic nature and a large range of chemicals known to be noxious, and not the last, large water consumption and energy expenditure), they are currently facing up to major environmental problems.

Integrating the environment protection into the quality concept is a priority objective of the hide processing field because of the need of reducing water consumption and energy expenditure, and pollution under the general economic context, limited and varying resources at the economic operators' disposal, and a new regulation on chemicals - REACH (Registration, Evaluation and Authorization of Chemicals) to be adopted by the EU [2].

One of main ways of pollution prevention is the implementation of so-called 'clean' or 'environmentally friendly' processes developed onto three directions: [3]

- reduced offer of chemical auxiliaries simultaneously with the application of hide support activation treatment;
- high bath exhaustion;
- replacing the 'classic' chemical auxiliaries of high toxicity and adverse environmental impact with others ones of low or no toxicity.

The development of new tanning agents is required to cope with the increasingly higher environmental pressure on the current tanning materials and processes such as tanning with chromium salts.

4. EXPERIMENTAL

Chromium is the major heavy metal polluting source in the leather sector. Basic Cr^{3+} salts are found currently in the effluents from tanning and wet finishing, and solid wastes from mechanical processing of leather and sludge resulting from the waste water treatment, all these falling within the class of hazardous wastes.

When dealing with the total or part removal of chromium in hide tanning and its replacement with other tanning compounds, even though some new product and processes have been developed, such a problem is kept on opened because of some drawbacks regarding the profitability and productivity while the environmental benefits are obvious.

There have been a variety approaches in obtaining new tanning materials in the last time, such as complicated syntheses, direct processing from ores, charging the chemicals directly into the (pre)tanning baths for in situ synthesis.

This work deals with the preparation of tanning solutions based on titanium by processing solid wastes resulting from the process of obtaining highly pure titanium and that cannot be recycled in the industry yielding them.

The main classification criterion for titanium wastes was their contaminant level [4]. The highest contaminant level in titanium wastes and titanium alloys is in cuttings resulting from the mechanical processing of ingots and cast articles (Figure 1).

Figure 1:
a) Titanium ingot b) Cutting and shaping the ingots c) Unrecyclable cuttings

Therefore, a part of the above wastes cannot be recycled in the remelting process as this is not profitable.

Chemical compositions of the titanium wastes placed at our disposal by SC ZIROM SA – Giurgiu, Romania is shown in Table 1.

Table 1. Titanium waste classification based on their chemical composition

Ref. No.	Alloy type	Ti [%]	Al [%]	V [%]	Nb [%]	Contaminants [%] (Al, V, Nb, Fe, Ni Cr, C, N, O, s.a.)	Remarks
1	Non-alloyed titanium	97	Cont.	Cont.	Cont.	3	Cont.- maximum level
2	Ti 6Al 4V	88	6	4	Cont.	2	Cont.- maximum level
3	Ti 6Al 7Nb	85	6	Cont.	7	2	Cont.- maximum level

Chemical composition of cuttings processed for trials is presented in Table 2.

Element	Ti	Al	V	Fe
%	89.61	6.25	4.07	0.00695

Chemical composition of the cuttings was established by plasma optical emission spectrometry.

The first step in obtaining new tanning solutions based on recovered titanium (from recyclable solid wastes-cuttings) involved the design of a new process for obtaining water soluble salts.

The dissolution of titanium wastes was carried out based on the properties of metals contained in them (considering that there are low levels of Fe, V and Al in such wastes).

Titanium is dissolved by acids at high temperature, the hydrofluoric acid having the best action; nitric acid has no action on the titanium, hydrochloric acid only acts at high temperature, and sulphuric acid at a concentration > 10 % acts at the room temperature.

Vanadium is attacked by nitric acid, concentrated sulphuric acid, perchloric acid, hydrobromic acid etc.

Iron is attacked by sulphuric and hydrochloric acid.

Aluminium is not attacked by the nitric acid while the other oxygenated acids acts on it at high rates even when highly diluted.

Considering the above features, the sulphuric acid was selected to dissolve the unrecyclable titanium cuttings according to the following reaction:

$$Ti + H_2SO_4 + O_2 + H_2O \longrightarrow TiOSO_4 \cdot 2H_2O$$

Following a large number of dissolution trials with solid titanium wastes (cuttings), the process for the preparation of solutions based on titanium/titanyl sulphate (containing V, Al and Fe) was designed and tried.

The framework process for obtaining water soluble salts such as titanium/titanyl sulphates (containing V, Al and Fe) is shown in Figure 2.

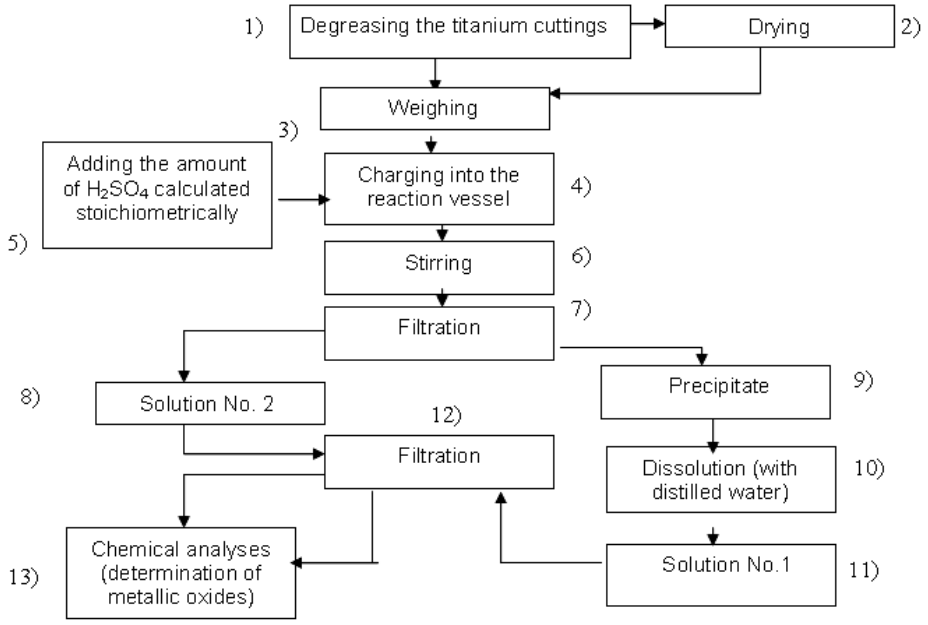

Figure 2. Framework process for obtaining water soluble titanium salts

Considering the difficulty in obtaining tanning compounds from titanium salts (single) because of their instability in solution (hydrolysis at relatively low pH values), the stabilizing possibilities by masking, complexing, basification, and/or combining them with more stable (of chromium and aluminium) or less stable (zirconium) compounds were investigated [6-16].

Analysis (plasma optical emission spectrometry) results for metal level in some of resulting environmentally friendly tanning products are shown in Table 3.

Table 3. Metal level in the new resulting tanning solutions

Sample	Ti	Al	V	Cr	Zr
Ti-Al	2,660	4,995	0,120	-	-
Ti	8,050	0,561	0,365	-	-
Ti-Zr	4,300	0,299	0,195	-	-
Ti-Cr	7,570	0,527	0,343	0,930	-
Ti-Zr-Al	3,680	2,046	0,167	-	-
Ti-Al-Cr	2,830	3,787	0,128	0,480	-

Tanning trials ere performed in laboratory as follows:

- pickled bovine hides of 25/30 type, unsplit (130-250 g);
- rotational speed of the drum(FAVE -Italy): 14 rpm;
- temperature of the tanning bath: 25^{o}C;
- ratio of tanning liquor: 300 %.

Leather resulting from application of the new materials in pre-tanning has shown a common appearance (smooth grain) and colours lighter then in chrome leather (Figure 3) in the most of cases.

Figure 3. Leather pre-tanned with some of the suggested solutions

5. RESULTS AND DISCUSSIONS

The tanning operation is difficult to be defined but it should to be based on o comparison of the raw hide with the tanned one by considering at least three criteria [17]:

- storage and preservation characteristics obtained by tanning;
- changes resulting in the leather structure following the tannage;
- characteristics resulting from tanning treatment.

The protein structures in the dermis have changed their reactivity following the tannage while remaining unsaturated chemically (becoming inactive or stable), imparting leather a long time preservation ability.

Following the treatment known as ‘’tanning’, leather shows such characteristics as follows:

- increased physical-mechanical resistance because of the increased fibrous structure isotropy;
- stability to the enzyme and bioenzyme attack;
- increased hydrothermal resistance as a result of the increased shrinkage temperature of the dermis:
- a porous character and acceptable wettability level in dermis after drying.

Considering the above features, the hydrothermal resistance values for the treated leather and characteristics of leather semi-finished products assessed by electron microscopy can be thought to provide the required information on the tanning characteristic of the environmentally friendly materials suggested in this work.

Shrinkage temperature was performed both by the common method of heating the sample immersed in water (Giuliany device-Italy) and DSC.

Shrinkage temperatures for leather samples tanned with the new tanning solutions are shown in Figure 4.

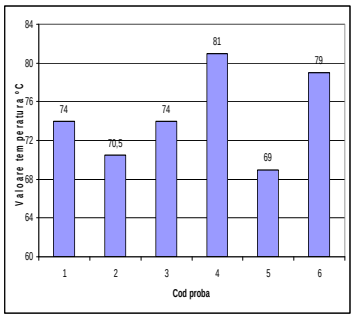

Figure 4. Shrinkage temperatures for leather samples tanned with the new tanning solutions

Figure 5. Leather tanned with the new tanning materials subsequently split

Hydrothermal resistance values for all the leather samples tanned with the new materials are not as higher as those tanned with chromium salts but provide a very good mechanical processing in the operations subsequent the tannage such as splitting and shaving (Fig. 5).

The results of thermal analysis [18] and electron microscopy [19] presented in Figures 6 and 7, and Figures 8 and 9, respectively have revealed the tanning characteristic of the suggested new materials.

6. CONCLUSIONS

- Obtaining low cost new auxiliary materials with low environmental impact and easy to be applied, resulting in leather of high quality is nowadays the aim of any investigation in leather manufacture.
- This work suggests to solve some of problems in the leather sector by making original use of some solid titanium wastes (cuttings), resulting from highly pure titanium and its alloy manufacture, to obtain tanning solutions.

- Increased eco-efficiency in the leather manufacture sector by making use of un recyclable wastes (because of the contained contaminants) resulting from nonferrous metal industry as abase for obtaining environmentally friendly products intended to substitute the chromium salts in hide tanning.
- Development of new simple methods for solid titanium waste (cuttings) processing to obtain soluble salts intended to be used in the preparation of new tanning materials, and results (values of hydrothermal resistance, and light coloured or white dense leathers showing smooth grains) obtained in (pre) tanning trials is reason to keep on with the investigations with the aim of improving the methods of waste processing to make them more efficient, and diversifying and rendering more rentable the tanning materials, application processes and wet-white leather semi-finished products.

Keywords: Biodiesel, Fleshings, Transesterification, Methyl esters, Beef tallow
Topic: Multi-scale and/or multi-disciplinary approach to process-product innovation

Abstract

Animal fat was extracted from fleshings, a residue from the leather industry, by a two step procedure. First the fleshings are mixed with water (60 ºC) and then the fat rich phase obtained is treated with n-hexane to extract the fat and leave the proteic residue. This fat presents a high acid value and therefore the direct transesterification to biodiesel with an alkaline catalyst was not possible. A pre-treatment step was performed, consisting of an esterification reaction with methanol in the presence of sulfuric acid, and acid values were lowered below 3 mg KOH/g. The transesterification with methanol was carried out with KOH as catalyst at 65ºC in two stages using 80% of the methanol/KOH solution in the first step and the remaining in the second step.

The methyl ester product was characterized and the parameters are, in most cases, within the specifications. The exception is the methyl ester content (94,2%) indicating that further adjustments are needed in the production process in order to improve the quality of the final product.

1 Introduction

Sustainable energy management is a main world concern, considering the fact that fossil fuels supplies are limited and energy demand continues to rise. Search for alternative renewable fuels has therefore gained fundamental importance. Among biofuels, biodiesel has very good utilization and environmental properties, and became a widely used alternative to fossil fuels, with ten years long commercial use in Europe and a rapidly growing world market. Biodiesel cost is mainly determined by feedstock prices. Presently, the cost of the cereals that are used to produce biodiesel is increasing due to the growing market demand. Also, this huge demand introduces a sustainability problem for the next coming years.

Significant research effort is being dedicated to the search for alternative feedstocks. Among these, animal fats from different sources, leather industry, butcher's and slaughterhouses, are potentially interesting. Furthermore, the re-use of these wastes is an environmental friendly disposal option.

Animal fats present usually a high acid value and its fatty acid composition shows a more saturated character than vegetable oils, as can be seen in table 1.

Biodiesel is a mixture of fatty acid esters, obtained by the transesterification of vegetable oils or animal fats with a low molecular weight alcohol, with glycerol as a by-product, as shown in fig. 1.

Table 1.Typical fatty acid compositions of vegetable oils and animal fats (Scrimgeour, 2005).

	Fatty acid (wt %)						
	Myristic (14:0)	Palmitic (16:0)	Palmitoleic (16:1)	Stearic (18:0)	Oleic (18:1)	Linoleic (18:2)	Linolenic (18:3)
Soybean oil	0.1	11	0.1	4	23.4	53.2	7.8
Beef tallow	2,7-4,8	20,9-28,9	2,3-9,1	7,0-26,5	30,4-48,0	0,6-1,8	0,3-0,7

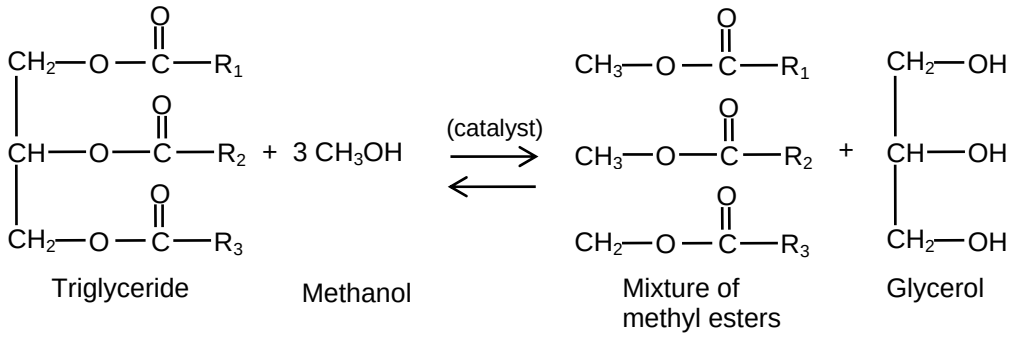

Figure 1. Transesterification reaction of vegetable oils or fats.

Almost all biodiesel production processes are based on the transesterification of triglycerides with methanol using an alkaline homogenous catalyst (NaOH or KOH), in batch or continuous plants. This process requires feed stocks with low free fatty acid (FFA) and water contents. Typical animal fats contain from 5% to 30% FFAs (Gerpen, 2005), and soap formation (fig. 2) occurs in considerable amounts, making product separation very difficult.

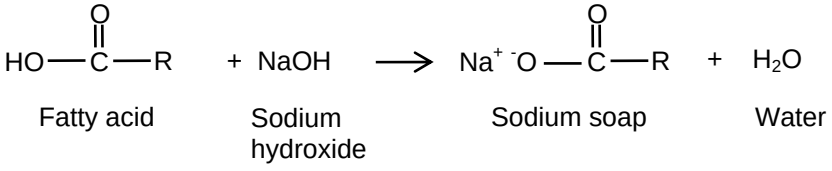

Figure 2. Saponification reaction of free fatty acids.

To avoid this problem, a pretreatment step is required to convert FFAs to methyl esters, thereby reducing the FFA level. This treatment consists of an esterification with methanol and sulfuric acid as catalyst, as shown in fig. 3.
After this reaction, the treated fat can be transesterified with an alkali catalyst to convert the triglycerides to methyl esters.

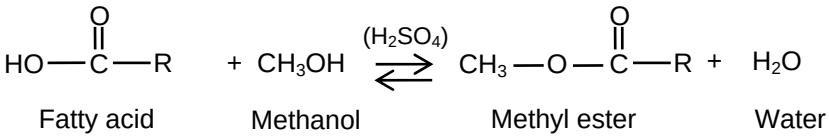

Figure 3. Esterification reaction of free fatty acids.

The purpose of this work is to investigate the possibility of using fleshings (bovine) from the leather industry in biodiesel production. These leather industry wastes contain 40 to 60 wt % of fat (dry basis). Beef tallow is also tested for comparison purposes, because it is a similar residue and previous works showed the feasibility of this feedstock for biodiesel production (Lebedevas, 2006).

2 Methods

Analytical methods

Acid value was determined according to EN 14104 Standard and iodine value was determined according to EN 14111 Standard.
Viscosity was determined according to EN ISO 3104 Standard and density was determined using a picnometer method.
Methyl ester content was determined by a GC method, according to EN 14103 Standard.

Fat extraction

To obtain the fat from beef tallow, the solid is melted at 140 ºC and the product is filtered to remove any solid particles that may be present.

To obtain fat from fleshings two steps are needed: first, the solids are mixed with water and heated in order to break the bonds between the fat and protein material. The optimal conditions for this step are solid:water mass ratio of 1:0.75, for 2h at 70 ºC. Three different phases are obtained, a fat rich phase, a water rich phase and a protein rich phase. In the second step, the fat rich phase is treated with n-hexane to extract the fat and leave the proteic residue. The operating conditions for extraction are: fat rich phase:solvent mass ratio of 1:10, ambient temperature and 1h. The product is filtered to remove the proteins and n-hexane is separated from the fat by distillation.

Biodiesel production

All these animal fats present high acid values depending on the source, and thus a pre-treatment step is needed. This pre-treatment consists of an esterification of the free fatty acids with methanol and sulfuric acid as catalyst at 70ºC. After the phases are separated, the fat phase is transesterified with methanol using potassium hydroxide as catalyst. Initial experiments with a single step transesterification of the fleshings (fat:methanol:KOH mass ratio of 1:0.238:0.01 at 65ºC and 3h) resulted in a product with a low ester content (70%). Therefore a two-stage operation procedure was performed (Baptista, 2008). The first step consisted of a transesterification using 80% of the total volume of the methanol/KOH solution at 65 ºC. The glycerol phase was then removed and the ester rich phase was reacted again with the remaining methanol/KOH solution. After the separation of the glycerol phase, the ester phase was washed with water and dried. The acid value, iodine number, ester content, density and viscosity of the product were determined.

3 Results and discussion

Concerning fat extraction, in the first step the mass of fat rich phase/mass of dryed fleshings ranged from 0,81 to 0,89. For the hexane extraction step, yields of 58-70% were obtained (mass of fat /mass of fat rich phase).
Acid esterification reaction times were studied and the results are shown in figure 4. As can be seen, one hour is sufficient to reduce the acid number to acceptable values for the transesterification step.

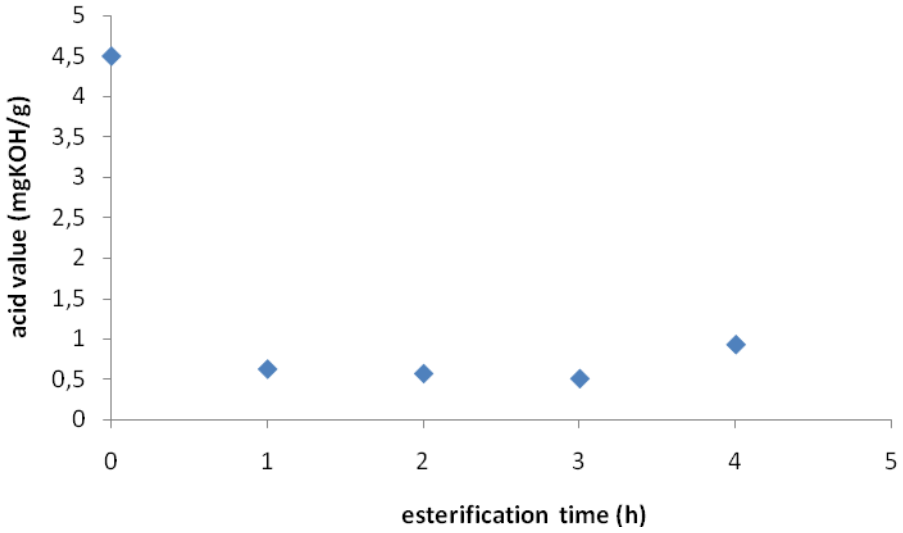

Figure 4. Acid value of the fat as a function of the esterification time.

The results of two step transesterification preliminary studies (3h+2h) presented in table 2, show that the methyl ester products from both raw-materials are similar. This behaviour was expected, as fat from bovine fleshings should have the same composition as beef tallow.

Further studies allowed to reduce reaction times to 1h+1h, and product characterization is presented in table 3.

Table 2. Characterization and yield of methyl ester product (reaction times 3+2h).

Fat source	Acid value (mg $_{KOH}$/g)	Ester content (%)	Density, 15ºC (g/cm^3)	Viscosity, 40ºC (mm^2/s)	Yield (%)
Beef tallow	0.17	94.2	0.87	4.8	65
Fleshings	0.18	94.1	0.87	4.8	57

Table 3. Methyl ester characterization (reaction times 1+1h).

Parameter	Result	EN 14214 reference values
Methyl esters (wt%)	94,2	≥ 96.5
Density, 15ºC (g/dm^3)	872	860-900
Viscosity, 40ºC (mm^2/s)	4,8	3,5-5,0
Acid value (mg $_{KOH}$/g)	0,172	< 0,5
Iodine value (g I_2 /100g)	48,5	< 120

The values obtained are, except for methyl ester content, within the specifications for biodiesel (EN 14214 standard). The product presents methyl ester contents close to the standard value, so further optimization of operating and purifying conditions is needed.

4 Conclusions

This study shows the feasibility of using the fleshings from the leather industry to produce biodiesel, but further adjustments are needed in the production process in order to improve the quality of the final product. Biodiesel produced from this kind of raw material, will present a high CFPP and will need to be blended (with biodiesel produced from vegetable sources or petroleum diesel) prior to final utilization.

Topic: Sustainable process-product development through green chemistry

Abstract

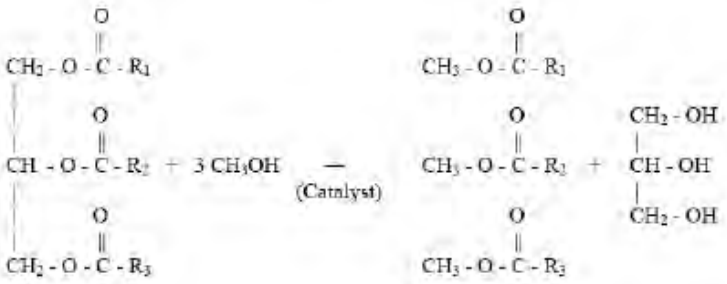
Due to the increasing cost and depletion of fossil fuels, there is a growing need for alternative fuels. Biodiesel, being a renewable, non toxic and biodegradable resource with positive influence in the environment, is the main alternative to fossil diesel. The production of biodiesel is usually achieved by an homogeneous transesterification reaction (catalysed by sodium hydroxide or methoxyde) between a lipid (vegetable oils or fats) and a short chain alcohol, such as methanol, to produce an ester and glycerol as a by-product. One of the main goals of this work was to study the effect of different transesterification reaction conditions as well as of the type of oils used on the final biodiesel properties. Another goal was to establish a relationship between the iodine value of the oils and the oxidative stability of biodiesel and the effect of the addition of several commonly used anti-oxidants. The results show that using a methanol/oil molar ratio of 6:1 and a temperature of 65ºC, it was possible to produce soybean biodiesel with a methyl ester content above 97%, using $NaOCH_3$ as catalyst. On the other hand, the samples produced from waste frying oils (WFO) presented low values for the oxidative stability (induction times between 2 and 3h) but this property can be improved by the addition of anti-oxidants.

1 Introduction

One of the main problems for biodiesel commercialization is its high cost. The feedstock, usually semi-refined vegetable oils, represents a wide part of the total cost of the biodiesel production. Therefore, these costs may be considerably reduced if biodiesel is produced from low cost materials such as waste frying oils (WFO) or animal fats. However, the quality of biodiesel must be guaranteed and the European Standard (EN) 14214 specifies the limits for 25 quality parameters. WFO and fats often contain significant amounts of free fatty acids (FFA) and water, which makes them inadequate for direct base catalyzed transesterification reaction. The presence of a small amount of water is a problem because it can lead to a decrease in the quantity of methyl esters produced because water promotes hydrolysis reactions, which convert the methyl esters in FFA. On the other hand, if the amount of FFA is high (> 2 mg KOH/ 100g) it is necessary the use of an extra amount of catalyst during the transesterification reaction to balance the oil acidity and/or a previous esterification reaction with an acid or with glicerol to convert the FFA into esters (Canakci, 2007).

The production of biodiesel is usually achieved by an homogeneous transesterification reaction (catalysed by sodium hydroxide or methoxyde) between a lipid (vegetable oils or fats) and a short chain alcohol, such as methanol, to produce an ester and glycerol as a by-product (Reaction 1) (Felizardo et al., 2006).

[*] Corresponding author: Tel + 351-21-8417344. E-mail: qjnc@ist.utl.pt



Reaction 1-Transesterification reaction. R1, R2 and R3 represent linear fatty acid chains.

This work presents the effect of different transesterification reaction conditions as well as of the type of oils used on the final biodiesel properties. The relationship between the iodine value of the oils and the oxidative stability of biodiesel and the effect of the addition of several commonly used anti-oxidants is also presented.

2 Materials and methods

All the chemicals were Analytical Grade and the aqueous solutions were prepared with deionised water. The acid value of the oils was obtained by titration with a KOH solution (prEN 14104), whereas the oils iodine value was determined by the Wijs method (prEN 14111). The oxidative stability of methyl esters, with and without antioxidant, was determined by the Rancimat method according to the European Standard EN 14112.
The samples' near-infrared spectra were acquired with an ABB BOMEM MB160 spectrometer equipped with an InGaAs detector and a transflectance probe from SOLVIAS (diffuse transflectance spectra). Spectra were recorded in duplicate for each biodiesel sample at room temperature, with the assistance of the Galactic Grams software package, between 12 000 to 4 000 cm^{-1} and with a spectral resolution of 16 cm^{-1}. The average of the two measurements was used to determine several previously calibrated properties (Felizardo et al., 2007; Baptista et al., 2008).

3 Experimental procedure

Biodiesel samples were prepared by transesterification of soybean, rapeseed, palm and WFO using the following procedure: 300 g of oil was transferred into a stirred tank reactor (1000 cm^3) immersed in a temperature-controlled water bath. For stirring, a single paddle round impeller (diameter = 6.5 cm) at 350 revolutions min^{-1} was used. The oil was heated until the desired temperature was reached (65°C). At this point, a mixture of methanol and sodium methoxide was added to the oil and the transesterification reaction began. The reactor was kept at around 65°C for 90 to 180 min. The majority of the reactions were performed using a molar ratio of methanol/oil of 6:1 and an amount of catalyst corresponding to 0.6% of the mass of oil sample. After the reaction, the two phases obtained, the glycerol-rich phase and the methyl ester (biodiesel) phase, were separated in a decantation funnel. Afterwards, the biodiesel was washed with water, with a 0.1M HCl solution and once again with water. It was centrifuged, filtered and finally dried at 80–90°C under vacuum using a rotary evaporator.

4 Results and discussion

1. Effect of the use of different transesterification reaction conditions on the biodiesel purity

It is known that several factors, including the reaction time and temperature, catalyst type and concentration (cat./oil) and alcohol/oil molar ratio (MeOH/oil), influence the efficiency of

the transesterification reaction and the biodiesel purity (Felizardo et al., 2006).

The results show that increasing the temperature from 55 to 75ºC influences very slightly the reaction kinetics, which is faster at higher temperatures. On the other hand, the methanol/oil molar ratio is one of the most important variables in methyl esters production. The quantity of methanol influences significantly the purity of the final product, which decreases with the decreasing of the molar ratio methanol/oil. Relatively to the amount of catalyst, it was possible to verify a decrease in the esters content in the purified biodiesel when, maintaining the remaining conditions, the quantity of $NaOCH_3$ decreased from 0.60 to 0.30%. However, the reduction of 1 to 0.45% of NaOH did not influence very much the final purity of biodiesel, although more time is required to meet the specification value for the methyl esters content (96.5%), when the amount of catalyst decreases.
The effect of the catalyst type was also studied in this work. The results show that, for the same amount of sodium added, in the form of NaOH or $NaOCH_3$, the methyl esters content of the produced biodiesel is similar, although the kinetic of the reaction is faster when $NaOCH_3$ is used as a catalyst. Hence, for a methanol/oil molar ratio of 6:1 and a temperature of 65ºC, it was possible to produced biodiesel with a methyl ester content above 97%, using NaOH or $NaOCH_3$ as catalyst.

2. Effect of the use of different types of oils on the biodiesel purity

As already mentioned, biodiesel can be produced from different vegetable oils. So, one of the aims of this work was to study the effect of the type of oil used in the transesterification reaction on the final content of methyl esters in biodiesel. The results showed that, independently of the types vegetable oil (soybean, rapeseed, palm oils, WFO or mixtures), the methyl esters content of the final biodiesel increases with the reaction time up to a certain value, which depends on the type of oil, and remains constant after that. The biodiesel samples produced from soybean oil and from the mixtures of soybean, palm and/or rapeseed oils presented the best results in terms of biodiesel purity, in some cases, above 98%. On the other hand, the worst results for the semi-refined oils were obtained with palm oil, which seems to need more time to reach the limit value established by the European Standard EN 14214. The soybean and rapeseed oils only required 30 min of reaction to reach the 96.5% methyl esters content limit.

3. Oils Iodine value
Another goal of the present work was to establish a relationship between the iodine value of the oils and the oxidative stability of the corresponding biodiesel. The iodine value is an important parameter to determine the unsaturation degree of the oil and/or of biodiesel and influences several important properties of biodiesel. In fact, it is known that oils and biodiesel with higher values of the iodine number have higher CFPP (Cold Filter Plugging Point) and a lower oxidative stability (Knöthe et al., 2005).
The iodine value of the oils samples used in this work varied from ≈60 g I_2/100 g for palm oils to values higher than 120 g I_2/100 g for the soybean oils (the EN 14214 imposes and iodine value for biodiesel lower than 120 g I_2/100 g). The results obtained allowed to confirm that the oxidative stability of biodiesel, measured in terms of its induction time, tends to decrease with the increase of the iodine value of the oil used in its production. In fact, the biodiesel samples with higher induction times (above 13h) were the ones produced from palm oil, whereas soybean and rapeseed biodiesel samples have induction times of 5.3 h and 5.8h, respectively. As expected, the samples produced from WFO presented the lowest values of the oxidative stability (induction times between 2 and 3h).

4. Determination of the oxidative stability. Addition of antioxidants
Due to the fact that oxidative degradation affects the biodiesel quality, the European biodiesel standard EN 14214 specifies a minimum induction time (IT) of 6h for the oxidative stability of biodiesel. As mentioned above, the biodiesel samples produced in this work with

higher induction times (above 13h) were the ones produced from palm oil. Soybean and rapeseed biodiesel have induction times of 5.3 h and 5.8h, respectively, whereas biodiesel produced from WFO presented induction times lower than 3h. Therefore, to comply with the EN 14214 specification it is often necessary to prepare blendings with, for example, palm oil biodiesel that presents the highest value of the IT, or to add anti-oxidants to the final biodiesel. Thus, to study the effect of the addition of anti-oxidants, five antioxidants (identified as A to E) were added to biodiesel samples produced from soybean, rapeseed and WF oils and the results are presented in Figure 1.

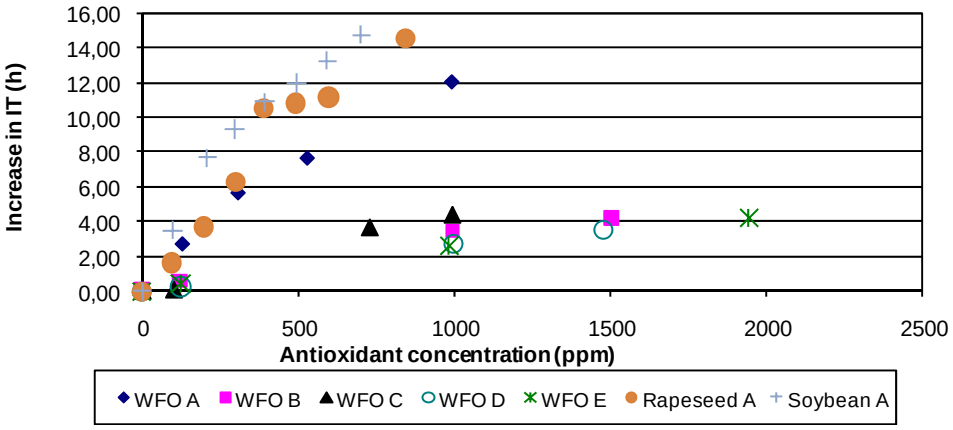


Figure 1 - Effect of the antioxidant concentration on the induction time.

As shown in Figure 1**,** the best results were obtained with the antioxidant A, even though all the antioxidants were able to increase the samples induction time. Furthermore, the curve obtained for the biodiesel sample produced from WFO with the anti-oxidant A was similar to the ones obtained for the soybean and rapeseed biodiesel samples. From Figure 1 it is also possible to conclude that the IT increases directly with the concentration of antioxidant for low concentration of the latter. For higher values the induction time reaches a plateau.

With the aim of testing the durability of the effect of the addition of the antioxidants and confirm the influence of light in the oxidative degradation, some of the samples (with and without antioxidant) were stored in a closed cupboard in dark jars, whereas others were exposed to the sunlight in transparent jars. After an exposure time between 14 and 69 days, the induction time was measured again with a Rancimat apparatus. With this experiment it was possible to confirm that, as expected, the samples exposed to the sun in transparent jars were quickly degraded (IT<1 h after 14 days). On the other hand, the decreases in the IT (degradation) of the samples that had been stored in a dark place were considerably small and never higher than ≈ 3h. Furthermore, for some of the tested antioxidants, it was possible to maintain the IT>6h after 62 days of storage in a dark place.

5 Conclusions

The transesterification reaction conditions and the type of oil used as raw-material affect the ester content of the biodiesel. However, for a methanol/oil molar ratio of 6:1 and a temperature of 65ºC, it is possible to produced biodiesel with a methyl ester content above 97%, using NaOH or $NaOCH_3$ as catalyst. Another goal of this work was to establish a relationship between the iodine value of the oils and the oxidative stability of the corresponding biodiesel. As expected, it was verified that the oxidative stability of biodiesel decreases with the increase of the iodine value. The effect of several anti-oxidants added to the biodiesel was also analysed. The results showed that some of the antioxidants studied

were very effective and allowed obtaining induction times higher than 6h (minimum value imposed by the EN 14214), even for the biodiesel samples produced from WFO after 62 days of storage in a dark place.

Topic: Sustainable process-product development through green chemistry.

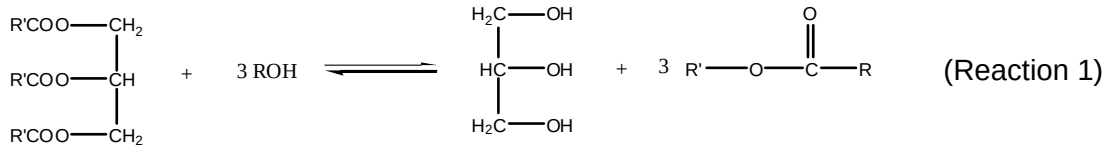
Abstract

Biodiesel is the main alternative to fossil diesel and it may be produced from different feedstocks such as several semi-refined vegetable oils, waste frying oils (WFO) or animal fats. However, WFO and fats often contain significant amounts of free fatty acids (FFA) that make them inadequate for the direct base catalyzed transesterification reaction (where the FFA content should be lower than 4%). The present work describes two possible methods for the pre-treatment of oils with high content of free fatty acids (20 and 50%) by esterification with methanol and glycerol. In order to reduce the free fatty acids content, the reaction between these FFA and an esterification agent is carried out before the transesterification reaction. The results showed that both methanolysis and glycerolysis are promising pre-treatments to acidic oils or fats (>20 %) because they led to the production of an intermediary material with a low content of FFA (< 4%) that can be used directly in the transesterification reaction for the production of biodiesel.

1 Introduction

Biodiesel (fatty acid methyl esters or FAME) is the main alternative to fossil diesel. The key advantages of its use are the fact that it is a non-toxic renewable resource, which leads to lower emissions of gaseous pollutants. European governments are targeting the incorporation of 20% of biofuels in the general fuels until 2020.

FAME can be produced through a transesterification reaction between a lipid source (vegetable oils and fats) and an alcohol (mainly methanol) to produce an ester and a by product, glycerol (Reaction 1). This reaction occurs stepwise, with mono and diglycerides as intermediate products.



(Reaction 1)

Triglyceride Methanol Glycerol Biodiesel

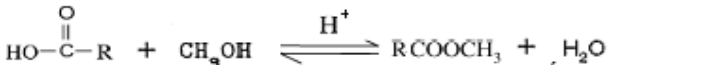
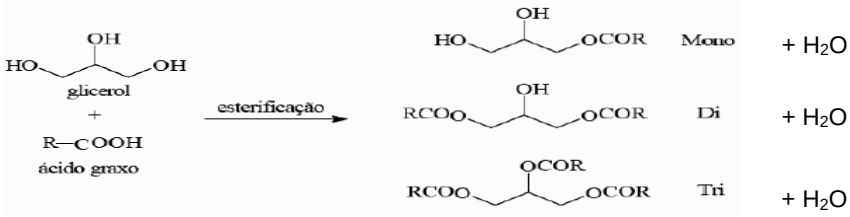
The feedstock represents a wide part of the total cost of biodiesel production. Therefore, these costs may be considerably reduced if biodiesel is produced from low cost materials, such as WFO, animal fats or soap-stocks. However, these raw-materials often contain significant amounts of free fatty acids (FFA), which makes them inadequate for direct base catalyzed transesterification. In fact, for acidic materials (FFA > 2 mg KOH/ 100g) it is necessary the use of an extra amount of catalyst in the transesterification reaction to balance the oil acidity (oils and fats with a FFA content below 4%) or to carry out a previous esterification reaction with methanol (Reaction 2) or with glycerol (Reaction 3) to convert the FFA into esters ((Felizardo et al., 2006; Canakci, 2007).



(Reaction 2)



(Reaction 3)

Reactions 2 and 3 show that both pre-treatments involve the reaction of the FFA with an alcohol, such as methanol (methanolysis), or with glycerol (glycerolysis), in order to produce the corresponding esters (methyl esters or glycerides, respectively) (Canakci et al., 2001, 2003; Pereda M. et al., 2003). Methanolysis or glycerolysis are used only when the free fatty acids content is high (5-60% of FFA). After these pre-treatments, the glycerides in the oil/ester phase can be transesterified by basic catalysis.

To study the influence on methanolysis efficiency of the several experimental variables, it was used a factorial design planning of the experiments with three factors (methanol to FFA molar ratio, catalyst to oil mass ratio and the reaction time) and three factor levels. Factorial experiments are especially important in the beginning of an experimental study and they reveal high precision with minimum experimental effort and they enable detection of factor interactions (Otto M., 1999). A full factorial three-level design is described as 3^k design that means *k* factors at 3 levels and 3^k experiments.

The present work describes the application of methanolysis and glycerolysis for the pre-treatment of acidulated soap-stocks with a high content of free fatty acids (20 and 50%). The potential use of these raw materials for biodiesel production is very interesting because they are available at low cost and present a regular quality.

2 Experimental procedures

Acidulated soap-stocks were produced in a lab scale reactor from industrial soap-stocks produced in the soybean oil neutralisation process. This material contains soaps, oil and salts and yields, after treatment, an oil rich phase with FFA and triglycerides, which is usually refered to as acidulated soap-stocks. The procedure used in this work to produce this acidulated soap-stock consisted in adding into the reactor 150 g of soap-stocks plus 150 ml of hydrochloric acid (37%) and 500 ml of water. After three hours of reaction at ≈100ºC, the reaction yields two immiscible phases, one containing the oil and the FFA and an aqueous phase containing the acid and salts (Figure 1). The oil-rich phase was then washed several times with water, and finally dried under vacuum at 90º C, resulting in an acidulated soap-stock with an acid value of 120 to 130 mg KOH/g (60 – 65% of FFA).

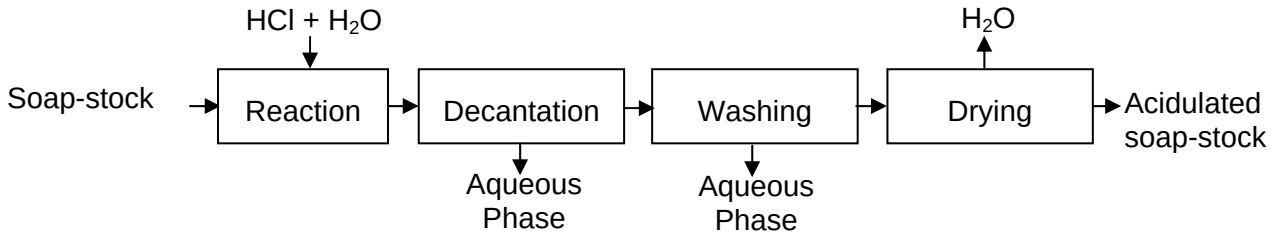


Figure 1 – Process for the production of acidulated soap-stocks

The methanolysis reactions were carried out using the following procedure: 200g of WFO (75% m/m) were mixed with the acidulated soap-stock (25% m/m) and transferred to a glass reactor equipped with a condenser and a mechanical stirrer. The resulting mixture presents an acid value of 40 mg KOH/g (≈ 20% FFA). The reactions were carried out at 350 rpm and 65 ºC.

As mentioned above, to study the influence on methanolysis efficiency of the several experimental variables, it was used a factorial design planning of the experiments with three factors (methanol to FFA mixture molar ratio, catalyst to oil mass ratio and the reaction time) and three factor levels. In this study, the MeOH:FFA molar ratio values were: 4:1, 8:1 and 12:1 and the Catalyst:Oil mass ratio values were: 2%, 3% and 4%. The effect of the reaction time was studied by collecting samples at 5, 90 and 180 minutes of reaction. Therefore, this factorial design led to the execution of nine (3^2) experiments. At the end of the pre-determined reaction time, the excess methanol was removed/recovered from each sample/final product by distillation at 50º C under vacuum in a Rotorvapor- RE-111 from BUCHI. The two phases formed were separated by decantation and the esters/oil phase was washed with water and dried at 90º C under vacuum.

The *Glycerolysis* was carried out using the following procedure: the industrial acidulated soap-stock and glycerol were added to a stirred reactor equipped with a condenser. The reaction was carried out at 200 ºC, 350 rpm for 2 hours. The glycerol was supplied by a biodiesel company (SPACE) and was neutralized with sulphuric acid before use. The samples withdrawn from the reactor were analyzed without further purification steps.

All chemicals used in this study that are not mentioned above were analytical grade and were supplied by Merck. The acid value of the samples was determined after sample purification according to EN 14104, whereas EN ISO 12185 was used to determine the samples' density. Whenever possible, fatty acid methyl esters content of the samples was estimated by Near Infrared Spectroscopy (Baptista et. al, 2008).

3 Results and discussion

3.1 Methanolysis

In order to understand the influence of the variation of the experimental conditions on the obtained results, the data was analysed using the Principal Components Analysis (PCA). This technique is a well establish method that greatly simplifies the analysis of complex interactions. Figure 2 presents the loadings analysis (Otto M., 1999) of the methanolysis experiments. From this Figure it may be concluded that that the acid value decreases with the increase of the MeOH:FFA molar ratio. This is an expectable result because the use of an excess of methanol drift the equilibrium towards the products (Reaction 2). It is also worth noting that the time is collinear with the methyl esters content (%ME). This reveals that increasing the reaction time increases the methyl ester content. Also, increasing the amount of catalyst enhances the formation of fatty-acid methyl esters.

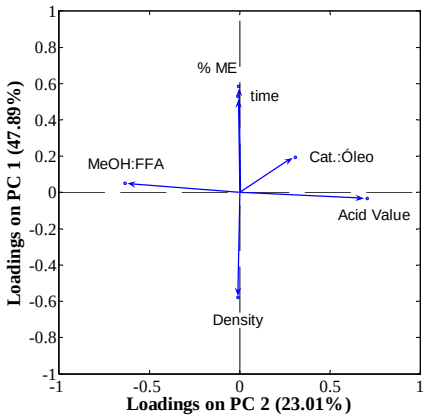

Figure 2 - Principle Component Analysis of Methanolysis

Factorial design analysis also shows that the amount of methanol is of major importance for the reduction of the acid value. Time, on the other hand, has little importance on the esterification reaction, although it was found to have a determinant effect on the reduction of the samples' density. Furthermore, the interaction between the studied factors is, in general, benign to the goals of the experiment.

Figures 3 A and B show the influence of the MeOH:FFA ratio on the samples acid value and methyl esters content, respectively. The results confirm the information obtained with the preliminary PCA. As a consequence, the increase of the MeOH:FFA ratio decreases the acid value and augments the methyl esters content. As anticipated by the analysis of Figure 2, Figure 3 shows that, in these experiments, the FFA content remains almost constant after the first 5 minutes of reaction, whereas the content of methyl esters continues to increase.

The results obtained concerning the ME content (Figure 3B) show that two reactions: the esterification of FFA (Reaction 2) and transesterification of triglycerides (Reaction 1) are occurring in the reaction vessel. In fact, the increase of the ME content to values up to 45%, higher than the initial content of FFA in the WFO-Soap stock mixture (≈20%), indicates the occurrence of both reactions. Furthermore, the decrease of the density is generally related to the transformation of triglycerides into fatty acid methyl esters. Figure 2 also shows that, as concluded from the factorial design analysis, the acid value is almost independent from the reaction time (they are almost orthogonal). This result indicates that after an initial decrease detected in the first samples, there is no significant change in the content of FFA with the increase of the reaction time.

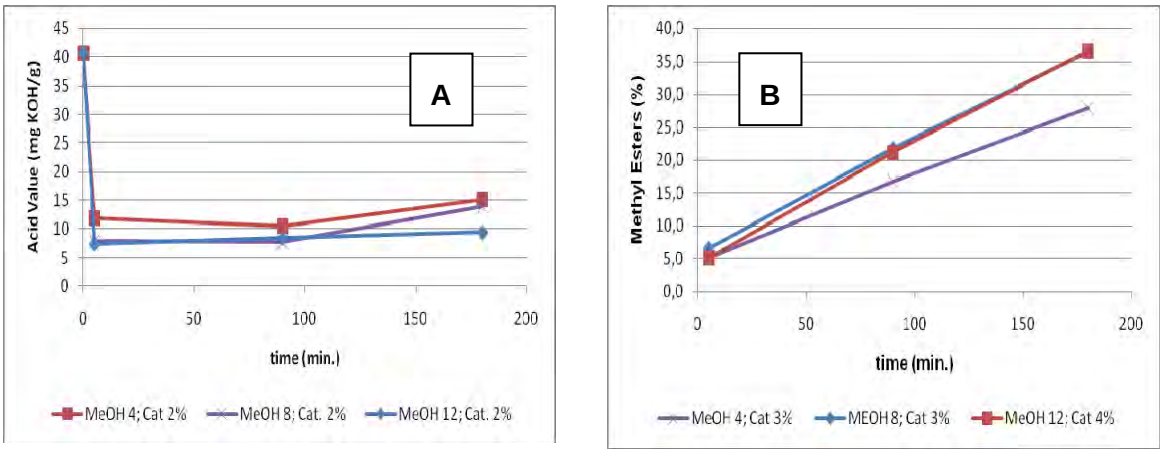

Figure 3A and 3B –Influence of the MeOH:FFA in the Acid value (A) and Fatty Acid Methyl Esters content (B).

The effect of the catalyst:oil mass ratio is shown in Figures 4 A and B. From these figures it is possible to conclude that, although the amount of catalyst has only a slight influence in the FFA content, the methyl esters content increases with the increase of the catalyst:oil ratio. Figure 4 B shows that the methyl esters content surpasses the content of FFA in the initial feed (≈20%), resulting in a mixture that has a higher amount of esters thus leading to a materials that can be easily transesterifyed.

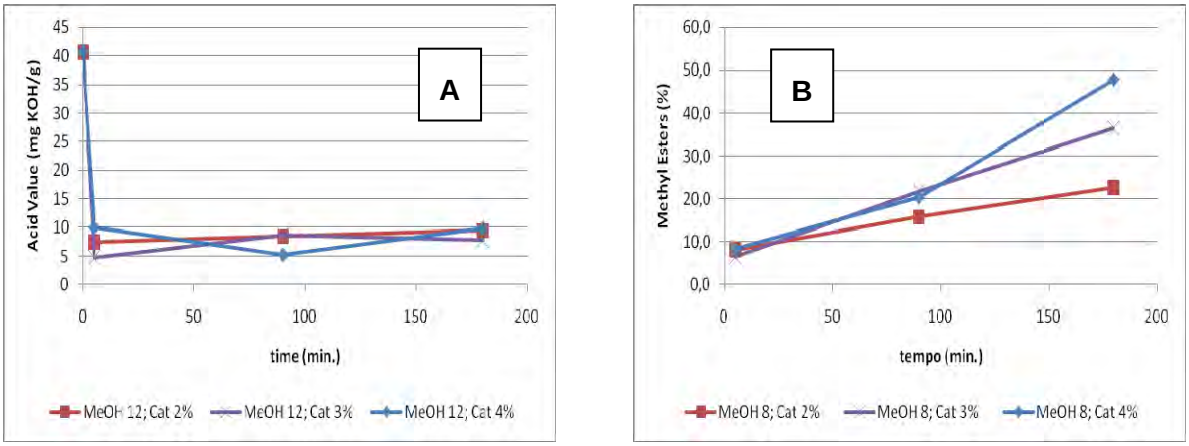

Figure 4 - Catalyst:Oil influence in Acid value (A) and Fatty Acid Methyl Esters content (B).

3.2 Glycerolysis

The preliminary study of glycerolysis was carried out with industrial acidulated soap-stocks produced from the soybean oil neutralisation process. For the glycerolysis experiments, three levels of glycerol:FFA molar ratios were used (1.1, 1.3 and 1.5) and Figure 5 presents the results. From this Figure it is possible to conclude that the addition of glycerol to the reaction mixture improved the kinetics of glycerolysis. However, for a molar ratio higher than 1.3, the final acid value obtained after 120 minutes of reaction is the same. The best results (acid value ≈ 10 mg KOH/g) were obtained using a ratio of glycerol:FFA of 1.3 or 1.5 and a reaction time of 180 minutes (Figure 5). The use of tetrapropyl orthotitanate as catalyst was also tested but no significant improvements were achieved.

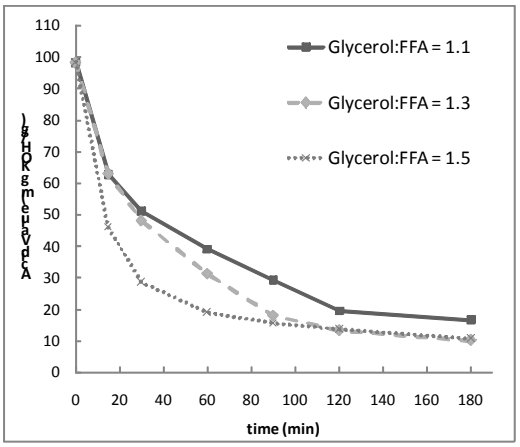

Figure 5 – Glycerolysis reaction kinetics

From Figure 5 it is possible to conclude that the rate of the reaction is lower when compared to the methanolysis. To reach a FFA content lower than 5% (Acid Value ≈ 10 mg KOH/g) it is necessary more than 3 h of reaction. The use of high temperatures is also a disadvantage of

glycerolysis, in spite of allowing the continuous removal of water and therefore the drift of the reaction towards the products. However, glycerolysis has the advantage of using as a reagent a by-product of the biodiesel production process.

4 Conclusions

The results presented in this work show that glycerolysis and methanolysis may be used to reduce the free fatty acids content in acidic and low-cost feedstocks for biodiesel production. In fact, it was possible to reduce the FFA content of a mixture of WFO and soap-stocks from 20% to 4% in 5 minutes by methanolysis. Glycerolysis, which has the advantage of using glycerol from the biodiesel production process, allowed reducing the content of FFA in an industrial soap-stock from 50 to 5 % after 3 hours of reaction at 200ºC. Also, it was effective in the reduction of the FFA content without the addition of any catalyst. However, the use of temperatures around 200º C is clearly a disadvantage, although it allows the continuous removal of the water formed in the reaction (Reaction 3) and the drift of the equilibrium towards the products. On the contrary, methanolysis takes place at 65 ºC and presents therefore lower energy costs. In this temperature range water is not removed from the process and this limits the esterification reaction after the equilibrium is reached. When compared to glycerolysis, methanolysis presents another disadvantage by requiring a large amount of methanol to obtain an effective reduction of the FFA content. It is however worth noting that one of the greatest advantages of methanolysis is the production of fatty-acid methyl esters (biodiesel) instead of mono-, di- and triglycerides, which is very interesting when the main objective is the production of biodiesel after the esterification. Furthermore, as shown above, the transesterification of the glycerides, which is the main goal of the global process, occurs simultaneously with the esterification reaction.

Acknowledgements

The authors thank Iberol and Space for supplying industrial samples of soap-stocks and the waste frying oils for the development of this work. Pedro Felizardo would also like to thank Fundação para a Ciência e Tecnologia (SFRH/BDE/15566/2005) and Space for his PhD financial support.

Topic: Sustainable process-product development through green chemistry - Environmental engineering & management

Abstract

The objective of the present study was to evaluate the difference of using sunflower oil or waste frying oil for the production of biodiesel through transesterification, using different concentrations of the currently more used catalyst in the industry (CH_3ONa). For that purpose, different experiments were conducted using a 6:1 methanol/oil molar ratio, temperature of 60 ºC, and varying the amount of catalyst used. The biodiesel yield was evaluated and so was the quality of the final product; the characterisation of the produced biodiesel was made according to the European Biodiesel Standard EN 14214.

It was possible to obtain a product in agreement with the EN 14214 using both oils. All samples fulfilled the specifications regarding the following parameters: acid value, density, flash point, copper corrosion and linolenic acid methyl ester content. In terms of iodine value, biodiesel from waste frying oil was within the limit but the one from sunflower oil showed a slightly higher value.

Viscosity and purity were the limiting parameters to select the best catalyst concentration; at 0.6 %, both samples fulfilled the specification in terms of kinematic viscosity; however, higher catalyst concentration (0.8 %) was needed to achieve minimum purity using waste frying oil.

The highest yield (93.4 %) and purity (99.4 %) was obtained using sunflower oil as raw material.

Considering the present study, the optimum catalyst concentrations were: i) 0.6% for the production of biodiesel with a yield of 90 % and presenting a purity of 99.4 % using sunflower oil; and ii) 0.8 % catalyst concentration for the production of biodiesel with a yield of 89 % and presenting a purity of 97.9 % using waste frying oil.

1 Introduction

Increased attention has been given to biodiesel, which is currently being used as an alternative fuel in compression-ignition engines. Biodiesel is an ester that can be produced by transesterification of vegetable oils or animal fats. During this reaction, the triglyceride is converted step by step into a diglyceride, monoglyceride and glycerol; at each step, one mol of ester is produced (Fig. 1). There are many parameters affecting the transesterification reaction. The ones known to greatly influence the reaction are: temperature, methanol/oil molar ratio, mixing rate, catalyst type and amount of catalyst (Meher, L. C., et al., 2006, Ma, F. and Hanna, M. A., 1999).

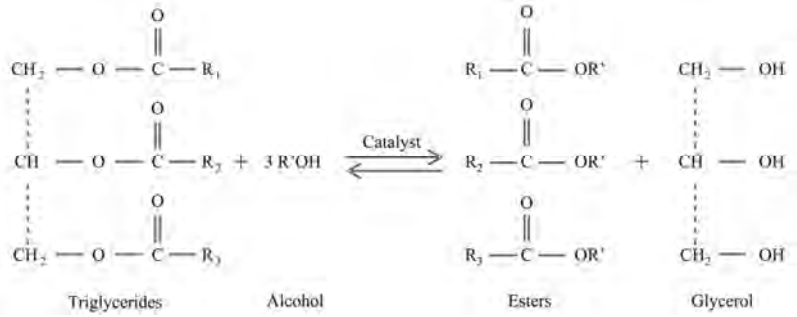

Fig.1 - Transesterification reaction of triglycerides (global reaction).

The increasing costs of refined oils are currently a great concern for biodiesel industry; therefore, alternative raw materials are being studied with more emphasis. The use of waste frying oils and other greasy wastes as raw materials for biodiesel production has two major advantages: i) decreases biodiesel production costs (because it uses readily available raw-materials with low economic value); and ii) reduces waste treatment costs (related with the waste management and wastewater treatment processes) (Wang, Y., et al., 2006, Encinar, J. M., et al., 2005, Tomasevic, A. V. and Siler-Marinkovic, S. S., 2003).

The objective of the present study was to evaluate the difference of using sunflower oil or waste cooking oil for the production of biodiesel through transesterification, using different concentrations of the currently more used catalyst in the industry (CH_3ONa).

2 Materials and Methods

2.1 Materials

The sunflower oil used was from the brand “3Ás equilíbrio” and was donated by Sovena, SA, Portugal. This oil was in agreement with Portuguese specifications for food oil. The waste frying oil was obtained from a voluntary collection system implemented at the Engineering Faculty of Oporto University and consisted of waste frying oil from different domestic sources. The reagents used during synthesis and purification procedures were: methanol 99.5% (analytical grade, Fischer Scientific), sodium methoxide solution 30% in methanol (synthesis grade, Panreac) and anhydrous sodium sulphate 99% (analytical grade, Panreac).

2.1 Methods

2.1.1 Raw materials Pre-treatment

Waste cooking oil was filtered under vacuum, after dehydrated using anhydrous sodium sulphate (left over night) and finally again filtered under vacuum.

2.1.2 Biodiesel Synthesis

Synthesis of biodiesel was made by transesterification. A defined amount of methanol (6:1 molar ratio to oil) was pre-mixed with CH_3ONa. The amount of catalyst varied from 0.4 to 1% of oil mass, in 0.2 intervals. The mixture of methanol and catalyst was then added to the reactor, which already had 200 g of the oil (sunflower 227.4 mmol and waste frying oil 227.9 mmol) preheated at the reaction temperature (60 ºC). At this point, the reaction started; the reactor consisted on a 1L flat-bottom flask immersed in a temperature controlling bath, equipped with a water-cooled condenser and a magnetic stirrer. Reaction occurred for 60 min under vigorous stirring; at the end of the reaction, products were left to settle for 2 hours to ensure the separation of the two phases: biodiesel and glycerol.

2.1.3 Biodiesel Purification

Both phases were separated and excess methanol was recovered from each phase, using a rotary evaporator under reduced pressure. After, biodiesel was washed, first with 50% (v/v) of an acid solution (0.2% HCl) and after repeatedly with 50% (v/v) of distilled water until the pH of the washing water was the same as the distilled water. To remove residual water, biodiesel was after dried over anhydrous sodium sulphate (left over night) and finally filtered under reduced pressure to obtain the final product.

2.1.4 Analytical methods

Different properties of the raw materials were determined: i) composition (using gas chromatography (GC) according to EN 14103 (2003) and NP EN ISO 5508 (1996)); ii) acid value, by volumetric titration according to the standard NP EN ISO 660 (2002); iii) iodine value, by volumetric titration using Wijs reagent, according to the standard ISO 3961 (1996); and iv) water content, using coulometric Karl Fischer titration.

The biodiesel quality was evaluated according to the European biodiesel standard EN 14214 (2003). The following properties were determined: i) acid value, by volumetric titration according to the standard EN 14104 (2003); ii) kinematic viscosity, determined at 40 ºC using glass capillary viscometers according to the standard ISO 3104 (1994); iii) density, determined using a hydrometer method according to the standard EN ISO 3675 (1998); iv) flash point, using a rapid equilibrium closed cup method, according to the standard ISO 3679 (2004); v) copper corrosion, using a copper strip test according to the standard ISO 2160 (1998); vi) water content, by Karl Fischer coulometric titration according to the standard NP EN ISO 12937 (2003); vii) ester and linolenic acid methyl ester contents, by GC according to the standard EN 14103 (2003) and; viii) iodine value, determined from ester content according to annex B of EN 14214 (2003). Regarding to chromatographic analysis, a Dani GC 1000 DPC gas chromatograph (DANI Instruments S.p.A.), with an AT-WAX (Heliflex capillary, Alltech) column (30 m, 0.32 mm internal diameter and 0.25 μm film thickness) was used. The injector temperature was set at 250 ºC, while the detector (FID) temperature was set at 255 ºC. The carrier gas used was N_2 with a flow of 2 mL/min. Injection was made in a split mode, using a split flow rate of 50 mL/min, the volume injected was 1 μL.

3 Results and discussion

3.1 Raw material characterisation

The fatty acid composition and the mean molecular weight (calculated from the composition) of the oil samples are presented in Table 1. Composition of waste frying oil did not vary much from the sunflower oil; main difference was found in C16:0 and C18:3 which might indicate the presence of a small fraction of soybean oil. Regarding C18:1 and C18:2; differences could be expected due to oxidation reactions with temperature; however, this was not the case and similar results have also been found in related studies. Çetinkaya and Karaosmanoğlu (2004) attributed this fact to sunflower oil exposed to high temperature for a short period of time. Because the waste frying oil used in this study was from a domestic source, this might justify these findings. Sunflower oil had an acid value of 0.08 mg KOH/g and an iodine value of 123 g I_2/100 g. Waste frying oil had an acid value of 0.82 mg KOH/g and an iodine value of 117 g I_2/100 g. The water content was 0.05 (% wt) for the waste frying oil and 0.04 (% wt) for soybean oil.

The acid value of the virgin oil was lower than the waste frying oil, however much higher acid values have been reported in waste frying oils; the previously discussed low variation in composition, which indicates smaller degree of oxidation reactions, should be related with such small value found.

Table 1: Fatty acid composition (% wt) and mean molecular weight (g mol^{-1}) of the sunflower oil and waste frying oil

	Sunflower oil	Waste frying oil
Fatty acid		
Palmitic (C16:0)	5.7	8.4
Palmitoleic (C16:1)	n.d	0.2
Stearic (C18:0)	4.0	3.7
Oleic (C18:1)	35.2	34.6
Linoleic (C18:2)	53.5	50.5
Linolenic (C18:3)	0.1	0.6
Arachidic (C20:0)	0.3	0.4
Eicosenoic (C20:1)	0.2	0.4
Eicosadienoic (C20:2)	0.1	n.d
Behenic (C22:0)	0.7	0.8
Docosadienoic (C22:2)	0.1	n.d
Lignoceric (C24:0)	0.2	0.3
Mean molecular weight	879.5	877.5

n.d. not detected

3.2 Biodiesel production yields

Table 2 shows production yields using both raw materials. The lowest yield obtained was for the highest catalyst concentration using both oils; the highest yield using waste frying oil was obtained at the lowest catalyst concentration; however, using sunflower oil, it was obtained using 0.8 % wt catalyst (differences were less than 2% compared to the lowest catalyst concentration). It can be seen that at lower catalyst concentrations (0.4, 0.6 %wt), the difference of using both oils was not very much reflected; however, at higher catalyst concentrations, biodiesel produced using CH_3ONa showed yields approximately 4 % higher for both catalyst concentrations. This fact should be related with the formation of soaps at higher catalyst concentrations, due to the higher fatty acid value of waste frying oil.

Table 2: Biodiesel production yields (wt %) using sunflower oil and waste frying oil as raw materials

Catalyst (% wt)	Sunflower oil	Waste frying oil
0.4	91.6	92.0
0.6	90.0	89.2
0.8	93.4	89.0
1.0	89.6	85.3

3.3 Biodiesel quality

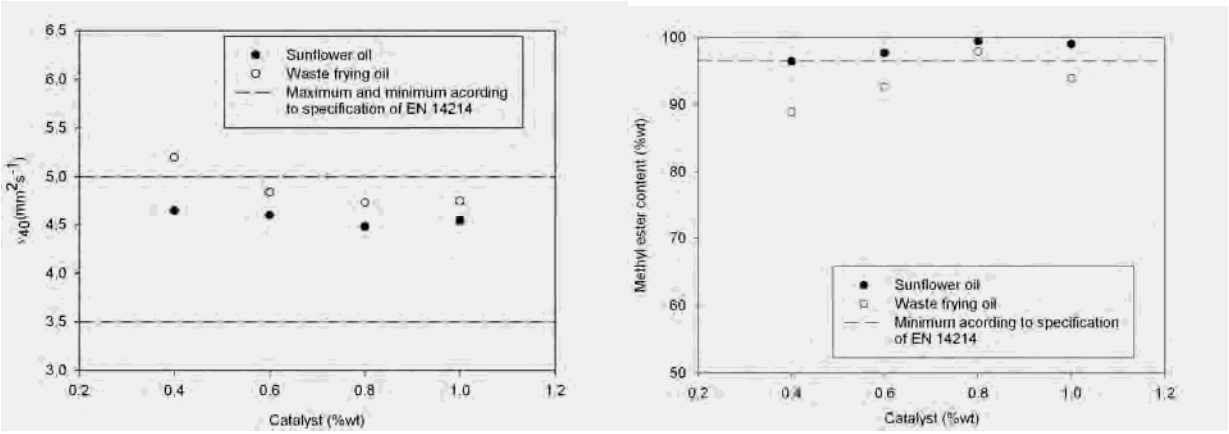
As it can be seen in Table 3, all samples fulfilled the EN 14214 regarding the following properties: acid value, density, flash point, copper corrosion and linolenic acid methyl ester content. From the parameters analysed in biodiesel samples, the ones that were not fulfilled in some cases were the kinematic viscosity and methyl ester content (purity); the ones that were not fulfilled in any case were the water content and the iodine value in the case of using sunflower oil as raw material.

Table 3: Quality parameters of biodiesel from sunflower oil and waste frying oil and the respective standard limits according to EN 14214

Parameter	Results	EN 14214
Acid value (mg KOH g^{-1})	0.09-0.27	<0.50
Water content (mg kg^{-1})	949-1216	<500
Kinematic viscosity at 40 ºC (mm^2 s^{-1})	4.48-5.20	3.50-5.00
Density at 15ºC (kg m^{-3})	881-886	860-900
Flash point (º C)	174-180	>120
Copper corrosion (3h/50 º C)	All samples-Class 1a	Class 1
Methyl ester content (wt %)	88.9-99.4	>96.5
Linolenic methyl ester content (wt %)		
Sunflower oil	0.1	<12.0
Waste frying oil	0.6	
Iodine value*(g I_2/100g)		
Sunflower oil	123	<120
Waste frying oil	119	

*Calculated from the methyl ester composition

It was found that biodiesel viscosity decreases with increasing catalyst concentration and purity increases with increasing catalyst concentration (Fig. 2). For both parameters, almost no restrictions regarding the fulfilment of EN 14214 were found using sunflower oil; however, using waste cooking oil, at least 0.6% catalyst was needed to fulfil viscosity requirements and only at 0.8% catalyst concentration it was possible to obtain enough purity.



(a) (b)

Fig. 2 - Biodiesel produced using CH_3ONa as catalyst: (a) kinematic viscosity (mm^2s^{-1}) and (b) methyl ester content (% wt).

Regarding the biodiesel water content, the adopted diagram production included a dehidration step using a salt (anhydrous sodium sulphate). However, the use of this salt was shown to be very ineffective. To reduce water content to acceptable values, a different procedure was evaluated using biodiesel from sunflower oil. The sample (water content of 0.10 (% wt)), was subjected to evaporation under reduced pressure using a rotary evaporator at 40 and 60 ºC (163 mbar, 45 min). The water content was then reduced to 0.04 (% wt) at 40 ºC and to 0.02 (% wt) at 60 ºC. These results show that evaporation under reduced pressure might be a suitable procedure to ensure the fulfilment of the European specification for water content.

Regarding the iodine value, as this parameter depends only on the raw material used, samples obtained using the same vegetable oil should present similar iodine value. That was confirmed in

results presented in Table 4, and, for this reason, sunflower oil is not a very attractive raw material aiming to fulfill this parameter.

3 Conclusion

It was possible to obtain biodiesel in agreement with the EN 14214 by transesterification of both virgin and waste frying oil; however, in terms of iodine value, sunflower oil showed a value slightly higher than the limit. Also, biodiesel water content was always above the limit and therefore, a dehydration step using an anhydrous salt was not effective. Evaporation at reduced pressure was evaluated and might be an efficient alternative.

Considering the variations in catalyst concentration, the following parameters were fulfilled in all cases: acid value, density, flash point, copper corrosion and linolenic acid methyl ester content. Viscosity and purity were the limiting parameters to select the best catalyst concentration; at 0.6 %, both samples fulfilled the specification in terms of kinematic viscosity; however, higher catalyst concentration (0.8 %) was needed to achieve minimum purity using waste frying oil.

The highest yield (93.4 %) and purity (99.4 %) was obtained using 0.8 % catalyst concentration and sunflower oil as raw material. However, in order to optimize production costs, a smaller amount of catalyst might be used (0.6 %).

Considering the present study, the optimum catalyst concentrations were: i) 0.6 % for the production of biodiesel with a yield of 90% and presenting a purity of 99.4 % using sunflower oil; and ii) 0.8 % catalyst concentration for the production of biodiesel with a yield of 89 % and presenting a purity of 97.9 % using waste frying oil.

Topic: Sustainable process-product development through green chemistry

Abstract:
This paper describes preliminary work done by the authors towards the development of new metallic heterogeneous catalysts that are to be used in the transesterification reaction of triglycerides, which is of considerable interest in the production of biodiesel. Biodiesel, is a mixture of mono-alkyl esters of fatty acids, and is currently manufactured by transesterification of triglycerides with methanol using NaOH or KOH as liquid base catalyst. Catalysts as such are corrosive to the equipment and another drawback is that these catalysts are in liquid phase and must be neutralized after the completion of the reaction, typically using HCl, thus producing salt streams. Moreover, due to the presence of free fatty acids it reacts to form soaps as unwanted by-products, hence requiring more expensive separation processes. Therefore, there is a great need on the development of industrial processes for biodiesel production using solid acid catalysts. The key benefit of using solid acid catalysts is that no polluting by-products are formed and the catalysts do not have to be removed since they do not mix with the biodiesel product.

Introduction:

Biofuels are all the fuel substances produced from Biomass and includes the Biodiesel (single alkyl ester of fatty acids), bioethanol and biogas (a mixture of methane and CO_2). The highway transports activity, in a global level, is 98% oil dependent. In the EU, this activity is responsible by more than 20% of total CO_2 emissions and, more than 50% of these emissions concerns to the individual transport, which increase 22% since 1999. The climate changes, the increase of crude prices and the supply energetic security leads to the growing interest about biofuels potential as substitutes of oil fuels, like gasoline's and diesel (OE, 2007). Actually, the biodiesel production is made essentially, from oleaginous plants by transesterification process (as shown in figure 3), which involves, as reactants, alcohol, essentially, methanol (CH_3OH) and a catalyst, preferably alkaline, liquid phase (NaOH, KOH, sodium methoxide). This process occurs with homogeneous catalysis. The main raw materials, which are the mentioned oils from oleaginous plants, previously refined, are, in majority, of colza, sunflower and soya. It can be done, also, by other plants, such as palm oil. Chemically, biodiesel is described as a mixture of methyl ester's of fatty acids, where, through the transesterification process, are produced those ester's (single, double and triple triglycerides), and produces also, Glycerine as co-product reaction (OE, 2007 and BRP, 2004). The quality of biodiesel must comply with several specifications in order to ensure a final product with good quality, main issue to guarantee his suitably introduction in the market. Naturally, the oil quality has significantly influence in the labour process qualification and in the biodiesel final specifications. It's important, also, refer that, to ensure those specifications, the production process has to be controlled, either at the reaction control level, either, basically, at the purification process level, where occurs the biodiesel/methanol,

biodiesel/catalyst and biodiesel/water separation steps, through the washing of biofuel. One of the most important control parameters of biodiesel is the maximum proportion of total glycerine, which is 0,25% in the European and American technical standards, in order to avoid the formation of particles in the combustion chamber and, also, to avoid the production of higher percentages of acrolein on the automobile combustion gases (BPR, 2004). Other important parameters are the viscosity, the water content, the iodine index, the proportion of single, double and triple triglycerides, the methanol proportion, the sulphur proportion, ashes, carbon residue, total contamination and cetane number. The biodiesel specifications currently available and used are described on the EN 14214 standard. The table 1 presents the goals stipulated by the EU to the incorporation of biofuels in the fuel oils until 2010, which includes the incorporation of biodiesel on the diesel fuel (Pelkmans, 2007). Figure 1 shows the process diagram of biodiesel production and figure 2 shows a generic flow-sheet of the same process.

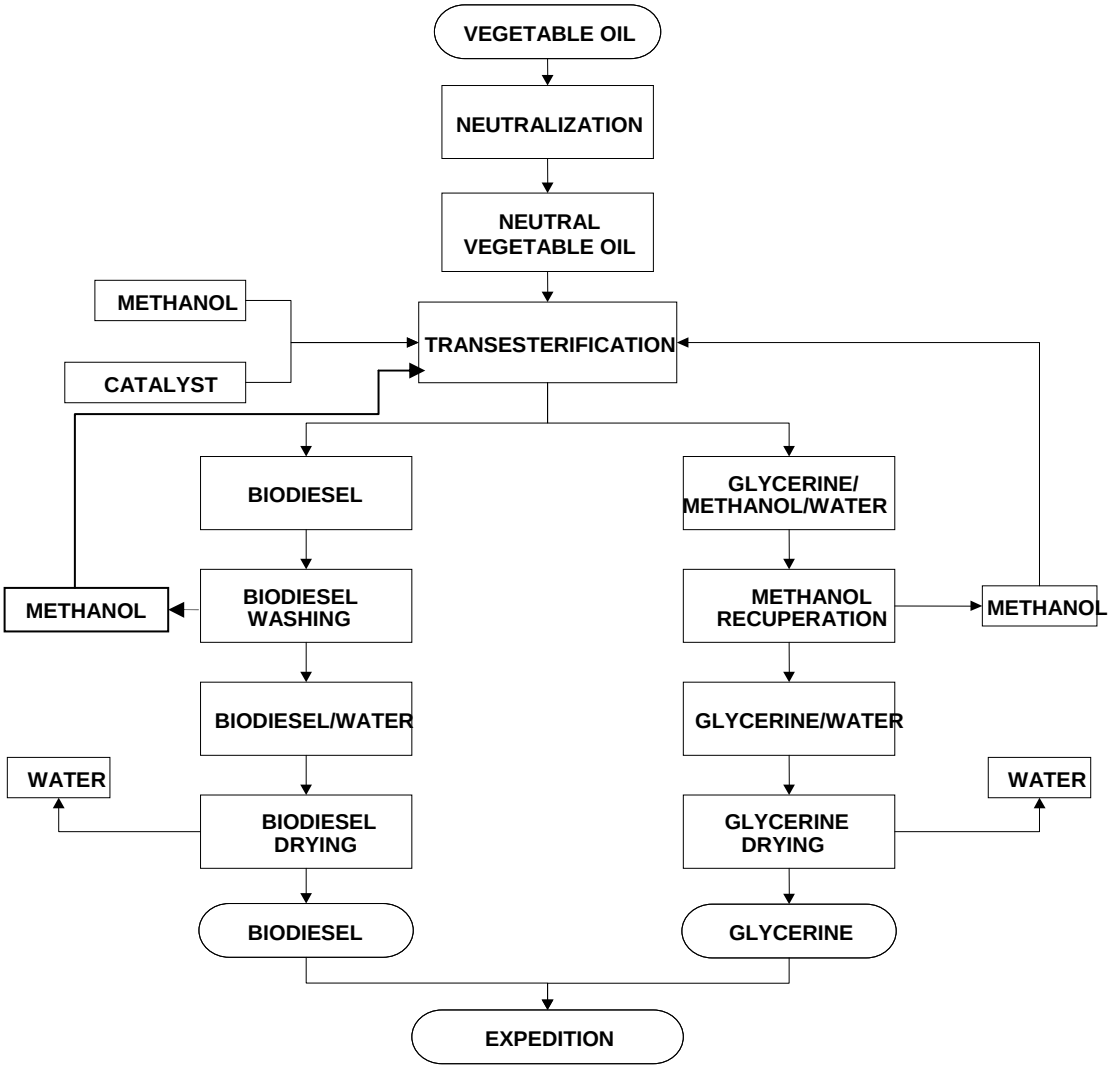

Figure 1: Schematic process diagram of biodiesel production

Development of newest heterogeneous catalysts for biodiesel production:
The transesterification reaction is considered the process with more technical effectiveness and with higher efficiency for biodiesel production using large scale, with minimization of co-products. Nevertheless, it's essential that, the raw materials (vegetable oils) keep a minimum level of quality, which can be achieved in the presence of acids, alkaline or enzymatic catalysts, simples or supported. The use of acid catalysts, like sulphur acid, leads to a reaction kinetic much lower when compared with alkaline catalysts. Other disadvantage in the utilisation of these kinds of catalysts is concerned with biodiesel separation from the process, in order to prevent possible damages to the engines structures, caused by the acid catalyst. On the opposite side, basic catalysts are faster and, in many cases, the steady-state is achieved at 15-30 minutes and leads to higher biodiesel yields, generally higher than 50%. However, they have the inconvenient of being sensible at the presence of water and free fatty acids. These last ones consume the catalyst and conducts to the formation of gels and soaps. These demands difficult the utilisation of used fried oils. On another hand, the enzymatic catalysts offer some advantages when compared with acids and alkaline catalysts, like, for instance, less sensibility to water presence, more catalyst recovery and more efficiency in the biodiesel separation steps. However, their utilisation implies higher costs (BRP, 2004). Other different option is the employment of heterogeneous catalysts in the biodiesel production, in order to replace the conventional homogeneous alkaline or acids catalysts, to eliminate the difficulties founded in the current biodiesel/catalyst separation. These new catalysts are solid. On another hand, these alternative and innovative solutions in the biodiesel production system allowed, more economic profitability and competitiveness to the process and, brings also, more environmental compatibility, when compared with the conventional processes. In this last issue, the use of heterogeneous catalytic systems in the transesterification of triglycerides implies the elimination of several washing/recovery biodiesel/catalyst process steps, in order to ensure a higher efficiency and profitability of the process, lowering the production costs.

There is, also, the strong possibility of being implemented in a continuous way, with the construction of a fixed bed catalytic reactor. The utilisation of heterogeneous catalysts implies higher lifetimes, because there is no need in their recirculation to the initial step (mixture), since the catalyst utilisation time is higher than the homogeneous catalytic processes. This means less catalyst replacements on the fixed bed catalytic reactor, which leads to a higher quality of the final product and, also, to the co-product, the glycerine. However, either the reaction conversion, either the *turnover number*, in order to keep constants, there is the necessity of optimize the operating conditions in the reactor. A literature search on these subjects was already done and the main results and contributions of several authors are synthesized in table 2. The optimization process at industrial scale needs, to perform a previous study, at laboratory scale, which concerns to perform several modifications of concentration ratios, temperature, catalyst structure and composition and time residence, in a fixed bed catalytic reactor. After that, we intend to optimize the biodiesel process production with heterogeneous catalysis, performing the scale-up in a pilot unit and quantify his composition, according to the EN 14214 standard specifications. Figure 4 shows a possible *flow-sheet* for biodiesel production process with heterogeneous catalyst.

The main aspects for Biodiesel production, in order to ensure that there aren't problems and difficulties in the vehicles performances, are, the following ones:

- Complete reaction;
- Glycerin removal;
- Catalyst removal;
- Alcohol and Water removal;
- Absence of Free Fatty-Acids.

Best results for supported alumina catalysts for alkaline catalysis, whilst the silica catalysts showed best results for acid catalysis.
Rosa *et al* (2007)	K_2CO_3, Na_2CO_3 e $CaCO_3$	Mamona oil transesterification with methanol, ratio oil/ methanol/ catalyst of 100/600/1, reaction time of 10 h. K_2CO_3 showed best catalytic activity and higher yields in biodiesel production. $CaCO_3$ do not show any catalytic activity.
Brito *et al* (2007)	Zeolite Y	Employment of used fried oils. Good results regarding biodiesel yield.
West *et al* (2007)	ZrO_2/SO_4^{2-},	Good results at catalyst activity and in the biodiesel yield production.
Santos *et al*(2007)	Hydrotalcytes of Mg and Al (ratio Mg/Al of 3), modified with Zn, Sn, Ba, Mn, Ce and Ca, with 5% catalyst (%w/w)	Soya oil transesterification with methanol, 70ºC, reaction time of 3 h, ratio methanol/oil of 9:1. Good results regarding biodiesel yield and product quality.

Conclusions:

On a first approach, it is possible to conclude that, the main advantages of replacing the actual homogeneous catalysts by heterogeneous catalytic matrices (solids structures), concerns with the establishment of surplus-values in a process, economic and environmental points of view, in which this last one depends of minimization of waste solid and liquid production on the labour process. On another hand, it's possible affirm that, through the experimental results searched on the performed bibliographic research that, either the catalytic activity, either the biodiesel yields obtained, either the biofuel quality (fulfilment of the control quality parameters stipulated in the EN 14214 standard) were maximized with supported metallic catalysts matrices, mostly the ZrO_2/SO_4 heterogeneous catalyst matrix, for several temperatures, preferably, the higher ones, in the gap between 65 and 70ºC, with large quantities of methanol, six times higher that the vegetable oil quantity and with percentages rounded 1% of catalyst comparatively with the vegetable oil used in the transesterification process.

Keywords: Biodiesel, Candida Antarctica, Fluidized Bed

Abstract

The objective this work was investigated a new route for biodiesel production using Immobilized Candida Antarctica in continuous Fluidized Bed Bioreactor. Conventionally, Biodiesel (fatty acid methyl esters) is produced by transesterification in which, oil or fat is reacted with a monohydric alcohol in presence of a catalyst. In recent years, the use of lipases as biocatalysts for biodiesel production has become of great interest due to its environment friendly. But some alcohols such as methanol inactivated the lipases to some extent and the enzymatic stability was poor. In order to enhance the stability of the lipase, three-step methanolysis was adopted, however, glycerol, as one of the products was easy to adsorb on the surface of lipase resulting in serious negative effect on the enzymatic activity. For to solve problems was used the interesterification kinetics of triglycerides and methyl acetate for biodiesel production was modeled. A heterogeneous model describing the interesterification process in an immobilized enzyme fluidized-bed bioreactor was developed. A simplified model based on Ping Pong Bi Bi with substrate competitive inhibition mechanism was proposed to describe the reaction kinetics of the interesterification.The model without any adjustable parameters was used to predict the interesterification process. The key parameters which measured the extent of external and internal mass-transport resistances, as well as the degree of back-mixing were quantified and discussed. The fluidized-bed bioreactor considered in this investigation is composed of two phases: a fluid phase comprised mainly of the triglycerides and methyl acetate and the product (Biodiesel); and a solid phase which is the immobilized enzyme. The effects of some operating and design parameters on the performance of the fluidized-bed bioreactor were also analyzed. The model was also tested for its sensitivity to changes in hydrodynamic parameters.

1 Introduction

Biodiesel is mono-alkyl esters of long chain fatty acids derived from renewable vegetable oils and animal fats. Biodiesel (fatty acid methyl esters) is produced by transesterification in which, oil or fat is reacted with a monohydric alcohol in presence of a catalyst. In the transesterification of vegetable oils, a triglyceride reacts with an alcohol in the presence of a strong acid or base, producing a mixture of fatty acids alkyl esters and glycerol. The overall process is a sequence of three consecutive and reversible reactions, in which monoglycerides are formed as intermediates. The stoichiometric reaction requires 1 mol of a triglyceride and 3 mol of the alcohol. However, an excess of the alcohol is used to increase the yields of the alkyl esters and to allow its phase separation from the glycerol formed. The alcohols employed in the transesterification are generally short chain alcohols such as methanol, ethanol, propanol butanol, and methyl acetate.

Biodiesel has become more attractive recently because of its environmental benefits and the fact that it is made from renewable resources (Schuchardt et al., 1998). The

transesterification of vegetable oils with methanol or ethanol as well as the main uses of the fatty acid methyl esters are studied in this paper. The general aspects of this process and the applicability of different types of catalysts (acids, alkaline metal hydroxides, alkoxides and carbonates, enzymes and non-ionic bases, such as amines, amidines, guanidines and triamino(imino)phosphoranes) (Jordan and Gutsche, 2001; Fangrui and Hanna, 1998; Filippis et al., 1995; Antolín et al., 2002) are described, and ambient or elevated pressures and temperatures.

Conventionally, biodiesel was produced by transesterification of triglycerides and alcohols in the presence of an acid or an alkaline catalyst. In recent years, the use of lipases as biocatalysts for biodiesel production has become of great interest due to its environment friendly. However, some alcohols such as methanol inactivated the lipases to some extent and the enzymatic stability was poor. In order to enhance the stability of the lipase, three-step methanolysis was adopted, however, glycerol, as one of the productswas easy to adsorb on the surface of lipase resulting in serious negative effect on the enzymatic activity Xu et al (2003), Dossat et la (1999) and Du et al (2004).

In order to solve the above-mentioned problems, we previously reported that using methyl acetate as acyl acceptor instead of methanol for biodiesel production could enhance the stability of the lipase significantly and in the process, triacetylglycerol instead of glycerol would be produced and it has been demonstrated that triacetylglycerol had no negative effect on the activity of the lipase. Moreover, triacetylglycerol was an important by-product with a higher value than glycerol and this novel route was thought to be very promising for large scale production of biodiesel.

2. Model Development

2.1 Kinetic Model

The enzymatic model used to describe the interesterification kinetics was based on the model Ping Pong Bi Bi with competitive inhibition for the substratum. The equation of that mechanism is shown:

$$V_i = \frac{V_{\max}[TG][AM]}{K_{M_{TG}}[AM]\left(1+\frac{[MA]}{K_I}\right)+K_{M_{AM}}[TG]+[TG][AM]} \quad (2.1)$$

where V_i was the initial reaction rate; [TG] and [A] the initial molar concentrations of triglycerides and methyl acetate, respectively; K_{mTG} and K_{mA} the apparent Michaelis constants for triglycerides and methyl acetate, respectively; K_i the apparent inhibition constant of methyl acetate and Vmax the initial maximum velocity of the reaction. The kinetic constants are shown in Table 2.1 Xu et al (2005).

Parameters	Value
V_{max} (mol/lmin)	1.9
K_{mTG} (mol/l)	1.0
K_{mA} (mol/l)	16
K_i (mol/l)	0.0455

2.2 Solid Phase Mass Balance

The fluidized-bed bioreactor considered in this investigation is composed of two phases: a fluid phase comprised mainly of the substrate (oil and methyl acetate) and the product (Biodiesel); and a solid phase which is the immobilized enzyme. The following assumptions are employed in the model: (1) the system is isothermal; (2) the movement of reactant within the biocatalyst can be described mathematically by Fick's law of diffusion where the effective diffusion coefficient is constant and independent of concentration; (3) the enzyme activity is uniform throughout the particle; (4) the fluid phase back-mixing can be quantified by an axial dispersion coefficient.

The general mass balance equation governing the concentration distribution in the fluid phase of the biocatalyst is given by:

$$D_L \frac{d^2 C_f}{dZ^2} - U_0 \frac{dC_f}{dZ} - (1-\varepsilon) r_V \tag{2.2}$$

and the Danckwert's boundary conditions are:

$$when\ Z = 0,\ -D_L \frac{dC_f}{dZ} + UC_f = UC_f \tag{2.3}$$

$$when\ Z = L,\ \frac{dC_{x,P,S}}{dZ} = 0 \tag{2.4}$$

This set of boundary conditions, that is equations 7 and 8, is widely used in modeling immobilized enzyme fluidized-bed bioreactors

2.3 Solid Phase Mass Balance

The general mass balance equation governing the concentration distribution in the fluid phase of the biocatalyst is given by equation 2.5.

$$\frac{dC_s}{dZ} = k_m (C_f - C_s) \tag{2.5}$$

with the boundary conditions given by:

$$when\ Z = 0,\ C_s = 0 \tag{2.6}$$

2.4 Evaluation of the relevant parameters

The relevant parameters relating to the dispersion coefficient, external mass-transfer resistance and bed voidage are evaluated using correlations obtained from the literature and are given below.

2.4.1 Dispersion coefficient

The dispersion coefficient, D_L, in the fluidized-bed containing light, non-porous, solid particles was evaluated using the correlation of Tang and Fan (1990) given by Equation (2.7) below.

$$D_L = \frac{U_0 H}{Pe} \tag{2.7}$$

$$\frac{1}{Pe} = 4.35 \left(\frac{\rho_s}{\rho_f} \right)^{2.64} \varepsilon^{1.467} \tag{2.8}$$

The external particle-liquid mass-transfer coefficient was obtained using the correlation of Nore et al. (1992) given by:

$$k_m = 1.1 \left(\frac{U_0}{\varepsilon} \right)^{0.43} D_p^{0.24} \tag{2.9}$$

The bed porosity in the bed is determined by the mechanics of fluidization. Hence, a realistic mathematical expression for the bed fluidization is necessary. For bed of uniform spherical particles, the following relation was proposed. The Richardson and Zaki (1954) relates bed voidage to the upflow superficial liquid velocity given as:

$$\varepsilon = \left(\frac{U_0}{U_t} \right)^{1/n} \tag{2.10}$$

The terminal velocity given by Equation (2.11) was obtained using the correlation of Khan and Richardson (1990).

$$U_t = \frac{\mu}{\rho_f D_p} \left(2.33 Ga^{0.018} - 1.53 Ga^{-0.016} \right)^{13.3} \tag{2.11}$$

where

$$Ga = \frac{\left(\rho_s - \rho_f\right)\rho_f D_p^3 g}{\mu^2} \tag{2.12}$$

The fractional conversion, Y, shown in Fig. 1 against the flow rate is defined by Equation (2.13).

$$Y = \frac{C_0 - C_L}{V_{\max} L/u} = \frac{X}{\theta} \tag{2.13}$$

where θ dimensionless residence time.

3. Results and Discussion

The modeling equations presented here constitute a system of non-linear boundary value problems which were solved by finite difference techniques. The details of solution methodology are omitted here for the sake of brevity.

Figure 1 shows the concentration of each composition triglycerides, methyl acetate and biodiesel against the height of the fluidized bed. From the Figure 2, it can be observed that, the model indicate the high concentration of biodiesel were reached in the end of the reactor. Indicating that the dispersion has influences in the interesterification of triglycerides for biodiesel production with methyl acetate.

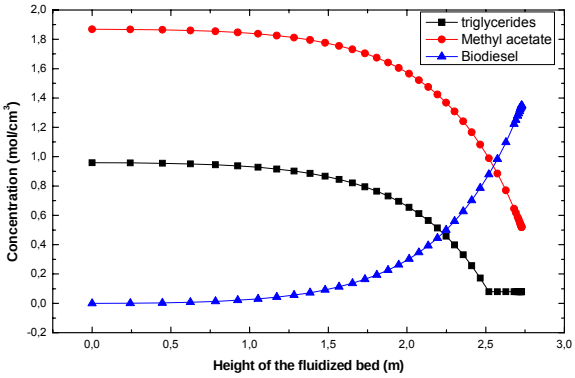

Figure 1: The concentration of triglycerides, methyl acetate and biodiesel.

The Figure 2 show the conversions obtained for the model for fluidized bed in function of the dimensionless residence time. It can be observed that the measure that the dimensionless residence time increases the values of the conversions increased. Therefore, they are high necessary times of residence for the reactor to reach high conversions.

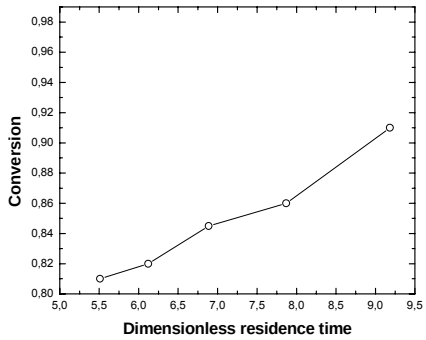

Figure 2: Conversion in fluidized bed bioreactor

Another parameter of common interest in the design of fluidized bed reactors is the Peclet number which is the measure of the degree of back-mixing in the flow vessel. As the Peclet number approaches infinity plug-flow behavior is approached, while complete mixing is approached for a Peclet number approaching zero. It is obvious from the plot of Peclet number against the dimensionless residence time. The according Equations 2.7 and 2.8 when the value the Peclet increases the dispersion coefficient value decrease. This is also indicative of dominance of mixing over segregation. Thus, the conversion increases when the value de Peclet increases.

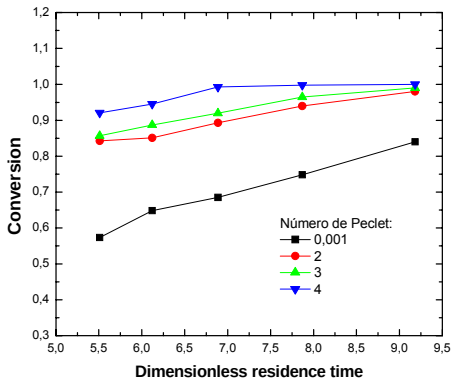

Figure 3: Effect of number of Peclet on the conversion de the fluidized bed.

4. Conclusions

In this work a continuous fluidized bed bioreactor model with Immobilized Candida Antarctica in continuous Fluidized Bed Bioreactor was developed for simulating the steady-state performance of a bioreactor for production biodiesel.

It was examined effect Peclet number and dimensionless residence time at conversion in fluidized bed. It the Peclet number decreases with the increase conversion production of biodiesel. It can be observed that conversion increased when the dimensionless residence time increased.

The model can be used to simulate the biodiesel production by interesterification in fluidized bed bioreactor and the results of the simulation were satisfactory.

Keywords: Biofuels, Biodiesel, Reaction engineering, Kinetic models
Topic: Sustainable process-product development through green chemistry.

Abstract

In this work, kinetic models were obtained from experimental data in the open literature, for both the alkaline (NaOH) and acid (H_2SO_4) homogeneous catalysis of the transesterification reaction used to produce biodiesel from vegetable oils. Two approaches, here designated as statistical and empirical, were adopted to obtain these models. For the alkaline catalysis, the results show that kinetic models fitted better a pseudo 2nd-order reaction, presenting an average error of 4% and 4.5%, using the empirical and the statistical approaches, respectively. In the acid catalysis, the kinetic models obtained fitted better a pseudo 1st-order reaction and presented average errors of 7.2% and 5.9%, also using the empirical and the statistical approaches, respectively.

1 Introduction

Currently, the transport activity in the EU accounts for approximately 30% of the total energy consumption, and is responsible for 67% of the oil demand. Consequently, oil prices and energy dependences assume a significant impact on the countries' GDPs, and represent an ever-increasing geostrategic weakness. To mitigate this, and also to comply with the Kyoto's protocol, the European Directive 2003/30/EC, transposed to Portuguese legislation in 2006, established a series of measures to promote a more intense use of biofuels, in order to attain a share of 5.75% in the transport sector, by 2010. The use of biodiesel (a mixture of fatty acid methyl esters) is one possible and attractive alternative to fossil fuels, because of its simple and established technology, and high combustion efficiency.

Biodiesel can be produced from distinctive renewable sources (edible and non-edible), e.g., greases, vegetable oils or animal fats, through a transesterification reaction with methanol, leading to glycerol as a main by-product, also with some interesting industry applications. Many process alternatives are available for biodiesel production, which can be classified by type of catalytic system used in transesterification reactions: homogeneous – alkaline or acid; heterogeneous – alkaline, acid or enzymatic; non-catalytic – supercritical alcohol. Numerous studies regarding the kinetics of transesterification and other aspects of the biodiesel production technology have been made; critical reviews by van Gerpen (2005), Sharma et al. (2008) and Vasudevan and Briggs (2008) are also available. Despite the considerable amount of work done relative to the kinetics of this system, no systematic study, which integrates experimental results from different authors, is available at the moment, in the open literature. This makes it hard to compare the performance of different catalysts at diverse reaction operation conditions, and difficults the comparison of alternative design configurations and set-up conditions for this process, based on systematic process optimization methodologies.

* Corresponding author. Tel + 351-239-798700. E-mail: nuno@eq.uc.pt

The goal of the present work is therefore to provide some preliminary results relative to kinetic models derived from experimental data available in the open literature, for the transesterification reaction of vegetable oils, through homogeneous alkaline and acid systems (the most common technologies used in industry).

Assumptions and considerations

Previous works (Noureddini and Zhu, 1997; Zheng *et al.*, 2006) studied the mass transfer limitations in the reaction's kinetics and concluded that the heterogenous effect is more pronounced for low intensity mixing rates and at the beginning of the reaction, leading to the formation of a lag phase and lower reaction rates. However, they also noted that with an intense mixing intensity (N_{Re}>6000) and with the formation of biodiesel (an emulsion agent), the reaction will be chemically controlled, and therefore the mass transfer resistance between the oil and alcohol phases is no longer important. Therefore, in this situation the reactant mixture can be considered as pseudo-homogeneous.
As described in Ma and Hanna (1999), the alcoholysis reaction consists in a group of parallel and reversible reactions. To prevent low yields of biodiesel and to avoid the formation of intermediary chemical components, an excess of alcohol is normally used, to push the equilibrium towards the products. Normally, a minimum molar ratio methanol/oil of 6:1 is chosen, making the reaction behave as practically irreversible, with a pseudo single step mechanism (Freedman *et al.*, 1984).
Freedman *et al.* (1984), Ma and Hanna (1999), and Canacki and van Gerpen (1999) reported that the free fatty acid (FFA) and water contents can have a significant inhibition effect on the reaction, for both catalysis types. In the alkaline catalysis, it was stressed that the FFA and water contents in oil should be below 0.5 % (w/w) and 0.3 % (w/w), respectively, to avoid soap formation that consumes catalyst and reduces the yield. With the acid catalysis, it was concluded that water and FFA strongly inhibit the reaction for concentrations above 0.5 % (w/w) and 5% (w/w), respectively. Water promotes the hydrolysis of triglycerides, fatty acids or esters, which is undesirable because it reduces the conversion efficiency of biodiesel. Hence, in industry, pretreatments are usually included to eliminate water and FFA in the transesterification reactors, preventing this negative effect (Zhang *et al.*, 2003).
To obtain kinetic expressions for the acid and alkaline catalysis as functions of the operating variables, the following major assumptions were considered: intense mixing rate; excess of methanol; negligible water and free fatty acid contents. Literature data was selected to fulfill the former conditions; consequently, the kinetic models obtained are only applicable to those situations.

Problem Formulation

We now describe the procedure used to obtain the kinetic models for the acid and alkaline homogenous catalysis. Considering the conversion of the limiting reactant (A), the mass balance for a batch system with a *nth* order of reaction is:

$$\frac{dX}{dt} = -kC_{A0}^{n-1}X \qquad (1)$$

At constant temperature, for the 1st and 2nd orders, if the initial time and conversion are both zero, k can be evaluated using values of conversion X_i and time t_i from

$$k_i' = \frac{-\ln(1-X_i)}{t_i} \quad [\text{min}^{-1}] \quad (2); \qquad k_i'' = \frac{X_i}{(1-X_i)C_{A0,i}t_i} \quad [\text{min}^{-1}\times\text{w(oil+methanol)/w oil}] \quad (3)$$

These expressions were used with available experimental data and fixed operating variables, such as temperature (T) in ºC, catalyst concentration in %(w/w oil) (xa) and dimensionless molar ratio methanol/oil (xm). In this case, oil is the limiting reagent, since an excess of methanol is used, and therefore C_{oil0} is used instead of C_{A0}, defined in mass units.

Two approaches, here designated as *statistical* and *empirical*, were used to fit the experimental data to the mathematical models, for each catalysis type. In the *statistical approach*, each experimental data set was used to fit the dependent variables to a set of possible predictors, using linear regression. The dependent variables considered were the kinetic constants for first (***K'***) and second (***K''***) order reactions, and their respective logarithmic transformations. As predictors, the main operating variables (***T***, ***xa***, ***xm***) and various transformations of them were considered, as shown in Table 1.

Table 1. *List of dependent variables and predictors used in the statistical analysis.*

Dependent variables	Predictors		
K'	T	xa	xm
K''	$(T+273.15)^{-1}$	xa^2	xm^2
$Ln(K')$	$Ln(T)$	$Ln(xa)$	$Ln(xm)$
$Ln(K'')$	$\sqrt{T}$	$\sqrt{xa}$	$\sqrt{xm}$
	T^2		

For each dependent variable (***Y)*** a multivariable linear regression was computed (4) with STATISTICA 7, using a forward stepwise regression procedure for variable selection, including the intercept (β_0). This guarantees that only predictors that showed statistically significant regression coefficients with a p-value of 0.05 were included in the final model. Data points that presented a standard residual greater than 2σ were considered outliers, and were consequently eliminated from both strategies.

$$Y = \beta_0 + \sum_{j=1}^{n} \beta_j X_j \tag{4}$$

In the *empirical approach*, models were obtained from a postulated general form of reaction kinetics for all species:

$$r_j = \alpha_j k(T) \prod_{i=1}^{n} (a_i^{\beta_i}) \tag{5}$$

$$a_i = \gamma_i C_i \tag{6}$$

Here β_i and α_i are, respectively, the reaction order and the stoichiometric coefficient of component *i*. If the reaction is taking place in a pseudo-homogeneous medium, from (5) and (6) we obtain:

$$r_j = \alpha_j k(T) \prod_{i=1}^{n} (\gamma_i^{\beta_i}) \prod_{i=1}^{n} (\theta_i + \frac{\alpha_i}{(-\alpha_a)} X)^{\beta_i} C_{AO}^{(\sum_{i=1}^{n} \beta_i)} \tag{7};$$

$$\theta_i = C_{io} / C_{Ao} \tag{8}$$

The activity coefficient γ_i describes the solution non-ideality, which we empirically relate with ***xa*** and ***xm***. Expressing $k(T)$ in Arrhenius law form, and considering the effects of ***xa*** and ***xm*** independent from each other, $K(T, xa, xm)$ can be expressed as:

$$K(T, xa, xm) = A e^{\frac{-Ea}{R \times (T+273.15)}} \prod_{i=1}^{n} (\gamma_i^{\beta_i}) = f(T) \times f(xa) \times f(xm) \tag{9}$$

$$r_j = \alpha_j K(T, xa, xm) \prod_{i=1}^{n} (\theta_i + \frac{\alpha_i}{(-\alpha_a)} X)^{\beta_i} C_{AO}^{(\sum_{i=1}^{n} \beta_i)} \tag{10}$$

Expression (10) can be simplified if all except one reactant (*A*) are in excess. In our case C_{A0} is replaced by C_{oil0} and the order of reaction β_A can be 1 or 2. Therefore:

$$r_j = \alpha_j K(T, xa, xm) C_{oil0} (1 - X)^{\beta_A} \tag{11}$$

A first estimate of $K(T, xa, xm)$ can be obtained through evaluation of the functions $f(T)$, $f(xa)$ and $f(xm)$ from careful chosen subsets of experimental data, changing only one variable at a time. For instance, considering a first order reaction in the acid catalysis, in order to obtain $K(T, xa, xm)$, $f(xm)$ can be determined by choosing data with $f(xa = 3)$ and $f(T = 60)$. Then for each run, $f(xm_i) = k_i'$ was considered. Here the program

CurveExpert® v1.3 was used for a rapid screen of various function families, in order to find the one that coud better fit the data. After $f(xm)$ was determined, $f(T)$ was obtained similarly, where for each run $f(T_i) = k_i' / f(xm_i)$ was considered. This was achieved with a linearization of the Arrhenius equation, leading to the values of the parameters ***A*** and ***Ea***. This sequential methodology allowed therefore a first guess of the function $K(T, xa, xm)$ for both types of catalysis, considering either first or second reaction orders. In these cases, the conversion of the reaction is given by:

$$X = (1 - e^{-K(T,xa,xm)t}) \qquad (12); \qquad X = \frac{K(T,xa,xm)C_{oil0}t}{1 + K(T,xa,xm)C_{oil0}t} \qquad (13)$$

The kinetic constant in (12) is given in *min*$^{-1}$ and in (13) is in *min*$^{-1}$× *(w(oil+methanol))/w oil*. The values obtained during this phase were afterwards used as initial guesses for a rigorous nonlinear regression of (11), considering all data points simultaneous. This was performed in *Mathematica 6*. After the kinetic models were obtained, the predicted and experimental conversions were compared for each run, and the mean relative errors were evaluated for each model, again considering first and second order reaction orders.

Results

In the acid catalysis, all studies used sulfuric acid; experimental values from Freedman *et al.,* (1984), Canacki and van Gerpen (1999), Goff *et al.* (2004), and Zheng *et al.* (2006) were considered. The regression results obtained are summarized below.

Table 2. *Mean relative error and correlation factors for acid catalysis using a statistical and an empirical strategy and considering a pseudo 1st and 2nd order.*

	1st order		2nd Order	
	Empirical	**Statistical**	**Empirical**	**Statistical**
Mean error / %	7.171	5.925	12.87	5.531
R^2 f(T)	0.9830	-	0.9996	-
R^2 f(xa)	0.8829	-	0.2931	-
R^2 f(xm)	0.9922	-	0.9565	-
R^2 K(T,xa,xm)	-	0.9866	-	0.9614

Table 2 shows that data from literature fits better to a 1st order kinetic model, since the mean error considering the average obtained for both strategies is lower and the correlation factors are consistently higher. The 1st order kinetic model expression obtained in the statistical approach is in (14) and expressions (15) to (17) are relative to the empirical approach. Using these expressions with the parameter values of Table 3 and (12) it is possible to calculate the time dependence of the with a given set of operating conditions (*T,xa,xm*).

$$K(T, xa, xm) = e^{(\beta_0 + \beta_1\sqrt{T} + \beta_2 T^2 + \beta_3\sqrt{xa} + \beta_4 \ln(xa) + \beta_5 \ln(xm))} \qquad (14)$$

$$f(T) = \beta_0 e^{\frac{-\beta_1}{(T+273.15)}} \qquad (15); \qquad f(xa) = \beta_0 - \beta_1 e^{-\beta_2 xa} \qquad (16); \qquad f(xm) = \beta_0 - \beta_1 e^{-\beta_2 xm} \qquad (17)$$

The alkaline catalyst studied here was sodium hydroxide and the experimental data was retrieved from Freedman *et al.* (1984), Noureddini and Zhu (1997), Jeong *et al.* (2004) and Leung and Guo (2006). Because in most kinetic studies with alkaline catalysis, *xm*=6 (methanol/oil=6:1), therefore *f(xm)=1* for all experiments which means that the kinetic constant will be only a function of the temperature and catalyst concentration (*K(T,xa)*). Table 4 presents the correlation factors and the mean relative error of the values predicted by each kinetic model, relatively to literature data.

Table 3. *Parameter values for expressions (14) to (17) considering a 1st order reaction, using data from Freedman et al. (1984), Canacki and Gerpen (1999), Goff et al. (2004) and Zheng et al. (2006).*

	Empirical			Statistical
	f(T)	***f(xa)***	***f(xm)***	***K(T,xa,xm)***
β_0	1.195E12	1.38382E0	2.088E-4	-1.586E1
β_1	9.189E3	1.378E0	1.721E-3	9.148E-1
β_2	-	3.357E-1	3.282E-2	1.971E-4
β_3	-	-	-	4.978E-1
β_4	-	-	-	1.131E0
β_5	-	-	-	2.792E-1

Table 4. *Mean relative error and correlation factors for alkaline catalysis using a statistical and an empirical strategy, and considering a pseudo 1st and 2nd order.*

	1st order		2nd Order	
	Empirical	**Statistical**	**Empirical**	**Statistical**
Mean error / %	8.542	8.564	4.029	4.512
R^2 f(T)	0.6216 0.7232	-	0.9003 0.9257	-
R^2 f(xa)	0.8067	-	0.9869	-
R^2 k	-	0.9309	-	0.9716

In Noureddini and Zhu (1997) the temperature effect is studied for a catalyst concentration of *xa*=0.2% (m/m oil), while other authors used *xa*=1%. To account all of these experiments, the *f(T)* function in the empirical approach was obtained for each of these catalyst concentrations, and a mean value of E_a was considered at the end. After the function f(xa) was obtained, the pre-factor *A* was re-estimated using (18), by calculating the mean value of *np* experimental values K_{exp} at a central set of operating conditions (*T*=60ºC, *xa*=1). Note that K_{exp} is evaluated from experimental data using expressions (2) or (3), depending on whether a 1st or 2nd pseudo-order kinetic reaction is considered, respectively. Again, these values were considered as initial estimates in a simultaneous nonlinear regression of all data, in the empirical approach.

Table 4 shows that data from literature fits better to a 2nd order kinetic model, since the mean error for both strategies is lower and the correlation factors are higher. The 2nd order kinetic model expression obtained in the statistical approach is in (19) and expressions (21) to (23) are relative to the empirical approach. Using these expressions with the parameter values of Table 5 and (13) it is possible to calculate the time dependence of the conversion with a given set of operating conditions (*T,xa*).

$$A = \frac{\sum_{i}^{np} K_{\exp,i}(T = 60^{o}C, 1\ \%(\text{m/m oil}))}{np \exp(T = 60) f(xa = 1)} \tag{18}$$

$$K(T, xa) = e^{(\beta_0 + \beta_1 \sqrt{xa} + \beta_2 \ln(T))} \tag{19}$$

$$f(T) = \beta_0 e^{\frac{-\beta_1}{(T + 273.15)}} \quad (20); \qquad f(xa) = \beta_0 + \beta_1 xa + \beta_2 xa^2 + \beta_3 xa^3 \quad (21); \qquad f(xm) = 1 \quad (22)$$

$$K(T, xa, xm) = e^{(\beta_0 + \beta_1 \sqrt{T} + \beta_2 T^2 + \beta_3 \sqrt{xa} + \beta_4 \ln(xa) + \beta_5 \ln(xm))} \tag{23}$$

Table 5. *Parameter values for the expressions (19) to (21) considering a 2nd order reaction, using data from Freedman et al.(1984), Noureddini and Zhu(1997), Leung and Guo(2006), and Jeong et al. (2004).*

	Empirical		Statistical
	F(T)	**F(xa)**	**K(T,xa)**
β_0	1.852E7	-1.090E-1	-1.277E1
β_1	5.575E3	2.333E0	4.303E0
β_2	-	-5.331E0	2.200E0
β_3	-	4.796E0	-

Conclusions

The results obtained show that for the acid catalysis (H_2SO_4) the best models assume a pseudo 1st-order reaction and were obtained, respectively, with a statistical and empirical approaches, with mean errors of 7.2% and 5.9%. In the alkaline catalysis with NaOH, the models fitted better assuming a 2nd pseudo-order reaction, with a mean error of 4% and 4.5%, also with the empirical and statistical approaches, respectively. This study is being extended to other alkaline catalysts, such as KOH, $NaOCH_3$ and $KOCH_3$, with the introduction of a catalytic activity correction factors in the kinetic models.

Topic: Sustainable process-product development through green chemistry

Abstract

Biodiesel is defined as the primary alkyl esters of long-chain fatty acids produced from renewable sources, such as vegetable oil or animal fats; it is intended to use in compression-ignition engines. In this work, biodiesel is obtained from soy oil refined by transesterification with ethanol and an acidic catalyst. The process is carried out in a batch stirred tank (1000 mL) with jacked cooling. Samples containing soy oil and ethanol (99.5%) are fed to the tank. The final result in the batch is the conversion of about 94-99% of the mixture into ethyl esters. Conventional analytical methods for the evaluation of the ethyl ester content are becoming common but, the time required for the analysis is long, and the on-line application in a transesterification plant is very difficult. This work aims to develop a quick method to give an indication of the ethyl esters content in a transesterification product to be used as a process control. The literature has revealed that the rate of reaction can be related to its kinematical viscosity. The use of Coriollis effect-based flow meters and the additional differential pressure transmitter makes possible to measure the viscosity of laminar flow of Newtonian fluid.

1 Introduction

One of the main problems in the study or in the industrial application of transesterification process for vegetable oils is how to measure the bio diesel content. Conventional analytical methods for the evaluation of the ethyl esters content are based on gas-liquid chromatography, or thin-layer chromatography/flame-ionization detector, high performance liquid chromatography and gel permeation chromatography systems.

Unfortunately these methods have some drawbacks – their results are often unreliable or directly misleading and high accuracy is required during sample preparation; moreover, chemical modification of the sample is often necessary for analysis, and the time required for the analysis is usually long (Fillipis et al., 1995). In this study, an experimental control method of ethyl esters content was applied using industrial transducers. This methodology involves the design of the viscometer system. This viscosity difference is sufficient to give an indication of the biodiesel content in a transesterification product.

2 The transesterification process

In Brazil, transesterification reaction has been extensively investigated due to addition in petroleum – derived diesel fuel. There are several advantages in using bio diesel; these are: lower concentration of sulphur compounds, carbon dioxide and aromatic polycyclic burned in diesel engines (Knothe *et al.*, 2006).

* Corresponding author. Tel + 55 19 35213969. E-mail:carulo@feq.unicamp.br

The use of vegetable oils in diesel engines is limited due to high viscosity. The transesterification process results in a lower viscosity through separation of glycerol by conversion of fatty acids to ethyl esters (Barnwal & Sharma, 2004). The viscosity is on of most important properties of fuels and it will determine the combustion quality. The highest viscosity of bio diesel when compared to diesel –petroleum is what makes the fuel more lubrificant; however, it results in a lower efficiency during the combustion process in diesel engine (Vicente *et al*., 2006; Knothe & Steidley, 2005).

Tate *et al.* (2006) obtained kinematic viscosity experimental values of biodiesel produced by canola oil, soy oil and fish oil in a range of temperatures of 20ºC until 300ºC. He noticed the viscosity decreased with an increase of temperature following a logarithmic equation.

Is very difficulty to determine the on – line viscosity in a transesterification process, therefore, various methods were studied to correlate the kinematics' viscosity with methyl/ethyl ester produced (Knoth & Steidley, 2005). A different level of viscosity in bio diesel was studied at 40ºC, in several compositions of it. It was concluded that the viscosity of bio diesel decreases significantly with an increase of in saturation of compounds and the presence of glycerides affects the viscosity measurement (Allen *et al.*, 1999). Similar results were obtained by Krisnangkura *et al.* (2006). He predicted the values of bio diesel viscosity at composition $C_{12:0}$ -$C_{18:0}$ in many temperatures. He noticed that this method provided good results when it is compared to experimental values of biodiesel produced from palm oil and cocoa oil.

2.1 Batch Transesterification Tank

The transesterification process is carried out in a batch stirred heater tank (1000mL), at 500W, according to Figure 1. The mixture containing soy oil (400 mL) and ethanol (450 mL) is added to the tank. After this, the addition of catalyst is made during a continuous stirring at 40 rpm to avoid low conversion rate. Inside the jacketed tank, the mixture goes under a range of operating conditions during the period in which the catalyst agent (sulphuric acid) is added.

In order to avoid the low conversion rate, the lower bound for bulk temperature is 45ºC and the cooling flow rate is manipulated through a variable speed pump (pump 2). The set point of bulk temperature is 50ºC. Calibrated PT-100 temperature sensors are located at the precipitation mixture bulk and at the inlet and outlet of cooling fluid (water) stream.

The on line viscosity system is used to monitor the conversion rate of the process.

3 The control method

The whole process of ethyl ester production is managed by the digital control system from Fieldbus communication. Fieldbus network is connected to our laboratory network and provides us with the following variables; Temperature, pressure and mass flow. These analog signals would be converted to the digital signals through analog to digital conversion (A/D).

The management of the digital control system is performed through a Foundation Fieldbus communication system, according to Figure 1. Four field devices compose the field bus network used to monitor and control the precipitation tank:

- Distributed Fieldbus Interface (DFI302): bridge to link different speed networks. It manages the communication between the Local Area Network (High Speed Ethernet) and the Fieldbus network (H1);

- Temperature Transmitter (TT302-3): performs temperature data acquisitions and transmits them to the interface (DFI302);

- Electric Current Converter/Fieldbus (IF302 -2) and (IF302 -3): receives 4-20mA signal from devices (Temperature transmitters, pressure transmitter and mass flow transmitter) and converts to digital signal to DFI302;
- Fieldbus/Electric Current Converter (FI302): receives digital signal from DFI302 and converts to 4-20mA to operate the variable speed pump.

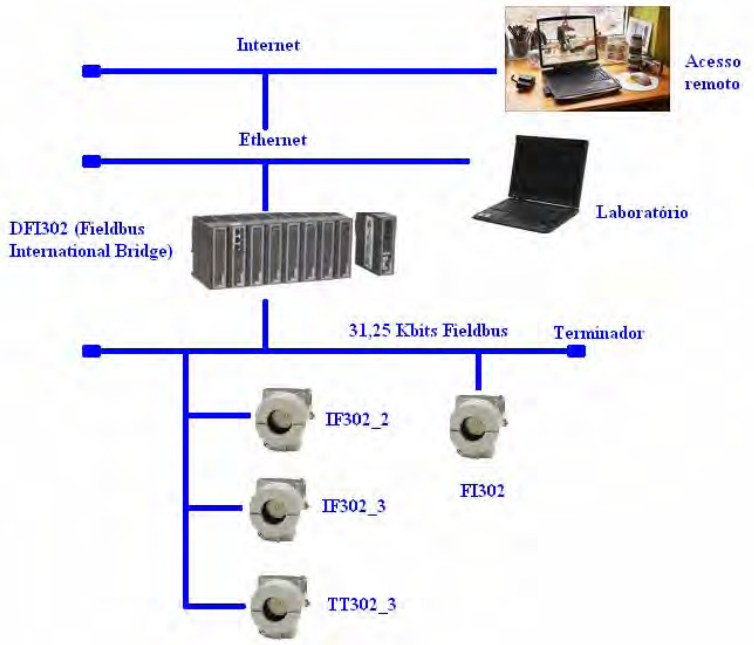

Figure 1. Fieldbus network for transesterification tank monitoring and control.

The digital signal sent to the pump is computed by controllers, which were implemented through the software Syscon (function blocks) and supervisory software Indusoft.

4 Materials and Methods

4.1 Materials

Soy oil refined and ethanol anidro (99,5%) from VETEC. Sulphuric acid (99, 9%) from VETEC.

4.2 Supervisory system development

The supervisory software INDUSOFT was employed in the development of the friendly graphic interface for real time monitoring of the transesterification reaction. The main tasks of this supervisory system are: display of monitoring screens and trends of process variables, the storage of measured data and the implementation of the controller equations.

4.3 A control method of ethyl ester content

The method of viscosity was employed for conversion rate monitoring purposes in biodiesel production. In a transesterification process a change of viscosity can be an indication of the chemical reaction status.

5 Results

5.1 Design procedures

The design of the viscometer system requires uniform flow velocity and Reynolds number for a laminar flow.
The reometer analysis was made to know about reological properties of soy oil and results are shown in Table 1. The reometer used in this work was HAAKE REO-STRESS.

Temperature (°C)	Absolute Viscosity (mPa.s)
20	62,789
25	50,675
30	41,392
40	28,746
50	20,844

Table. 1. Absolute viscosity values for soybean oil.

The fluid is not shear sensitive and Newtonian. In summary, the shear rate itself does not affect the apparent viscosity of the process fluid. In the Table 2 are shown density and kinematic viscosity values of soybean oil.

Temperature (°C)	***Density (g/m***	Kinematic viscosity (cSt)
20	0,902	68,307
25	0,9169	55,320
30	0,9134	45,355
40	0,9066	31,731
50	0,8997	23,181

Table. 2. Density and kinematic viscosity for soybean oil

The number Reynolds obtained must be lower that 2300. The values of biodiesel kinematic viscosity at 40°C is 4,20 mm^2/s and specific gravity at 15,5°C is 0,885 (Tate *et al*., 2006).

Fluid	**Velocity (m/s)**	*Reynolds number (max.)*
Soya oil	3,92	338
Biodiesel	7,99	1905

Table. 3. Velocity and Reynolds number values calculated

All things considered, the soybeans oil did not exhibit time-dependent rheological properties and this approach can be used for viscosity measurement. Fortunately, the laws of physics are not limited to the application of online viscosimeter in this study.

Initially experimental tests were carried out by loading the stirred tank only with oil. The real kinematic viscosity values were obtained through reometer analysis. Table 4 shows results.

Kinematics viscosity biodiesel (cSt)	
Reometer	On-line viscosimete
50,32	55,32
42,3	45,35
28,14	31,73
21,52	23,18
15,79	17,146

Table. 4. Kinematic viscosity of soy oil of 20°C until 60°C

5.2 Transesterification tests

The process is carried out in batch with stirred heated tank (1000mL), with cooling jacket in order to keep the heating temperature in desired value, the heater has a power of 400W and mechanical mixing process is driven by electrical motor rotating at 40 rpm both heat and mechanical movement are the energy input of the system. The set point of bulk temperature is 50ºC. Soybean oil, ethanol and an acidic catalyst are used to accelerate the reaction. In the early moments of catalyst addition, there is a heat generation that immediately cause an decrease on the heating in the closed-loop system. The pump operates at fixed flow rate (220 mL/s) and the batch time is one hour, five samples are withdrawn in time intervals of 15 min.

The transesterification product, a mixture of ethyl esters, unreacted oil, and mono-and diglycerides, was analyzed by gas chromatography (GC). The final result of this process is a batch of ethyl esters with conversion rate of about 95% of the mixture. The results are shown in the Table 5.

Table 5. Comparison between ethyl ester contents measured by GC and calculated from Viscosity of mixture data at 50°C ($\eta_{50°C}$)

Samples	Time (min	ln ($\eta_{50°C}$)	$\eta_{50°C}$ (cSt)	Ethyl ester (wt %)		Error (%)
				by GC	from ($\eta_{50°C}$)[a]	
1[b]	0	-	16,1130	45		
2	15	2,6588	14,2793	86	86	0,0

[b]If the ethyl ester content is higher than 85% the correlation allows the determination by a single viscosity measurement.

6 Conclusions

This paper discussed the use of online viscosimeter. It was accomplished through high precision viscosity measurements for the transesterification process. The viscosity is an important parameter because provide specified characteristics of the biodiesel obtained.

The viscosity difference is sufficient to give an indication of the biodiesel content in a transesterification product. Initially, the samples were analyzed in laboratory to determine the rate of conversion of biodiesel. To gather accurate measurements, the on line viscosimeter was used replacing tedious sampling and procedures.

On line viscosimeter is suitable for the control ethyl ester content in a transesterification process.

Topic: Sustainable process‐product development through green chemistry. Sustainable & clean technologies

Introduction

The world is experiencing a growing shortage of raw materials which is especially severe in the energy sector and being worsened by the unfavourable environmental impact of a consumerist culture revolving around the exploitation of non-renewable resources. Accomplishing sustainable development and renewability entails finding and using new resources and chemical and consumer products where lignocellulosic biomass constitutes a “necessary” source of raw materials on account of its ubiquity, availability and low polluting power. In fact, lignocellulosic biomass has been widely acknowledged as the largest source of renewable energy available in the world to respond to the decline in fossil fuel sources (Ozcimen and Karaosmanoglu, 2004; Jefferson, 2006; Semelsberger, 2007). Processing the whole material rather than only its sugar and amylaceous fractions to obtain ethanol by fermentation, its fibre fractions to produce cellulose pulp and some residual fractions or all for burning is the only way of exploiting the whole potential of such an abundant resource (Kim and Dale, 2004).

The alternative to integral exploitation of lignocellulosic biomass in a single process (usually of the thermal type) inevitably involves its fractionation; this is hindered by the inability to separate its main components without degrading the chemical structure of some. The complex structure, composition and network of chemical and physical bonds of lignocellulosic biomass precludes the use of separation techniques such as distillation, precipitation, crystallization and extraction for this purpose (Nimz and Casten, 1986). Extensive research in this field has focussed on a variety of highly specific issues and hindered systematic, comprehensive compilation of available fractionation methods. In dealing with such methods, Rijkens (1984) discriminates between those based on delignification (i.e. the solubilization of lignin) and those relying on hydrolysis (i.e. the solubilization of polysaccharides). This was the origin of the “lignocellulosic material biorefinery” concept as the source of a wide range of products by analogy with the oil refinery concept. Although a number of refining schemes have been tested at the laboratory or pilot plant scale, none has to date been implemented on a commercial scale (Kamm and Kamm, 2004).

In this context, the most promising approaches to the integral valorization of lignocellulosic biomass by fractionation revolve around the obtainment of ethanol from hydrolysis products of the raw material by using a “biorefinery” scheme. Bioethanol can be used as an automotive fuel (Hamelinck and Faaij, 2006). Also, it would be desirable to utilize the different polymer fractions

(lignin, hemicelluloses and valorizable compounds) to obtain other valorizable products or by-products in order to help offset the associated storage, pre-treatment and post-treatment costs. Identifying the most suitable pre-treatments or steps for the fractionation of lignocellulosic material is one of the most interesting areas for scientific research and development (Mosier et al., 2005).

The interest in this topic is justified by the renewability and environmental sustainability of the raw material, and also by the increasing awareness of the need for and advantages of its integral exploitation and economic valorization. In fact, lignocellulosic materials can be used to extract fermentable substrates, xilooligosaccharides and chemical products such lignin or furfural

Lignocellulosic raw materials are abundant and renewable. In fact, an estimated 10 - 50 billion ton dry matter of this type is produced each year in the world (Claassen et al., 1999; Galbe and Zacchi, 2002).

The integral fractionation of lignocellulosic biomass can be addressed by using hydrolysis (hemicellulose, cellulose) and delignification reactions.

Delignification has been accomplished by using chemical processes involving organic solvents and high temperatures. The earliest such process was probably the ethanol pre-treatment developed in the 1970s by General Electric to obtain biofuel (Yonghao and Van Heiningen, 1996). The process also provided high-quality unaltered lignin with various potential industrial uses (Lora and Glasser, 2002). Using ethanol as the technological core for refining lignocellulosic materials has led to organosolv processes such as Lignol, which uses temperatures in the region of 200ºC and pressures of 400 psi to maximize extraction of lignin from wood chips and other types of lignocellulosic biomass. Fractionation processes based on a delignification treatment usually focus on the subsequent hydrolysis or saccharification of the cellulose fraction in order to obtain fermentable media for producing ethanol (Mai et al., 2004; Pan et al., 2005; Pan et al., 2006).

Incorporating the hydrolysis of hemicelluloses into a more general process involving the integral fractionation of the raw material can be easier if the use of chemical reagents other than those strictly needed for separation is minimized. This can be specially easy with autohydrolysis. At high temperatures, acetyl groups in the lignocellulosic material give acetic acid, which catalyses the solubilization of hemicelluloses. The resulting liquor essentially contains oligomers, acetic acid, furfural (or hydroxymethylfurfural) and some lignin (Garrote et al., 1999).

In this work, we characterized the raw material and the liquor resulting from the autohydrolysis of five different lignocellulosic materials (*viz. Eucalyptus globulus*, *Arundo donax*, sunflower stalks, *Chamaecytisus proliferus* (tagasaste) and *Pawlonia fortunei*) with a view to assessing their utility for the obtainment of energy and chemical products by integral fractionation based on autohydrolysis.

The final aim was to establish the viability of using effective crops in order to reduce the dependence of Spain on foreign countries as suppliers of energy materials and chemical products, and also to reduce agrifood surpluses by using a fraction of agricultural land to crop alternative plants.

Material and Methods

Characterization of the raw Materials

Chips of materials samples were milled to pass a 8 mm screen, since no diffusional limitations were observed for this particle size in preliminary studies. Samples were air-dried, homogenized in a single lot to avoid differences in composition among aliquots, and stored. Aliquots from the homogenized wood lot were subjected to moisture determination (drying at 105 ºC to constant weight), quantitative acid hydrolysis with 5 mL of 72 % sulfuric acid for an hour and quantitative posthydrolysis with 4 % H_2SO_4 (adding water until 148.67 g) at 121 ºC during 60 min. Before HPLC analysis, the solid residue from posthydrolysis stage was recovered by filtration and considered as Klason lignin, sugar degradation and acid soluble

* Corresponding author. Tel + 34-959 219 982. E-mail:juan.garcia@diq.uhu.es

lignin. The monosaccharides and acetic acid contained in hydrolysates were determined by HPLC in order to estimate the contents of samples in cellulose (as glucan), hemicelluloses (xylan, araban), and acetyl groups.Chromatographic determination was performed using an Agilent 1100 HPLC equipped with an ion-exchange resin Aminex HPX-87H column under the following conditions: mobile phase, 0.05 mol·L-1 of sulphuric acid; flow rate, 0.6 mL·min-1; and column temperature, 40 °C. The volume injected was 20 µL.

Hydrotermal treatment

Raw materials were mixed in the desired proportions, heated in a 2 L stainless steel Parr reactor. Temperatures between 175ºC and 200ºC were ensayed. The solid/liquid ratio was fixed at 1/8 kg oven-dry raw material/kg water for *Arundo donax*, *Paulownia fortunei* and sunflower stalks and 1/6 for eucalyptus and tagasaste.

After treatment, solid residues were recovered by filtration, washed with distilled water, and milled to a particle size less than 0.5 mm to determine α-cellulose (glucan), hemicellulose (xylan, araban and acetyl groups) and lignin, using the same methods as for the raw material.

The liquor was filtered through membranes of 0.45 µm pore size and used for direct HPLC determination of oligosaccharides, monosaccharides (glucose, xylose and arabinose), furfural, 5-hydroxymethylfurfural (HMF), and acetic and formic acids. A second aliquot of the liquid phase (25 mL) were subjected to quantitative posthydrolysis (with sulphuric acid at 4% at 121 °C during 60 min) before HPLC analysis. The increase in the concentrations of monosaccharides and acetic acid caused by this posthydrolysis measured the concentration of oligomers and acetyl groups bound to oligosaccharides.

Results and discussion

Table 1 summarizes the chemical composition of various materials studied here. Because *E. globulus* is the most widely studied material, its values can be used as references for comparison with the others. In fact, the operating conditions used were based on previous work by Garrote (2001) on this material where oligosaccharide extraction was found to be maximal (10.3%) at 196ºC. Note the low glucose contents and high xylose contents in the liquor remaining upon autohydrolysis –which suggest that the polymer retains most of its integrity even at high temperatures–, and also the increased amounts of xylose extracted from all materials.

The holocellulose contents of tagasaste and sunflower stalks exceed those of eucalyptus by 20% and 10.9%, respectively, and are comparable or higher than others materials. On the other hand, the glucan content of eucalyptus is 20.3% and 38.5% higher than that of tagasaste and sunflower stalks, respectively; also, the lignin content is 15.5 and 15.5% higher, respectively, than those of the latter two. Based on these contents, one can expect increased yields in oligosaccharides and xylose in the liquor resulting from the hydrolysis of eucalyptus. Finally, the contents in hemicelluloses (holocellulose-glucan) of tagasaste (41.1%) and sunflower stalks (40.4%) are higher than that of eucalyptus (20.1%).

The xylan contents of tagasaste and *A. donax*, 19.0% and 19.9%, are similar or higher than those of eucalyptus. The highest value for the studied materials is that for sunflower stalks (23.9%). Other authors (Ververis, 2004) have obtained similar glucan and lignin contents, but substantially lower xylan and araban contents, for *A. donax*. *P. fortunei* exhibited the lowest holocellulose content and highest cellulose content among the studied materials. Our xylan, araban and acetyl contents are similar to those found in other materials.

Table 2 shows the concentrations of oligomers, sugars and various other substances in the liquors resulting from the hydrothermal treatments. The table also contains additional data for the less widely studied materials (tagasaste, sunflower stalks and *P. fortunei*) as obtained at hydrolysis temperatures below and above those used with *E. globulus* and *A. donax* (175ºC to 200ºC), however.

* Corresponding author. Tel + 34-959 219 982. E-mail:juan.garcia@diq.uhu.es

Overall, solubilization increased with increasing temperature of the hydrothermal treatment (especially in tagasaste, where the amount of oligomers dissolved rose by a factor of 4 from 175ºC to 195ºC). Xylose and acetic acid were also solubilized maximally at high temperatures (185ºC-195ºC). As noted earlier, the oligomer yield for tagasaste exceeded that for eucalyptus at temperatures from 185ºC to 195ºC. Arabinose was solubilized in very high proportions with respect to its content in the raw material (viz. 95.2% at 195ºCC); however, its concentration was very small in absolute terms owing to its low proportion in the raw material.

Solubilization of oligomers in sunflower stalks increased by 28% from 180ºC to 190ºC and then decreased up to 200ºC by effect of their thorough hydrolysis to simple sugars or other decomposition products. In fact, the content in acetic acid at 200ºC (4.6 g/L, equivalent to 3.7% of the dry mass of raw material) was much higher than that for any other raw material at any temperature. The concentration of formic acid reached levels of up to 1 g/L, but those of furfural and 5-hydroxymethylfurfural never exceeded 0.1 g/L. The oligomer yield of this raw material was higher than were those of eucalyptus and tagasaste (viz. 21.5% with respect to dry mass of raw material and 90.0% of oligomers, which were the highest figures of all).

Oligomer solubilization in *P. fortunei* increase 1.9 times from 180ºC to 200ºC; however, the increase from 190ºC to 200ºC was less marked and accompanied by a decrease in the proportion of xylose extracted.

Only 3.1% of cellulose present in the raw material was solubilized under the most drastic heating conditions used in the autohydrolysis of tagasaste (195ºC); this suggests that the process is quite selective and cellulose is scarcely degraded, so it can be useful for other purposes such as obtaining cellulose pulp. This is an advantage as it allows scarcely degraded cellulose to be obtained as a valorizable product. Similar results were obtained with the other materials and temperatures: cellulose degradation never exceeded 2.8% and 1.6% relative to glucan in the raw material for sunflower stalks and *Pawlonia fortunei*, respectively; these values, however, are still higher that those for *E. globulus* wood, which never exceeded 0.5%.

The amounts of oligomers that can be extracted from tagasaste (13.9%), sunflower stalks (21.5%) and *P. fortunei* (11.7%) at the highest operating temperature (195ºC with the former and 190ºC with the latter two) are greater than those for eucalyptus. The amounts of oligomers obtained from tagasaste at temperatures below 185ºC (3.3%-9.4%) and sunflower stalks below 180ºC (16.8%) are greater than those obtained from eucalyptus wood (8.7%) in some cases. Note the small amounts of degradation products such as furfural present in their liquors and in those resulting from the autohydrolysis of *P. fortunei.*

A. donax exhibited the highest proportions of extracted oligomers and xylose in addition to relatively high proportions of glucose and acetic acid in the hydrolysis liquor. This make it the least suitable material for exploitation by autohydrolysis of all studied here.

Overall, both sunflower stalks and *P. fortunei* can be efficiently hydrolysed at 180ºC and 190ºC while minimizing degradation of the solid phase and maximizing the extraction of xylan. At temperatures in the region of 200ºC, Heitz et al.(50) and Garrote (51) observed substantial depolymerization of cellulose and a decreased amount of cellulose fibers in the autohydrolysis process.

Keywords: Green coconut fiber, *Candida antarctica* B lipase, Immobilized enzyme, stability, chemical treatments
Topic: Integration of life sciences & engineering

Abstract

Chemical treatment for surface fiber has been reported to remove some impurities, to improve wettability and to modify microstructure and surface chemical groups. In this study we investigated the effect of different chemical treatments on the immobilization of *Candida antarctica* lipase B (CALB) in green coconut fiber. For this purpose, two immobilization strategies were used: adsorption and covalent attachment. The results showed that the chemical treatment with H_2O_2 was more efficient in the removal of the pigments and residues of waxes and fatty acids from fiber surface. During the immobilization process, the chemical treatments not promoted considerable influence on enzyme loading.

1 Introduction

Lipases (triacylglycerol ester hydrolases, E.C. 3.1.1.3) are enzymes that catalyze both the hydrolysis and synthesis of esters from glycerol and long-chain fatty acids. These enzymes, under special conditions, can also catalyze interesterification, aminolysis and thiotransesterification reactions (JAEGER and REETZ, 1998). Thus, the increase on lipases applications in enzymatic synthesis and biotransformations impelled the study of immobilized biocatalysts preparation.

Considering the high cost of some available commercial support matrixes to enzyme immobilization, studies have been intensified in order to obtain cheaper supports. Some papers have reported the use of agroindustrial wastes as immobilization matrix for α-amylase, invertase and lipase. These studies showed that agroindustrial wastes are a suitable raw material source for immobilization matrix. In Brazil, an increase in the green coconut water market had a direct impact on the increase in coconut husk production, an agroindustrial waste (BRÍGIDA *et al*., 2007). However, the presence of impurities on the surface of green coconut fibers requires treatment studies.

Chemical treatment for surface fiber has been reported to improve wettability and to modify microstructure, surface topography, surface chemical groups and tensile strength of fibers (SILVA *et al.*, 2000; ROUT *et al.*, 2001). These characteristics influence enzyme – support interaction and it is an important factor for immobilization process. Moreover, the distribution of surface chemical groups is intrinsically linked to success of functionalization step for immobilization by covalent attachment (FERREIRA *et al*., 2003). Therefore, the aim of this study was to investigate the effect of different chemical treatments on the immobilization of *Candida antarctica* lipase B (CALB) in green coconut fiber. For this purpose, two immobilization strategies were used: adsorption and covalent attachment. In order to evaluate the immobilization process in different chemical treated supports, the lipase loading and stability of the obtained derivates was evaluated.

2 Material and Methods

Materials: Commercial *C. antarctica* lipase type B was kindly donated by Novozyme Latin America Ltd. Substrate p-nitrophenyl laurate were obtained from Fluka and 3-glycidoxypropyltrimethoxysilane (GPTMS) was obtained from Sigma-Aldrich Chemical Co. All chemicals were of analytical grade.

Chemical treatments: Green coconut fiber was obtained from green coconut husks through a process developed by Embrapa Agroindústria Tropical, Ceará State, Brazil. Before being used as support, green coconut fibers were previously cut and sieved to obtain particles between 32 and 35 mesh, washed with distilled water, dried at 60ºC and then they were submitted to three different treatments: (i) 2 g of coconut fibers were submitted to oxidation using 40 mL of a H_2O_2 solution in basic medium (0.05 g NaOH and 18 mL of H_2O_2 30%, v/v, for 100 mL of solution), at 85ºC for 2 h; (ii) 5 g of fibers were soaked in 100 mL of 0.4% NaOCl (v/v, in glacial acetic acid) for about 2 h at 85ºC, and (iii) the last treatment was performed by soaking 5 g of fibers in 100 mL of a solution NaOCl 4-6% (v/v):H_2O (1:1) for 2 h at 30ºC and, after this time, the fibers were washed with water and soaked in 100 mL of 10% NaOH for 1 h at 30ºC.

Support activation: The support activation procedure was a four-step sequential process. The first step was the support protonation with nitric acid (10%, v/v) under low stirring for 30 min at 30 ºC. It was then rinsed with nitric acid (10%, v/v) and acetone-water solutions (20, 50 and 100%, v/v) and dried at 60ºC for 1 h. The support was then silanized using a GPTMS solution at pH 8.5 under low stirring for 5 h at 60ºC. The fiber was rinsed with water, acetone-water solutions, and dried. In the third step, the hydrolysis of epoxy groups was done with 0.1M sulphuric acid at 85ºC under low stirring for 2 h. Again, the fiber was rinsed with water, acetone and dried. For each gram of dry support used in the previous stages, 30 mL of each solution was used. Finally, oxidation process was achieved by reaction with 0.04 M sodium periodate solution (5 mL/g fiber) under low stirring at room temperature for 1 h. After oxidation, the activated fiber was thoroughly rinsed with water and, later, with 5 mM sodium phosphate buffer pH 7.0. Before immobilization, activated fiber was dried under vacuum (BRÍGIDA *et al.*, 2007). In this study, GPTMS solution concentration was evaluated at 1, 2.5 or 5 %, v/v.

Preparation of immobilized enzyme: Lipase was immobilized by adsorption or by covalent attachment by contact at room temperature using treated or treated and functionalized fiber, respectively. The enzyme and support were mixed using a rotative stirring. For each gram of dry support, 10 mL of lipase solution in 25 mM sodium phosphate buffer pH 7.0 were used. After immobilization, the biocatalyst was separated by filtration, rinsed with phosphate buffer (10 mL) and dried at vacuum for 10 min.

Assay of hydrolytic activity: The hydrolysis of p-nitrophenyl laurate was defined as standard method to determine lipase activity from commercial *C. antarctica* lipase type B (CALB) solution and CALB immobilized in coconut fiber. For enzyme solutions, the reaction occurred at 37 ºC by the addition of 0.2 mL of enzyme solution to 1.8 mL of 560 µM p-nitrophenyl laurate (pNP-laurate) dissolved in 50mM potassium-phospate buffer (pH 7.0), containing 1% (v/v) of dimethyl sulfoxide (AMARAL *et al*., 2005). For immobilized enzymes, the reaction occurred at 37ºC by addition of 0.3 g of CALB immobilized to 30 mL of pNP-laurate solution. The reaction development was followed for 100 seconds or 10 minutes, for soluble and immobilized enzyme respectively, in a spectrophotometer (HACH, DR/4000U) at λ= 410 nm. One unit (pNPLU) is defined as the amount of enzyme which releases 1 μmol of p-nitrophenol per minute at pH 7.0 and 37ºC.

Scanning electron microscopy: In order to evaluate changes in the surface provoked by the chemical treatment, natural and treated fibers were analyzed by scanning electron microscopy (SEM) using a Zeiss DSM 940A SEM operating at 15 kV. All samples were glued onto special stubs and gold-coated with a Sputter Emitech K550 to avoid electrostatic charge and to improve image resolution.

Thermal stability: Thermal stability of soluble or immobilized enzyme was determined by incubating the biocatalyst in 100 mM sodium phosphate buffer pH 7 at 60ºC. Periodically, samples were withdrawn and their residual activities were assayed by the hydrolysis of pNP-laurate. Residual activity is given as percentage of initial activity (hydrolytic activity before incubation).

3 Results

Several studies has reported chemical treatment of coconut fiber to remove somes impurities and to improve wettability (SILVA *et al.*, 2000; ROUT *et al.*, 2001). In this study, we evaluated three treated fiber as matrix to immobilization. Figure 1 shows scanning electron micrographs of natural fiber and treated fibers. A visual analysis showed that, for treatment with NaOCl, the presence of residues of waxes and fatty acids in derived fiber samples still occurs in high concentrations (Figure 1b). Already NaOCl treatment followed by treatment with NaOH, showed a liberation of celulose helical spiral, probably caused by the removal of part of hemicellulose and lignin that link the fibrils forming fibres (Figure 1c), while the presence of residues of waxes and fatty acids is still observed. Regarding the treatment with H_2O_2, this was the most efficient in the removal of the pigments in coconut leading to colour change. Thus, the color of natural fiber (brown) switched to a light yellow after treatment. Also, among the three treatments studied, this was the most efficient in removing residues of waxes and fatty acids (Figure 1d).

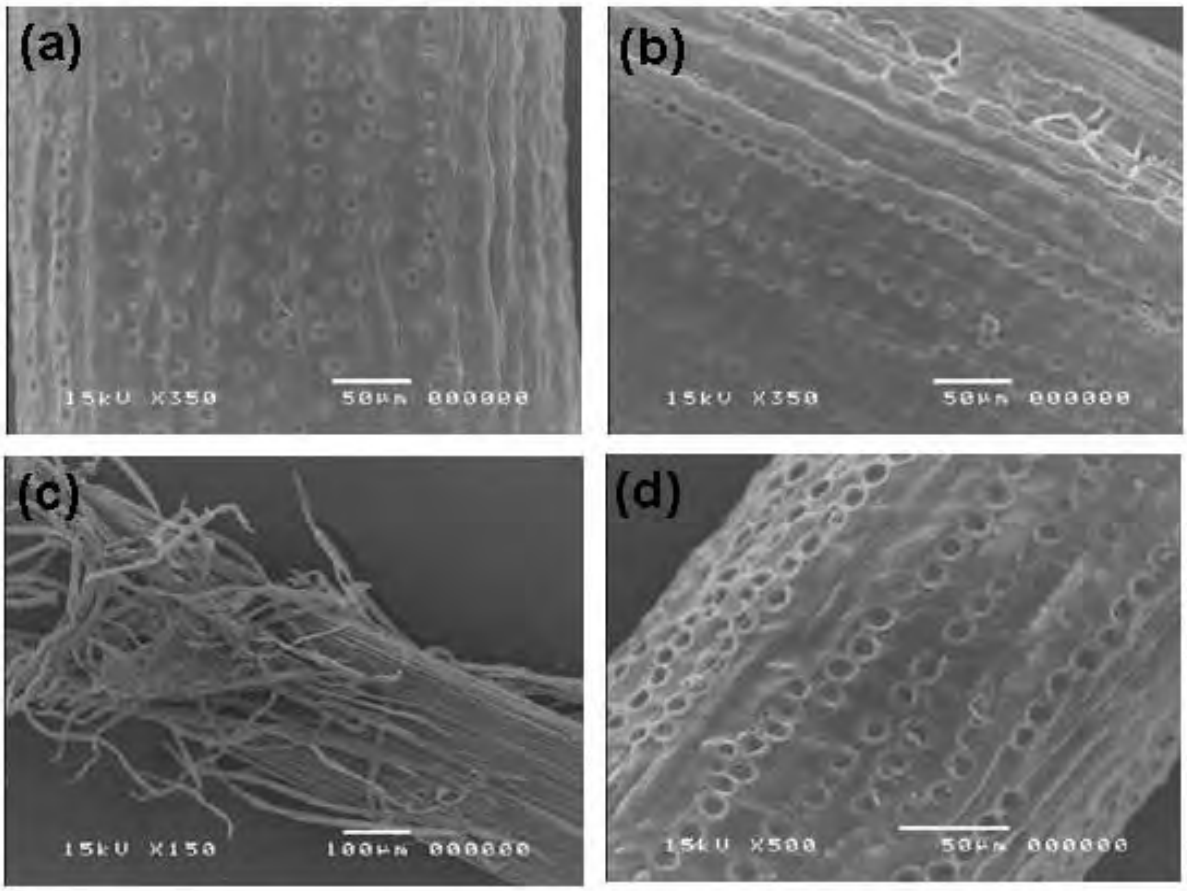

Figure 1 – Scanning electron micrographs of: (A) natural green coconut fiber; (B) NaOCl treated fiber; (C) NaOCl and NaOH treated fiber; (D) H_2O_2 treated fiber.

In addition to structural changes, chemical treatments can possibly modify the distribution of available groups on fiber surface. These changes can have influence on enzyme – support interaction and it is an important factor for immobilization process. Thus, to investigate chemical treatments influence on the immobilization process, immobilization studies of CALB

in natural and treated coconut fiber were realized both by adsorption and covalent attachment.

Immobilization studies showed that lipases immobilized by adsorption had similar activity when immobilized in natural fiber and in treated fiber with NaOCl and NaOCl - NaOH, 263.0 ± 17.5 U/kg, 246.6 ± 26.5 U/kg and 233.1 ± 10.13 U/kg, respectively. On the other hand, a slight increase in activity were achieved by lipase immobilized in H_2O_2 treated fiber, 307.7 ± 1.3 U/kg. All immobilizations carried out with treated fibers showed lower catalytic efficiency (59.0%, 51.2%, 48.3% and 47.0% for natural, H_2O_2, NaOCl and NaOCl – NaOH treated fiber, respectively) and lower thermal stability (Figure 2) when compared to the enzyme immobilized in natural fiber. In addition to physical changes, observed by scanning electron microscopy, variations in the surface charge, indicated by pH change, may have influenced the immobilization process.

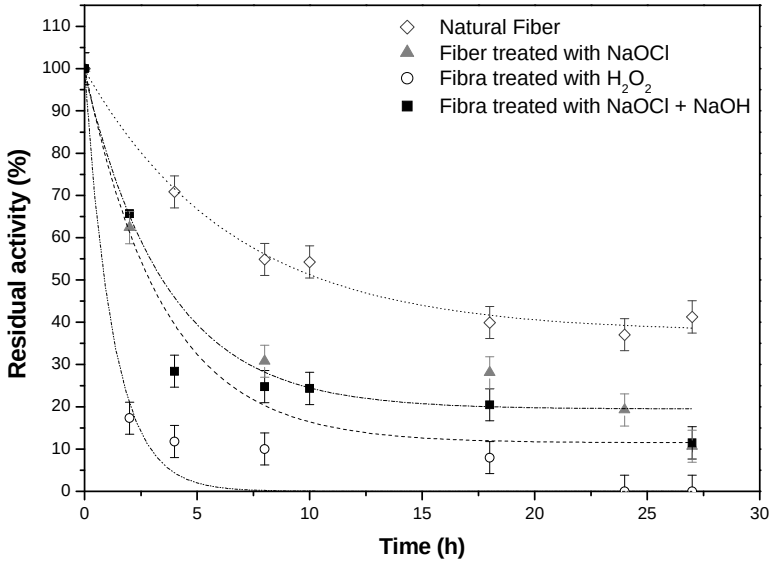

Figure 2 – Influence of chemical treatment in thermal stability of lipase immobilized by adsorption in coconut fiber.

For immobilization by covalent attachment, a GPTMS solution of 1% (v/v) was initially adopted. Immobilization studies showed that lipases immobilized by covalent attachment had similar activity when immobilized in natural and in treated fiber with NaOCl and H_2O_2, 160.9 ± 10.5 U/kg, 156.4 ± 8.0 U/kg and 155.3 ± 10.5 U/kg, respectively. On the other hand, a reduction in activity was achieved by lipase immobilized in NaOCl-NaOH treated fiber, 123.5 ± 9.0 U/kg. These values are lower than those found in adsorption studies. The degree of activation of fibers by silanization with GPTMS at 1% was 104.5, 104.2, 104.8 and 105.1 μmol de CHO/g de fibra, for natural, H_2O_2, NaOCl and NaOCl-NaOH treated fibers, respectively.

To evaluate the silanization efficiency and stability of immobilized enzyme, thermal stabilitiy analyses of CALB immobilized in natural or treated coconut fibers were realized (Figure 3). It was observed that stability of CALB immobilized by covalent attachment in natural coconut fiber is similar to that obtained with H_2O_2 treated fiber. For NaOCl-NaOH and NaOCl treated fibers, deactivation was slightly higher. It was expected that with the removal of some impurities and waxes and fatty acids residues through the chemical treatment of coconut fiber, a greater number of OH groups could be protonated, promoting a more efficient silanization and, consequently, greater stability. However, it was observed that during the last stage of activation (oxidation with sodium periodate), the obtained degree of fiber activation

by silanization with GPTMS to 1% (v / v) was similar in the different types of treatments evaluated. This fact shows that, in covalent attachment immobilization employing 1% GPTMS, there isn't a significant influence on the enzyme stability.

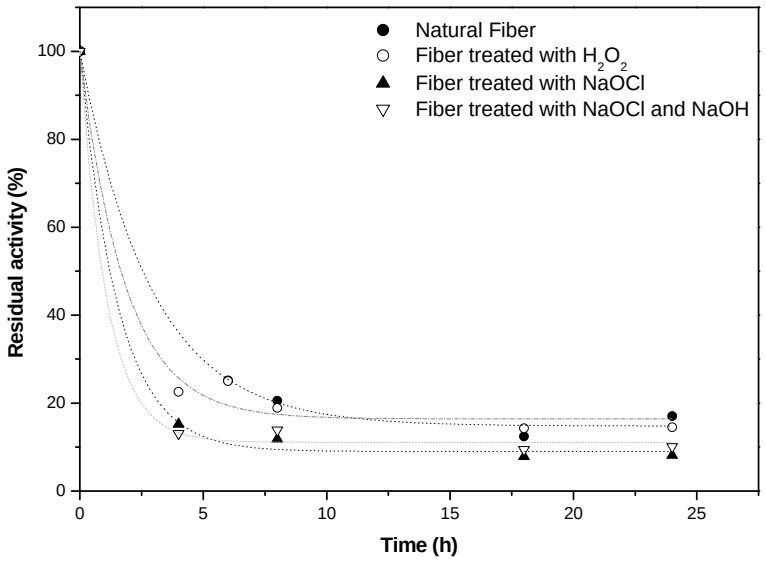

Figure 3 – Influence of chemical treatment in thermal stability of lipase immobilized by covalent attachment in coconut fiber.

In other studies, it was observed that GPTMS concentration during silanization step may influence the derivate stability (FERREIRA *et al.*, 2003). Thus, stability studies with lipases immobilized by covalent attachment in silanizated fibers under different concentrations of GPTMS should be made. Figure 4 shows thermal stability of CALB immobilized by covalent attachment in natural coconut fiber for different GPTMS concentrations. It can be seen that only for GPTMS at 5%, a significant increase in immobilized enzyme stability was detected. Studies of functionalization fibres treated using different concentrations of GPTMS must be made. In addition, other GPTMS concentrations could be studied, considering that the cost of the imobilization procedure can raise, not providing a biocatalyst of low cost.

Conclusions

Among the chemical treatments realized to remove some impurities from natural coconut fiber, treatment with H_2O_2 was more efficient in pigments and residues of waxes and fatty acids removal from fiber surface. From the immobilization studies it is possible to conclude that chemical treatments do not promote considerable difference in the immobilized enzyme charge. However, they may interfere in a negative way on the stability of these enzymes. To effectively assess the influence of such treatments in immobilization by covalent attachment, further studies should be carried using different concentrations of GPTMS during silanization.

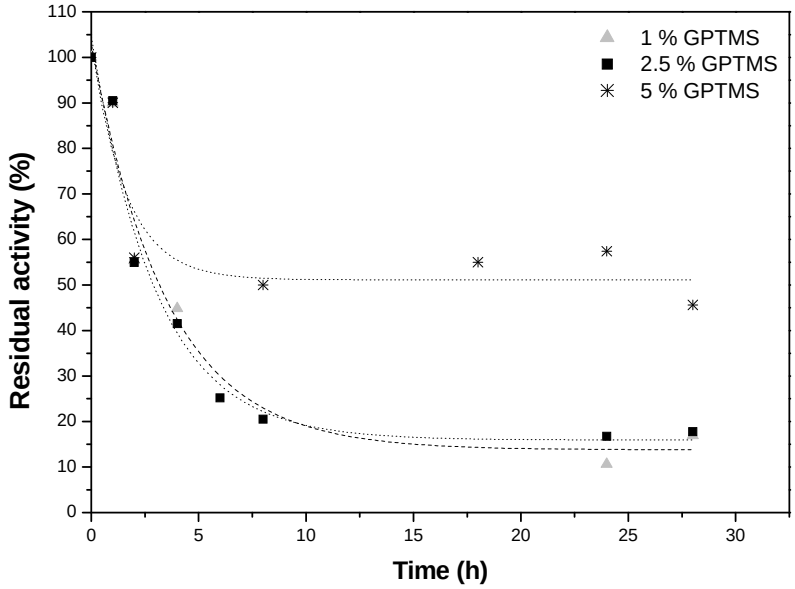

Figure 4 – Influence of GPTMS concentration in thermal stability of lipase immobilized by covalent attachment in coconut fiber.

Information CALS-model of the innovation technology of biologically active additives of a new generation

Arkadiy M. Bessarabov*, Alexey A. Alyakin, Alexey L. Kochetigov
The State Scientific-Research Institute of Chemical Reagents and High Purity Chemical Substances (IREA), Bogorodsky Val, 3, 107076, Moscow, Russia

Keywords: System analysis, CALS-technologies, Biologically active additives, Drying-agglomeration.
Topic: Systematic methods and tools for managing the complexity.

At the present time, as a promising information technology, methods of the Continuous Acquisition and Life Cycle Support (CALS) concept are widely implemented (Bessarabov et al., 2002). The CALS concept is based on a complex of unified information models and the standardization of methods for information access and correct information interpretation according to the international standard ISO 10303 (STEP). A series of CALS projects were developed for a number of technologies for producing special-purity substances (Bessarabov et al., 2006, 2007); however, in all the cases, CALS methods were used only to create project documentation.
In this work, using CALS methods, an information model was elaborated which includes all the steps (marketing, design, production, service and repair, and realization and sale) of the technology of producing biologically active additives of a new generation from an extract of medicinal herbs and gelatin--starch complex (Bessarabov et al., 2003). In recent years, biologically active food additives---therapeutic and prophylactic preparations produced from herbal raw material---have successfully competed with synthetic drugs.
Let us sequentially consider elements of the information model that correspond to various steps of the technology of biologically active additives.

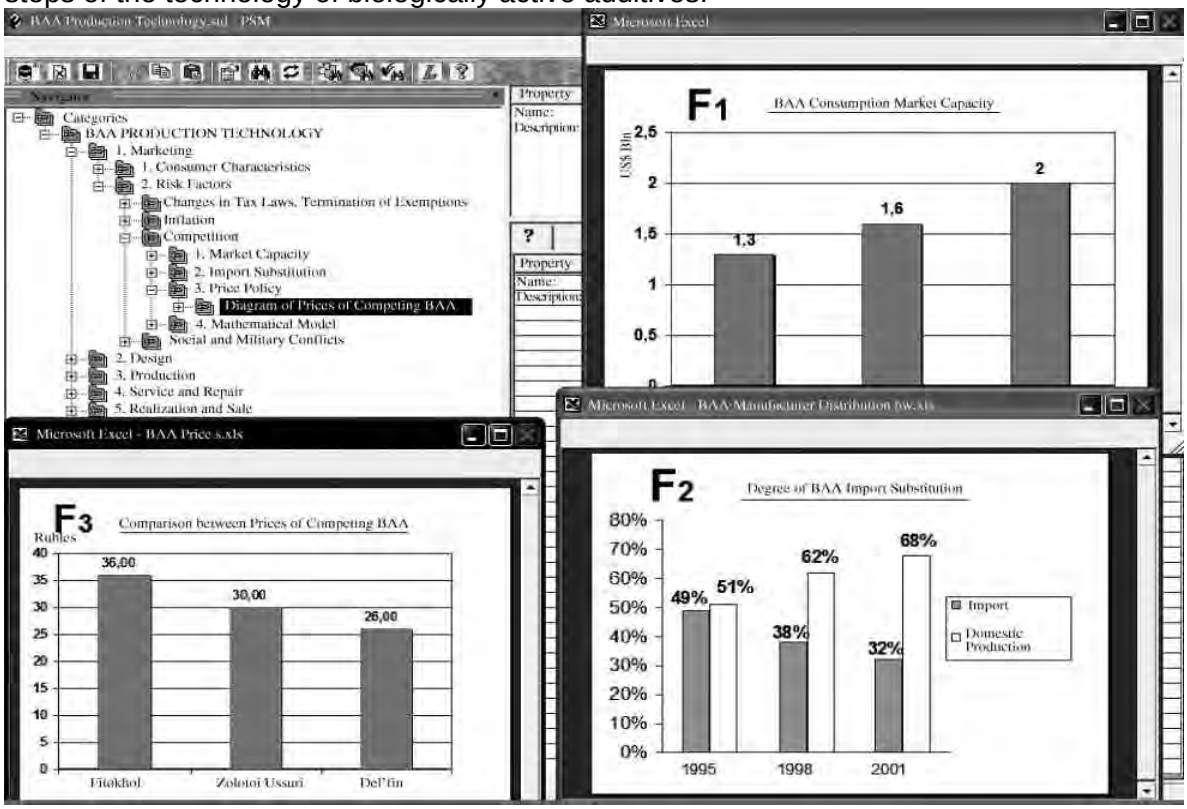

Fig. 1. CALS Project element at the marketing step.

* Corresponding author. Tel + 7(495)963-7527. E-mail:bessarabov@irea.org.ru

On the basis of marketing research results, at the marketing step, two information-analytical blocks are formed: consumer characteristics and risk factors. Each of the blocks includes lower-level parameters, whose analysis gives a complete pattern of the entire analytical block. For convenience of using the system, the parameters are inputted in text and table formats, as well as in graphic form. As basic consumer characteristics, the income, age, and sex distributions of consumers are analyzed. In this block, the reasons for buying biologically active additives and the main factors affecting the purchase decision are also studied. In the block of risk factors (Fig. 1), an analysis is undertaken regarding the possibility of a change in tax laws and concerning inflation and competition, market capacity, degree of import substitution, and prices for similar products. At the marketing step, a conclusion is drawn about the expedience and prospects of developing technology and equipment for producing biologically active additives of new generation.

At the design step (Fig. 2), the initial data for design are analyzed, which contain information on six basic stages: grinding of medicinal raw material, extraction, concentration, mixing, drying--agglomeration, and packing. Particular attention was given to the limiting stage---drying--agglomeration.

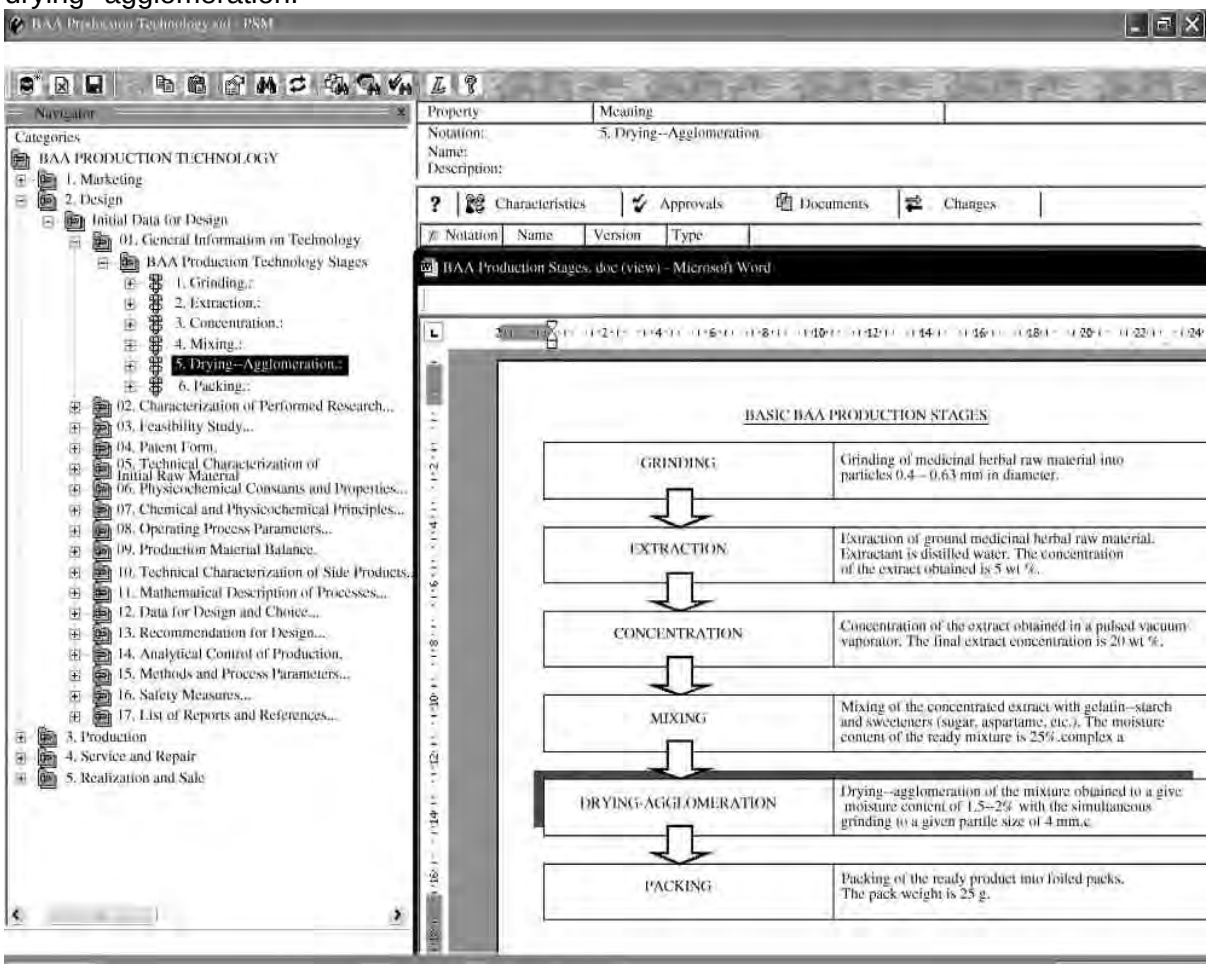

Fig. 2. CALS Project element at the design step (basic stages of the technology of biologically active additives).

The main methods for drying biologically active additives were analyzed; these are spray drying, fluidized-bed drying, infrared drying, and drying in a vacuum dryer equipped with a rake agitator. It was shown that the equipment considered is inefficient if the product contains astringent substances (fructose, lactose, gelatin--starch complex, and others), which, during drying--agglomeration, form clots, stick to moving parts and the housing of the apparatus, and can render the apparatus inoperative. Therefore, a continuous convective agitator dryer was proposed, which gives a product of required quality and given particle size distribution (Fig. 3).

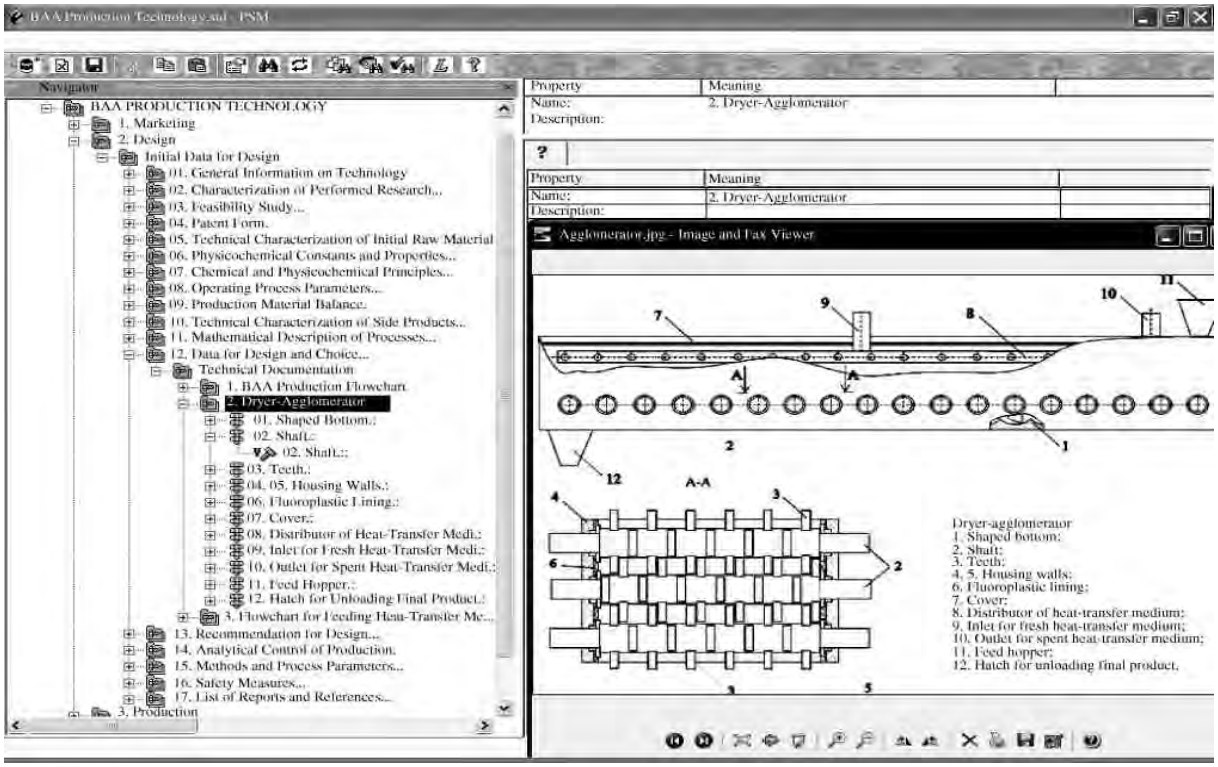

Fig. 3. CALS Project element at the design step (dryer–agglomerator design).

At the design step, four variants of agitator design are considered (Fig. 4). The ultimately chosen variant was the design that ensured required product quality at minimal energy consumption, with the agitator of this design being constructed at minimal material and labor expenditures. Three methods for introducing a heat-transfer medium were analyzed, and the optimal variant ensuring the maximal uniformity and efficiency of heat transfer was chosen. Intermediate and final variants described in text and graphic files were included into the CALS project.

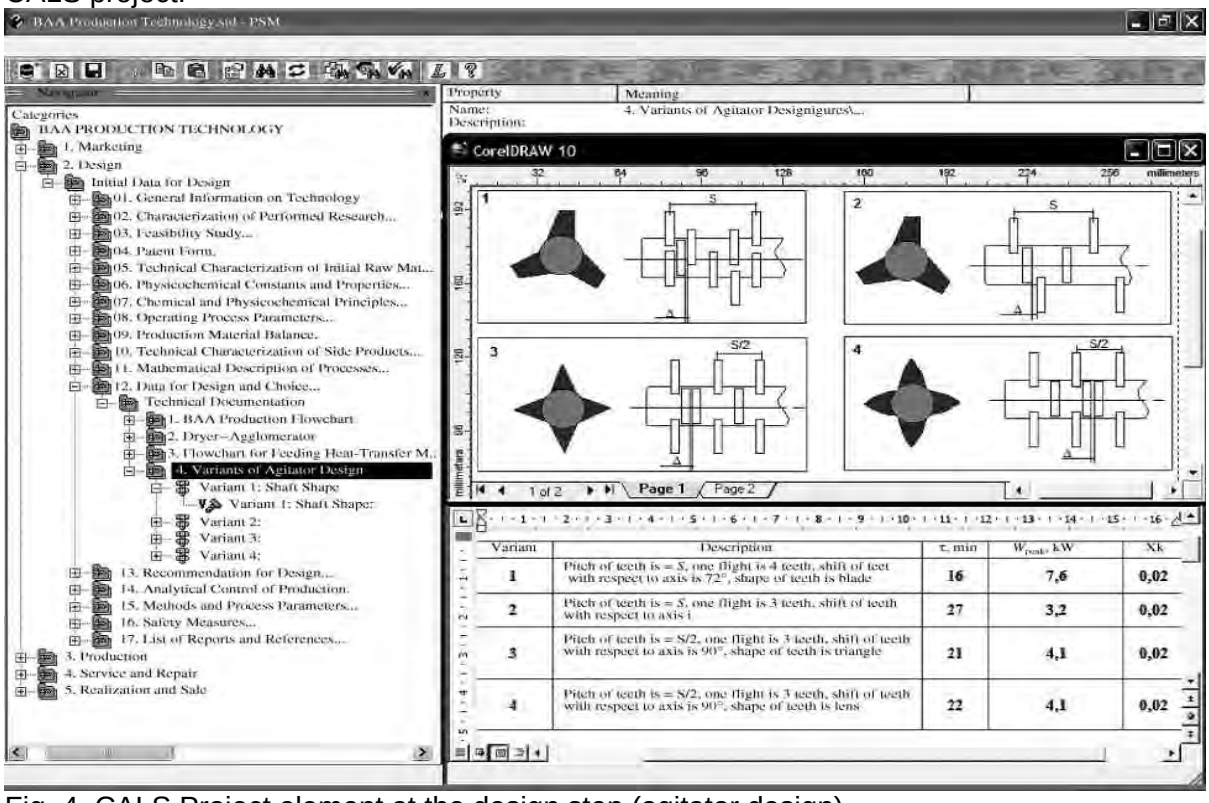

Fig. 4. CALS Project element at the design step (agitator design).

At the production step, technical documentation of extractors, dryers--agglomerators, and other equipment is analyzed by industrial equipment manufacturing plants.
At the service step, technical information on the main stages (switching on, operation, switching off, washing) of service of extractors, dryers--agglomerators (Fig. 5), and other equipment is introduced.

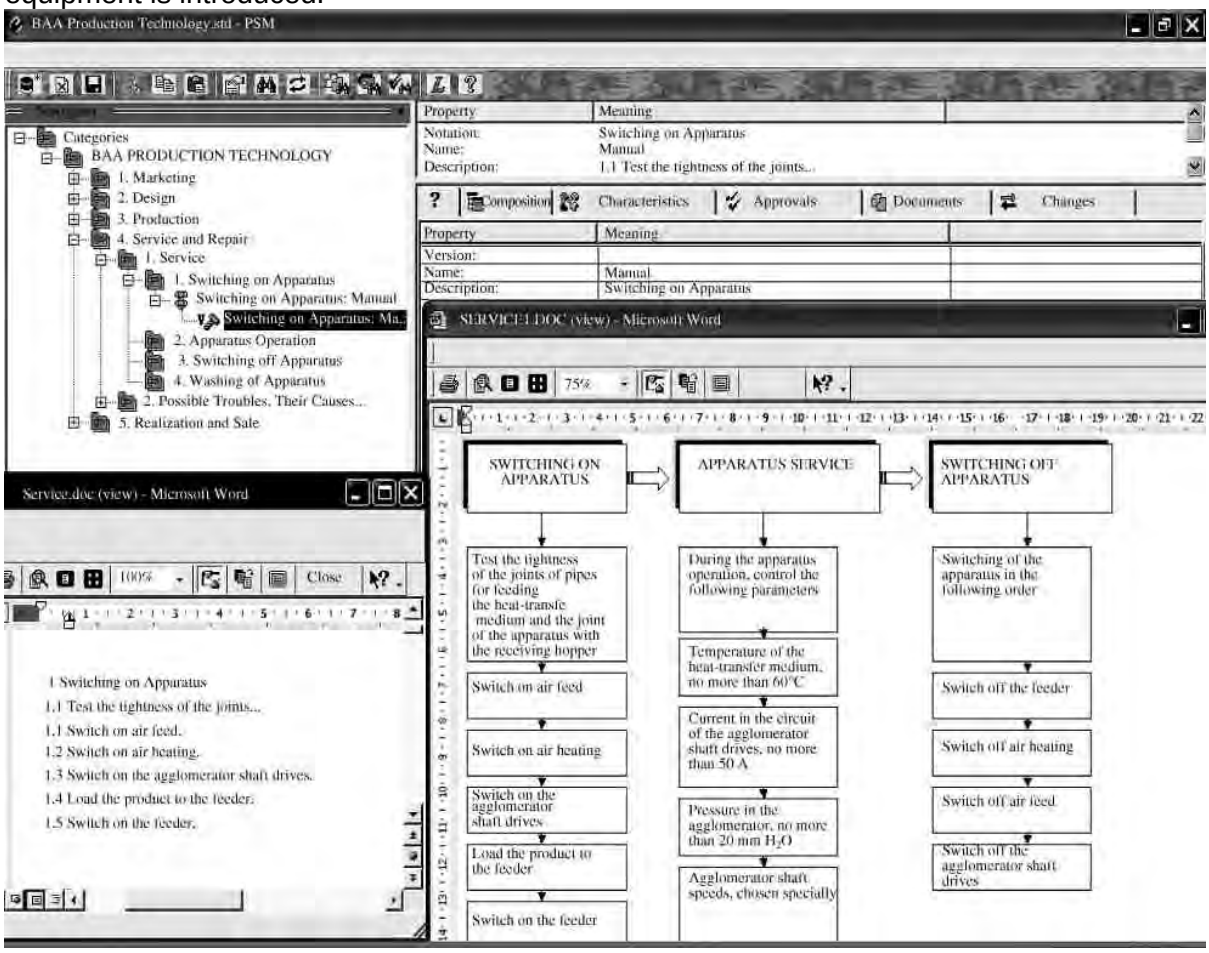

Fig. 5. CALS Project element at the step of service of the dryer–agglomerator.

Information at the repair step (Fig. 6) is structured at three levels: trouble--cause--troubleshooting. The developed module enables one to promptly, in dialog mode, select the optimal variant of troubleshooting.
The step of realization and sale includes product promotion to market (advertising in printed and electronic mass media; participation in exhibitions, contests, tenders, etc.) and also analysis of information on the use of the developed equipment not only in the technology of biologically active additives but also in the chemical and pharmaceutical industries. Under the conditions of the rapid development of the Internet with allowance for its potentialities, one of the elements of this step is the development of the information web site of OOO Ob''edinenie IREA-PENZMASh, the parent organization in the production of the biologically active additives considered in this work and promising equipment for drying highly viscous extracts of medicinal raw material. On the basis of accumulated information, the optimal structure of the web site was developed, necessary information contents were analyzed, and a system for rapidly surfing the site was implemented. The site combines two main Internet systems: FTP and WWW. The WWW system is used to illustratively and conveniently store information, to structure information, and to easily move between sections. The FTP service is used for data (file) storage and exchange.
Basic elements of the CALS project for the technology of biologically active additives are placed on the Internet on the CALS-khimiya (CALS Chemistry) web site in the Pilot Projects section. Also here are links to CALS files containing data in STEP exchange format. The files

themselves are located on an FTP server and are accessed via FTP protocol with an ordinary WWW browser. This scheme (in which information is place in FTP rather than WWW) is chosen for new files to be conveniently uploaded to the CALS-khimiya web site by various developers, rather than solely by the server administrator. The CALS-khimiya web site is one of the promising elements for training scientists and specialists of industrial plants in implementing CALS methods to the chemical industry.

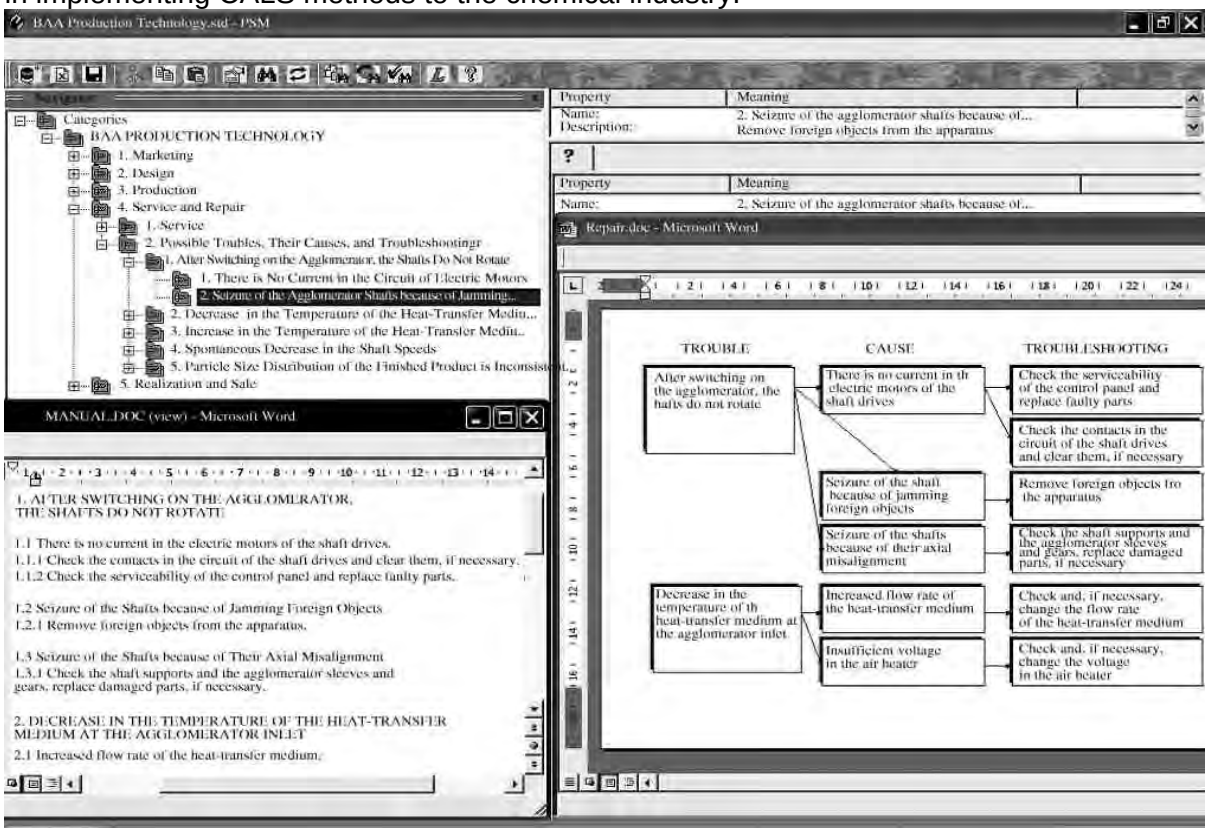

Fig. 6. CALS Project element at the step of repair of the dryer–agglomerator.

The results of this work were implemented at plants of the OOO Ob''edinenie IREA-PENZMASh. The developed CALS documentation significantly reduces the service, maintenance, and repair costs. According to predictions of foreign specialists, after 2005, it will be impossible to sell high-tech products in the international market without electronic documentation created in compliance with international CALS standards (ISO 10303 (STEP)) (Bessarabov et al., 2002). Therefore, one can believe that the electronic description of the technology of biologically active additives in accordance with the international CALS standard ISO 10303 (STEP) enables one to increase sales of new equipment.

Topic: Sustainable process-product development through green chemistry

Abstract

In this work we attempted to evaluate the stability of penicillin G acylase (PGA) from *Escherichia coli* in their native form and free *Candida antarctica* lipase B (CaLB) at low water content. The hydrolysis of penicillin G to 6-aminopenicillanic acid (6-APA) and phenyl acetic acid (PAA) catalysed by PGA and the synthesis of butyl butyrate from vinyl butyrate and 1-butanol catalyzed by CaLB were chosen as activity tests. The influence of these new solvents on enzyme stability was studied by incubating the enzyme (PGA or CaLB) in ionic liquids based on dialkylimidazolium cations associated with perfluorinated and dicyanamide anions at 40°C and 30°C, respectively. Stability studies indicate that CaLB and PGA exhibited greater stability in water-immiscible ionic liquids than in water-miscible ionic liquids. Specifically, native penicillin G acylase shows greater stability in IL media than in organic solvents. For example, a half-life time of 23 h was obtained in 1-ethyl-3-methylimidazolium bis{(trifluoromethyl)sulfonyl}imide, $[emim^+][TfN_2^-]$, which was about 2000-fold higher than that in 2-propanol. The higher half-life time of CaLB was observed in $[omim^+][PF_6^-]$ ($t_{1/2}$=84 h).

1. Introduction

In nature, enzymes act as catalysts of living systems and are designed to function in aqueous solutions. However, anhydrous conditions are needed for synthetic transformations using enzymes. The use of organic solvents as non-aqueous environments offers the possibility of carrying out synthetic reactions by hydrolytic enzymes, increasing the solubility of organic substrates (Klibanov, 2001). However, volatile organic solvents have a detrimental impact on the environment, and it is therefore necessary to develop new alternatives for enzyme-catalyzed synthesis in environmentally friendly reaction media. ILs have recently been shown to be an appropriate non-aqueous media for many enzyme-catalyzed reactions, including the synthesis of aminoacids (Eckstein et al., 2002) and aliphatic esters (Berberich *et al*., 2003), the kinetic resolution of rac-aromatic alcohols (Noël et al., 2004) and the carbohydrate ester synthesis (Kim et al., 2003). Ionic liquids are organic salts that are liquid close to room temperature. They normally consist of an organic cation, being the most commonly used dialkylimidazolium and tetraalkylammomiun salts, and a polyatomic inorganic anion having a strongly delocalized negative charge (e.g. hexafluorophosphate, tetrafluoroborate) (Brennecke and Maginn 2001).

From an environmental point of view, the most important properties of ionic liquids are their negligible vapour pressure, which makes them environmentally benign solvents compared with volatile organic solvents and their good chemical and thermal stabilities (Sheldon 2001). Additionally, the physical-chemical properties of ionic liquids, such as their hydrophobicity, density, viscosity, melting point, polarity and solvent properties, may be modified by altering

* Corresponding author. Tel + 034-968-367363. E-mail:gvillora@um.es

the anion or the cation (Dzyuba and Bartsch 2003). Indeed, this feature is a key factor for realizing successful reactions since appropriate combinations of the cationic and anionic parts of the solvent can be made. In this sense, ionic liquids are often referred to as designer solvents (Freemantle 1998). Lipase has shown good behaviour as a catalyst in non-conventional media (Hernández et al. 2006, Paiva et al. 2002). Among the ionic liquids used for lipase-catalyzed reactions, those containing alkylimidazolium cations are showed to be one of the most interesting. In spite of this, it is known that some of these ionic liquids have a strong impact on the activity and stability of lipases (Lau et al. 2004). On the other hand Penicillin G acylase (PGA; EC 3.5.1.11) is the key enzyme used in the industrial production of β-lactam penicillin antibiotics. This enzyme hydrolyzes the side chain of penicillin G and related β-lactam antibiotics, releasing 6-amino penicillanic acid (6-APA), which is the building block in the manufacture of semisynthetic penicillins. PGA can also be used for the production of semisynthetic β-lactam antibiotics, in which the enzyme catalyses the condensation of an acyl group and a 6-APA molecule. The use of non-conventional media such us organic solvents or water-cosolvent mixtures has increased the performance of enzymatic β-lactam synthesis (Illanes *et al*., 2002). Thermodynamic equilibrium could be shifted toward the synthesis using hydrophobic solvents in the reaction medium. It has been demonstrated that PGA is highly active in apolar organic solvents, catalysing the resolution and protection of L-amino acids, D-amino acids and amines (Carboni et al., 2004).

This work studies the stability of free *Candida antarctica* lipase B (CaLB) and penicillin G amidase (PGA-450) in several ionic liquids consisting of dialkylimidazolium cations combined with a range of anions, including hexafluorophosphate, bis(trifluoromethylsulfonyl)imide and dicyanamide (see Figure 1), as well as in a common organic solvents.

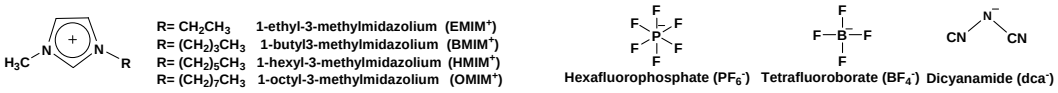

Figure 1. Ions involved in the assayed ionic liquids.

Butyl butyrate synthesis from vinyl butyrate and 1-butanol catalyzed was chosen as reaction model (see Figure 2) for CaLB. The hydrolysis of penicillin G (PG) to 6-aminopenicillanic acid (6-APA) and phenyl acetic acid (PAA) was chosen as activity test for PGA. A comparison of the stability of CaLB and PGA in ionic liquids was also performed.

2. Materials and Methods

2.1. Materials

A commercial lipase (EC 3.1.1.3) preparation was used as catalyst: free *Candida antarctica* lipase B aqueous solution (Lipozyme® CaLB L), which was a gift from Novo España S.A. Prior to use, the enzyme solution was 4-fold diluted in 20 mM phosphate buffer at pH 7. Penicillin G acylase (EC 3.5.1.11) from *Escherichia coli* was purchased from Sigma-Aldrich-Fluka Chemical Co., 29 U/mg. Activity units (U) are reported based on the manufacturer´s determination of activity using the hydrolysis of a 2% (w/v) solution of penicillin G potassium salt (PG) in 0.1 M phosphate buffer pH 7 at 37 ºC.

[bmim$^+$][PF_6^-], [hmim$^+$][PF_6^-], [omim$^+$][PF_6^-], [bmim$^+$][BF_4^-], [hmim$^+$][BF_4^-], were purchased from Solvent Innovation (purity > 99%). The ionic liquids [emim$^+$][TfN_2^-] (purity >99%) and [bmim$^+$][TfN_2^-] (purity >99%) were purchased from Sigma-Aldrich-Fluka Chemical Co. and Strem Chemical Inc., respectively and [hmim$^+$][TfN_2^-] (purity >99%) from Merck KgaA. *1-Butyl-3-methylimidazolium dicyanamide, [bmim$^+$][dca$^-$]* was synthetized as described in a

previous work (de los Ríos et al., 2007). Substrate, solvents and other chemicals were purchased from Sigma-Aldrich-Fluka Chemical Co., and were of the highest purity available.

2.2. CaLB stability in ionic liquids

Mixtures containing 457 μL of ionic liquid and 10 μl of *Candida antarctica* lipase B (8.5 mg mL^{-1} in 20 mM phosphate buffer at pH 7) were incubated at 30 ºC in different screw-capped vials of 1.5 mL total volume. At different incubation times, 19.2 μL (150 μmol) vinyl butyrate and 13.8 μL (150 μmol) 1-butanol were added and the activity of CaLB was measured as described bellow.

2.3. CaLB activity in ionic liquids

19.2 μL (150 μmol) vinyl butyrate and 13.8 μL (150 μmol) 1-butanol were added to 1.5 mL screw-capped vials containing 457 μL of each ionic liquid, or hexane. The reaction was started by adding 10 μL of *Candida antarctica* lipase B (8.5 mg mL^{-1} in 20 mM phosphate buffer at pH 7) and run for 2 h at 30ºC. At different times, 15 μL aliquots were extracted and suspended in 485 μL hexane. The biphasic mixture was strongly shaken for 2 min to extract all the substrates and products into the hexane phase. Then, the hexane solution of ethyl hexanoate (internal standard) (100 μL, 30 mM) was added into the hexane extract (400 μL) and resulting solution (5 μL) was analyzed by GC. The synthetic activity was defined as the amount of enzyme that produces 1 μmol of butyl butyrate per minute.

2.4. PGA stability in ionic liquids

Into a screw-capped vial of 1.5 mL total volume containing 490 μL of ILs or 2-propanol, 10 μL of 35 mg/mL of PGA in 0.1 M phosphate buffer were added and the mixture incubated at 40ºC. At different times, a 30 μL aliquot of the incubation medium was taken and the hydrolytic activity of PGA was measured as described below.

2.5. Enzymatic hydrolisis of penicillin G

The reaction was started by adding a 30 μL aliquot of the incubation medium (PGA incubated in the IL or 2-propanol at 40ºC as described in 2.4) into a screw-capped vial of 1.5 mL total volume containing 470 μL 50 mM PG in in 0.25 M phosphate buffer pH 8 and run at 40 ºC for 24 h. At different times, 50 μL aliquots were extracted and dissolved in 150 μL of 50 mM HCl to stop the reaction and then 50 μL of this solution were added to 575 μL of 0.72 mM resorcinol in 0.25 mM phosphate buffer (internal standard). Finally, 5 μL of the resulting solution was analyzed by high-performance liquid chromatography (HPLC). One unit of hydrolytic activity was defined as the amount of enzyme that produces 1 μmol of PAA per minute at 40ºC pH 8 from 50 mM PG in 0.25 M phosphate buffer.

2.6. Analytical methods

Substrate and product concentrations of penicillin G hydrolysis were determinated by HPLC using a LiChrospher RP-18 column (25 cm length and 4 mm internal diameter, 5 μm particle size and 10 nm pore size). Samples were eluted isocratically with 80% (v/v) 20 mM potassium phosphate buffer pH 6,0 and 20% (v/v) acetronitrile at a flow rate of 0.8 ml/min, and analysed by a UV detector at 220 nm.

GC analysis of the substrates and product of butyl butyrate synthesis was performed with an Agilent 6890 N instrument equipped with FID detector and a Nukol™ capillary column (15m × 0.53mm ×0.5μm, Supelco), using ethyl hexanoate as internal standard. The chromatographic conditions were as follows: carrier gas (N_2) at 1.89 psi (51 mL /min total flow); temperature program: 40 ºC, 4 min; 5 ºC/min, 135ºC; split ratio: 7.9/1; detector: 220 ºC.

3. Results and Discussion

A key criterion for selecting an enzyme-IL system is the stability of the catalyst within the reaction medium. The influence of these new solvents on *Candida antarctica* lipase B stability was studied by incubating the enzyme in different ionic liquids at 30ºC and 2% (v/v) water content. The ionic liquids selected for this study were: [bmim$^+$][PF_6^-], [hmim$^+$][PF_6^-], [omim$^+$][PF_6^-], [hmim$^+$][TfN_2^-], [hmim$^+$][BF_4^-] and [bmim$^+$][dca$^-$]. In all cases, the activity loss followed a second order deactivation kinetics, which permitted the half-life time ($t_{1/2}$) of the enzyme to be determined (see Table 1).

Table 1. Half-life times of *Candida antarctica* lipase B exhibited by incubation in diferent ionic liquids at 30ºC.

Medium	Half-life time (h)
[bmim$^+$][PF_6^-]	48
[hmim$^+$][PF_6^-]	78
[omim$^+$][PF_6^-]	84
[hmim$^+$][NTf_2^-]	72
[hmim$^+$][BF_4^-]	7
[bmim$^+$][dca$^-$]	1.5

As can be seen, the stability of CaLB seems to increase with the increase in the alkyl chain length of the cation, which agrees with the increase in ILs hydrophobicity, although no significant differences in stability has been observed between [hmim$^+$][PF_6^-] and [omim$^+$][PF_6]. These results are in accordance with those obtained by Lozano et al. (2004), who found that the enzyme was very sensitive to deactivation when hydrophobicity decreased, at 2 % water content. The most important effect on CaLB stability was observed by changing the nature of IL anions, as can be observed in Table 1 by comparing the half-life times of CaLB in ionic liquids containing the same cation. For the ionic liquids containing the cation [bmim$^+$], the half-life times increased in the following order: [bmim$^+$][dca$^-$] < [bmim$^+$][PF_6^-], and for those containing the cation [hmim$^+$] in the following order: [hmim$^+$][BF_4^-]<[hmim$^+$][TfN_2^-]< [hmim$^+$][PF_6^-]. Bearing in mind the nucleophilicity sequence for the anions [dca$^-$]> [BF_4^-] >[TfN_2^-]> [PF_6^-] (Irimescu and Kato 2004b, Muldoon et al. 2001), the increase in half-life time was in agreement with the decrease in this parameter. This could be explained by the fact that the most nucleophilic anion may interact more strongly with the enzyme, causing changes in the active enzyme structure. [omim$^+$][PF_6^-], composed of the least nucleophilic anion and the most hydrophobic cation, was seen to be the best IL for protecting the enzyme, with a half-life time of 84 h. In contrast, [bmim$^+$][dca$^-$], which contained the most nucleophilic anion and the least hydrophobic cation, produced a fast fall on CaLB activity, with a half-life time of 1.5 h. The same tendency was observed by Kaar et al. (2003) with Novozym® 435, which was more stable in [bmim$^+$][PF_6^-] than in [bmim$^+$][NO_3^-] and by Persson and Bornscheuer (2003) [33] using an esterase from *B. stearothermophilus*, which showed greater stability in [bmim$^+$][PF_6^-] than in [bmim$^+$][BF_4^-]. The influence of ILs on PGA stability was studied by incubating in several ILs: [bmim$^+$][BF_4^-], [bmim$^+$][PF_6^-], [omim$^+$][PF_6^-], [emim$^+$][NTf_2^-], [bmim$^+$][NTf_2^-] and in organic solvents (2-propanol, toluene, dichloromethane) at 40 ºC.Half-life times of PGA are shown in Table 2.

Table 2. Half-life times of Penicillin G acylase exhibited by incubation in diferent ionic liquids at 40ºC.

Medium	Half-life time (h)
[emim$^+$][Tf_2N^-]	23.21
[bmim$^+$][Tf_2N^-]	9.42
[bmim$^+$][PF_6^-]	1.27
[omim$^+$][PF_6^-]	0.80
[bmim$^+$][BF_4^-]	0.29
2-propanol	0.01

Full enzyme deactivation was practically instantaneous in toluene and dichloromethane, so the only assayed organic solvent in which PGA showed significant stability at the assayed conditions was 2-propanol. As can be seen from Table 1, the half-life time of PGA in ILs was notably improved with respect to 2-propanol. As CaLB, the most important effect on PGA stability was observed by changing the nature of IL anions by comparing the half-life times of PGA in ionic liquids based on the same cation. As can be seen in Table 1, in ionic liquids containing the [bmim$^+$] cation the half-life times increased in the following order: [bmim$^+$][NTf_2^-] > [bmim$^+$][PF_6^-] > [bmim$^+$][BF_4^-]. The low half-life time of PGA in [bmim$^+$][BF_4^-], which is fully miscible with water, could be attributed to the interaction with the absolute amount of water indispensable for acquisition and maintenance of the catalytic conformation of the enzyme. This solvent could strip off the tightly bound water molecules, resulting in either alteration or sometimes distortion of the catalytic conformation and consequently result in deactivation of the enzyme (Nara et al., 2002). The cation also exerts a strong effect on the denaturation of PGA, since, contrary with CaLB, the enzyme is more stable when suspended in the ILs containing cation with shorter 1-alkyl chain length. This effect was even more evident in the most hydrophobic ionic liquids, those based on [NTf_2^-] anions. This behavior has been also described by Basso *et al*. (2005) using the enzyme in an immobilized form, PGA-450.

4. Conclusions

The stability of *Candida antarctica* lipase B and Penicillin G acylase was tested for a wide range of 1,3-dialkylimidazolium based ionic liquids. In both cases, The most important effect on enzyme stability was observed by changing the nature of IL anions. It is worthing to note how the presence of ILs enhance the stability of PGA and, in the case of [emim$^+$][NTf_2^-], an over-stabilization phenomenon is produced, increasing the half-life time by about 2000-fold with respect to 2-propanol, used as reference organic solvent. The lower half-life time of enzymes was observed in [bmim$^+$][BF_4^-] for PGA and in [bmim$^+$][dca^-] for CaLB. This could be explained by the fact that these ILs are fully miscible with water, so they could interact with the absolute amount of water indispensable for acquisition and maintenance of the catalytic conformation of the enzymes.

Accordingly, the potential advantages of these new solvents, together with the unique stabilization effect on enzymes, may open up the possibility of development of new biocatalytic processes based on ionic liquids.

Keywords: Sucrose, Fermentation, *Aspergillus japonicus*, Fructooligosaccharides, Immobilization.
Topic: Multi-scale and/or multi-disciplinary approach to process-product innovation.

Abstract

The fructooligosaccharides (FOS) production using immobilized cells of the fungus *Aspergillus japonicus* ATCC 20236 was evaluated. Polyurethane foam, stainless steel sponge, vegetal fiber sponge, pumice stones, zeolites and cork were tested as immobilization carrier during the fermentation under submerged conditions. Experiments were carried out in 500 ml Erlenmeyer flasks containing 1 g of carrier and 100 ml of sucrose medium (165 g/l) enriched with nutrient sources. The flasks were agitated in an orbital shaker at 160 rpm, 28°C, for 48 h. Samples were withdrawn during the fermentation to determine the consumption of sucrose, liberation of glucose and fructose to the medium, production of FOS (1-kestose (GF_2), 1-nystose (GF_3) and 1-β-fructofuranosyl nystose (GF_4)) and enzymatic activity of β-fructofuranosidase. At the fermentation end, the cell mass adhered to the carrier was quantified. The microorganism adhesion to the carrier varied to each tested material. Consequently, the FOS production and enzymatic activity also varied to each medium, due to the differences in the amount of free and immobilized cells present. The highest values of immobilized cells, FOS production and enzymatic activity were achieved by using vegetal fiber sponge as immobilization carrier, while cork gave the worst results.

1 Introduction

Fructooligosaccharides (FOS) are naturally occurring sugars that have beneficial effects as food ingredients, because of its low calorie, noncariogenic nature and ability to promote the growth of beneficial bifidobacteria-rich intestinal flora and immune system modulation. Although FOS is present in several plants, the concentration of them in these sources is low and choice of plants as a source of FOS is limited by seasonal conditions (Wang & Zhou, 2006). Hence, microbial FOS production by the action of fungal fructosyltransferase on sucrose is more feasible at industrial level (Sangeetha et al., 2005).

In the process of FOS production with fructosyltransferase, the main problem is that the activity of the enzyme is severely inhibited by glucose, which is generated as a byproduct. As a result, maximum conversion yield of sucrose to FOS ranges from 55 to 60% (w/w) due to unreacted sucrose and glucose. Since the produced FOS mixture contains considerable amounts of sucrose and glucose, its use has been limited (Yun, 1996). Therefore, the development of processes that permit the FOS production in industrial scale with higher yields, and lower necessity of purification of the final product, is necessary.

The use of immobilized enzymes or cells can be useful for the development of effective and economic methods for large-scale production of FOS. Nevertheless, the selection of the immobilization material is essential to design an effective system for this purpose. The aim of the present work was to evaluate the FOS production using immobilized cells of the fungus *Aspergillus japonicus* ATCC 20236. Polyurethane foam, stainless steel sponge, vegetal fiber

sponge, pumice stones, zeolites and cork were tested as microorganism carrier during the production of FOS under submerged fermentation conditions.

2 Material and methods

2.1. Carrier's preparation

Six porous carriers were tested: Polyurethane foam, stainless steel sponge, and vegetal fiber sponge (Scotch Brite, 3M Spain, SA), pumice stones (Elite, purchased at a local department store), zeolites molecular sieves type 4A (BDH Chemicals Ltd., Poole, England), and cork. Polyurethane foam, vegetal fiber sponge and cork were 0.3 cm^3 cubes. Stainless steel sponge was used as cuttings of irregular size. Pumice stones were granules of 8–24 mesh (2.36 mm to 0.71 mm – sieve opening), and zeolites were approximately 0.1 cm in diameter and 0.4 cm length. To be used as immobilization carrier, all the materials were pre-treated by boiling for 10 min, washed three times with distilled water, and then dried overnight at 60 ºC. Prior to use, all the carrier materials were autoclaved at 121 ºC for 20 min.

2.2. Microorganism maintenance

The strain *Aspergillus japonicus* ATCC 20236 was used in the experiments. The strain was maintained on potato dextrose agar (PDA - Difco) plates at 4 ºC, and the spores were maintained mixed with glycerol solution in ultra-freezer at −80 °C. For the production of spores the strain was grown on PDA medium, at 25-30 ºC for 7–8 days.

2.3. Fermentation conditions

The fermentation experiments were carried out in 500 ml Erlenmeyer flasks containing 1 g of carrier and 100 ml of culture medium with the following composition (% w/v): sucrose 16.5, yeast extract 2.75, $NaNO_3$ 0.2, K_2HPO_4 0.5, $MgSO_4 \times 7H_2O$ 0.05, and KCl 0.05. Sterilization of the medium was carried out at 121 ºC for 20 min.

Flasks were inoculated with 1.0 ml of a spore suspension containing around 1.8×10^7 spores/ml, which was prepared by scrap down the spores from the PDA plates with a sterilized solution of 0.1% w/v Tween 80, and counted in a Neubauer chamber. The inoculated flasks were incubated in a rotary shaker at 28 °C and 160 rpm for 48 h. Cells were immobilized in situ in the flasks by natural adsorption.

Samples for analysis were collected at regular intervals and filtered, using 0.2 μm filters to separate the cell pellets from the culture fluid. In the filtered broth, FOS (1-kestose, 1-nystose, and 1-β-fructofuranosyl nystose), residual concentration of other sugars (sucrose, fructose, and glucose), pH and extracellular enzyme activity were measured. The concentrations of free and immobilized cells were determined at the fermentation end.

All the fermentation experiments were conducted in duplicate and the average values are reported. The relative standard deviation was less than 5%.

2.4. Analytical methods

Cell mass concentration. Free cell mass concentration was determined by dry weight per volume (g/l). At the end of the fermentation, the biomass was collected by vacuum filtration of the fermentation broth through pre-weighed 0.45 μm membranes, washed with distilled water and dried at 105 °C to constant weight.

The amount of biomass attached to the carriers was determined after washing the support material with distilled water for three times, and drying at 105 °C to constant weight. The biomass dry weight was determined from the difference between the cells plus carrier and the carrier itself.

Enzymatic activity: Samples of the fermentation media were filtered (through 0.2 μm membranes) to remove the cell mass and the filtrate was utilized as extracellular enzyme

source. The β-fructofuranosidase (FFase) activity was determined by measuring the amount of glucose produced from sucrose (Yoshikawa et al., 2006). The reaction mixture contained 100 ml of the crude FFase extract, 300 mmol of sucrose and 50 mmol of sodium acetate buffer (pH 5.0) in a total volume of 1 ml. After incubation for 20 min at 30 ºC, the reaction was stopped by heating for 5 min at 100 ºC. After cooling, the amount of glucose released into the supernatant was measured by high-performance liquid chromatography (HPLC, see below). One unit (U) of the FFase activity was defined as the amount of enzyme required to release 1 µmol of glucose per min, from sucrose under the above conditions.

Transfructosylating and hydrolyzing activities. The reaction was carried out for 180 min using 0.5 U/ml of FFase in the reaction mixture described above (Yoshikawa et al., 2006). Transfructosylating activity (Ut) and hydrolyzing activity (Uh) were determined by measuring the concentrations of 1-kestose and fructose by HPLC, respectively. One unit of transfructosylating activity was defined as the amount of enzyme required to transfer 1 µmol of fructose per min. One unit of hydrolyzing activity was defined as the amount of enzyme required to release 1 µmol of free fructose per min.

Sugars and FOS concentrations. FOS (1-kestose, 1-nystose, and 1-β-fructofuranosyl nystose) and other residual sugars (sucrose, glucose, and fructose), were directly analyzed by high performance liquid chromatography (HPLC) on an equipment LC-10 A (Jasco, Japan) with a Prevail Carbohydrate ES column (5 um, 250 x 4.6 mm, Alltech) at room temperature, and a refractive index detector. The response of the refractive index detector was recorded and integrated using the Star Chromatography Workstation software (Varian). A mixture of acetonitrile and 0.04% ammonium hydroxide in water (70/30 v/v) was used as mobile phase at a flow rate of 1.0 ml/min. Before injection, the samples were filtered through 0.2 µm filters and diluted with Milli-Q water when needed. The sugars and FOS concentrations were determined from standard curves made with known concentrations of each compound. The total yield of FOS (Y_{FOS}) was calculated as the sum of 1-kestose (Y_{GF2}), 1-nystose (Y_{GF3}), and 1-β-fructofuranosyl nystose (Y_{GF4}), to initial sucrose concentration.

3 Results and discussion

3.1. Immobilized cells concentration

Concentration of cells immobilized in the different carriers is given in Table 1. It can be noted that all the evaluated materials were able to immobilize cells, but with different capacities. Among them, pumice stones, cork and zeolites gave the lower immobilized cells concentration. A major quantity of cells was adhered into polyurethane foam, but the highest cell mass was adhered into stainless steel and vegetal fiber sponges, with the result of vegetal fiber sponge being 10% higher than that of stainless steel sponge.

Table 1. Free and immobilized cells concentration during FOS production by *A japonicus* immobilized in different materials.[a]

Immobilization carrier	Immobilized cells (g/g carrier)	Free cells (g/l)
Pumice stones	0.13	20.83
Zeolites	0.19	19.36
Stainless steel sponge	1.13	2.59
Polyurethane foam	0.48	6.44
Vegetal fiber sponge	1.25	5.09
Cork	0.14	9.97

[a] Values after 48 h of fermentation

All the experiments presented free cells in the medium besides those immobilized. Pumice stones, cork and zeolites, which gave the lowest immobilized cells concentration, presented the major amounts of free cells; while stainless steel sponge and vegetal fiber sponge, which immobilized the major proportion of cells, resulted in the lowest free cells concentration.

3.2. Sucrose consumption and FOS production with immobilized cells

Fermentation with the different carriers had similar behaviors of sucrose consumption and FOS production, with an initial lag phase of approximately 12 h where few substrate was consumed (Figure 1A). As a consequence, practically was not observed FOS production during this period (Figure 1B). Nevertheless, in the subsequent 12 h the process attained the maximum FOS production for practically all the carriers evaluated, as result of the almost depletion of sucrose from the media. 1-Kestose was the main FOS formed in the media at this time, followed by 1-nystose and 1-β-fructofuranosyl nystose that required a larger fermentation time to be formed. On an average, maximum 1-kestose concentration was observed in 24 h of fermentation; 1-nystose concentration was maximum around 36 h of fermentation, while the concentration of 1-β-fructofuranosyl nystose required approximately 48 h to attain the highest value. Similar behavior was observed by Cruz et al. (1998) during the FOS production by *Aspergillus japonicus* immobilized in calcium alginate. According to these authors, the fructooligosaccharide synthesis was always sequential in the sense $GF \rightarrow GF_2 \rightarrow GF_3 \rightarrow GF_4$ as a consequence of the increasing *Km* values for such products presented by the transfructosylase. Thus, high concentrations of the preceding oligosaccharide are always necessary for the synthesis of its homologue with one more fructose unit. This would also explain why the content of 1-kestose is higher at the beginning of the enzymatic reaction.

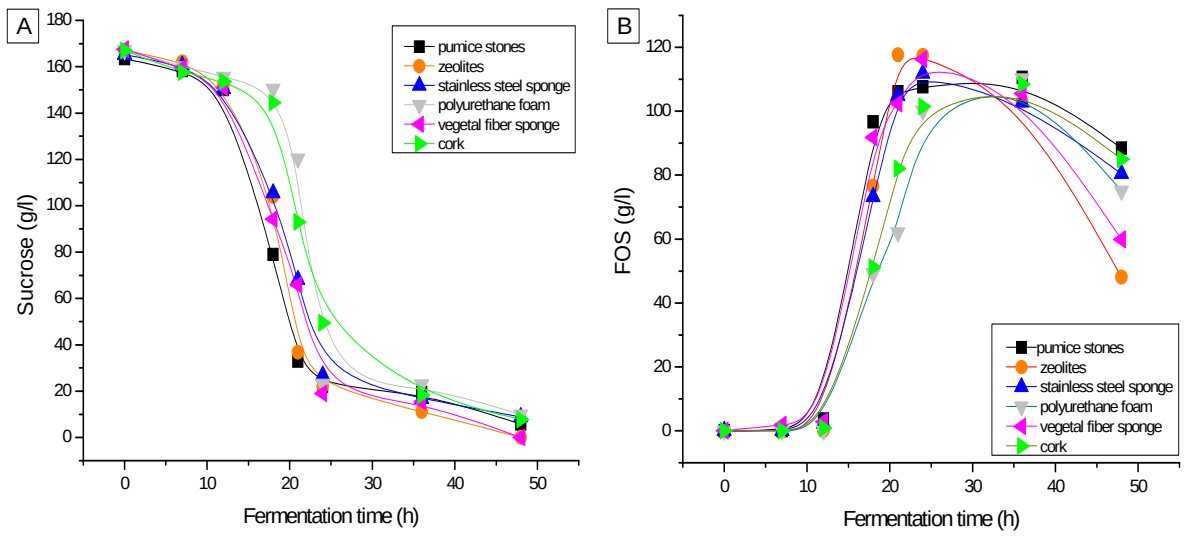

Figure 1. Sucrose consumption (A) and FOS production (B) using *A. japonicus* immobilized in different carriers.

After the initial 24 h fermentation, due to the sucrose exhaustion from the media, the microorganism passed to consume 1-kestose, and therefore, even being observed formation of the other two FOS, the total FOS concentration started to decrease in all media, as can be noted in Figure 1B. Consequently, when the reaction time was extended to over 48 h, changes in the total FOS content occurred, with an increase in GF_3 and GF_4 contents, and a corresponding loss of 1-kestose.

Although the kinetic behaviors of sucrose consumption and FOS production have been similar for all the assays, the fermentative parameters were different to each one of them,

due to the differences in residual sucrose content and total FOS produced, probably as a consequence of the different values of free and immobilized cells. As can be observed in Table 2, the medium containing zeolites gave the best results, but cells in this medium were mostly free (only few amounts were immobilized in the carrier – see Table 1). The media containing vegetal fiber or stainless steel sponges as carriers gave fermentative parameters values for FOS production close similar to those achieved with zeolites, but with an important advantage that in these cases the carrier was able to immobilize the large amounts of cells (Table 1). This means that using vegetal fiber or stainless steel sponges as carrier, it was possible to immobilize large amounts of cells and produce FOS with elevated yields. The medium containing cork as carrier resulted in the lowest values of FOS concentration, $Y_{P/S}$, and Q_P.

Table 2. Fermentative parameters of FOS production by immobilized *A. japonicus*.

Immobilization carrier	Maximum FOS (g/l)	Fermentation time (h)	$Y_{P/S}$ per total substrate (g/g)	$Y_{P/S}$ per consumed substrate (g/g)	Q_P (g/l.h)
Pumice stones	110.55	36	0.68	0.76	3.07
Zeolites	117.45	24	0.70	0.81	4.89
Stainless steel sponge	111.80	24	0.68	0.81	4.66
Polyurethane foam	110.26	36	0.66	0.76	3.06
Vegetal fiber sponge	116.26	24	0.69	0.78	4.84
Cork	108.47	36	0.65	0.73	3.01

3.3. Enzyme activity

Results for the FFase activity by *A. japonicus* immobilized in the different carriers are shown in Figure 2. The best value of enzyme production (42.92 U/ml) was found after 36 h with cells immobilized in vegetal fiber sponge. These values can be favorably compared to those obtained during FOS production by other fungus species. For example, under optimized cultivation conditions, *A. japonicus* JN-19 yielded the highest FFase activity of 55.42 U/ml at 96 h fermentation (Wang and Zhou 2006). In the present study, the maximum FFase activity was achieved after only 36 h fermentation, giving thus a much higher productivity.

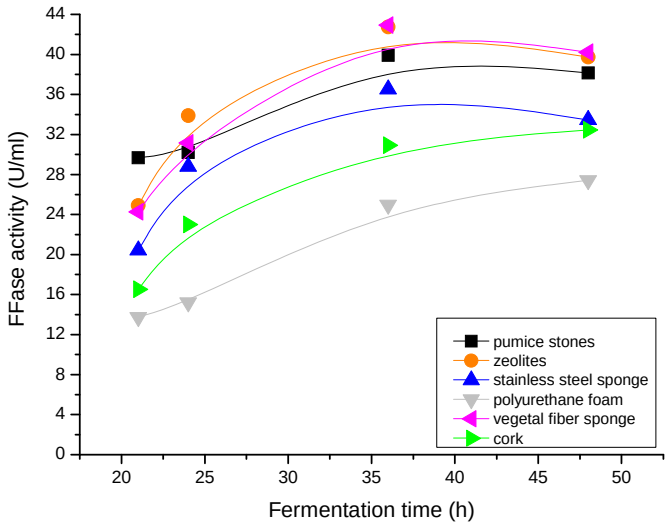

Figure 2. FFase activity by *A. japonicus* cells immobilized in different carriers.

FFases commonly possess both hydrolytic (Uh) and transfructosylating (Ut) activities. Nevertheless, for an efficient FOS production it is preferable to have a high Ut/Uh ratio (Chen & Liu, 1996). Table 4 shows the Ut/Uh, ratio of FFase obtained for *A. japonicus* immobilized in the different carriers. Maximum values were achieved at 48 h fermentation using vegetal fiber sponge as immobilization carrier.

Table 3. Ratio between the transfructosylating and hydrolyzing activities of FFase during FOS production by immobilized *A. japonicus*.

Immobilization carrier	Ut/Uh ratio at 48 h fermentation
Pumice Stones	4.31
Zeolites	3.12
Stainless steel sponge	2.93
Polyurethane foam	4.15
Vegetal fiber sponge	4.82
Cork	2.34

Conclusions

Among the six different materials evaluated for immobilization of the fungus *Aspergillus japonicus* during FOS production, vegetal fiber sponge proportioned the best fermentation results, being able to immobilize the major amount of cells, and giving the highest values of FOS production and FFase activity. Such material was thus selected for use in subsequent experiments aiming to maximize the FOS production by *Aspergillus japonicus* ATCC 20236.

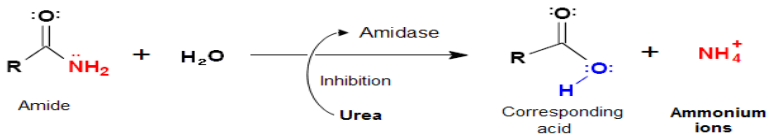
Keywords: Urea in milk; Amidase from *Pseudomonas aeruginosa*; Biosensor based on ISE; Membranes; Active-site inhibitor
Topic: Sustainable process-product development through green chemistry.

Abstract

The present work involves the development of a biosensor based on ion-selective electrode (ISE) for assay of urea in milk by using a novel enzymatic method. Urea is a powerful time-dependent active-site directed inhibitor for aliphatic amidase (acylamide amidohydrolase EC 3.5.1.4) from *Pseudomonas aeruginosa* which catalyses the hydrolysis of a small number of aliphatic amides producing the corresponding acid and ammonia (Martins *et. al*. 2006; Tata *et al*, 1994) according to the following reaction:



Increasing concentrations of urea were found to inhibit proportionally amidase activity which was detected by the hydrolase reaction. Therefore, urea concentration in samples was inversely proportional to amidase activity which was measured with acetamide as substrate by using ISE for ammonium ions.

Cell-free extracts containing amidase activity were immobilized on nylon and polyethersulfone membranes in the presence of gelatin and glutaraldheyde as the bi-functional reagent. Membranes containing immobilized amidase activity were used to set up a biosensor based on ISE for ammonium ions by using acetamide as the substrate and the enzyme reaction was followed by measurement of ammonium ions due to hydrolysis of the aliphatic amide (Fig.1)

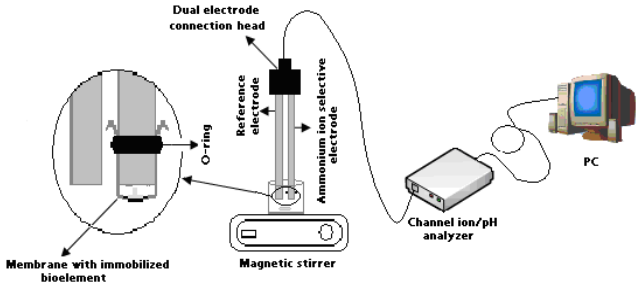


Fig.1 - Experimental set-up for potentiometric biosensor: ammonium ion selective electrode containing polyethersulfone membrane with immobilized cell-free extract and reference electrode, electrochemical cell, magnetic stirrer, ISE analyser and PC.

Subsequently, this biosensor was washed and incubated with milk containing increasing concentrations of urea in the range of 0 – 1.0 mM, for 1 h. After the incubation period, the biosensor containing amidase activity was assayed again by using acetamide as the substrate. There was a linear relationship between a decrease of the biosensor response in mV and urea concentration in milk. This biosensor exhibited a linear response in the range of 2.0 – 10.0 x 10^{-6} M of urea either in a buffer solution or in milk and a response time of 60 s.

The biosensor containing amidase activity could be re-used again by reactivating enzyme activity with hydroxylamine for 2h. This biosensor was stable for at least 1 month since it did not lose enzyme activity and it is cheap because cell-free extracts containing amidase activity can be used for quantification of urea in milk.

Introduction

The food processing industry requires suitable analytical methods for quality control of food which are fast, reliable, specific and cost-effective since current wet chemistry tests are time-consuming and some may require highly skilled labour as well as expensive equipment (Verma *et al.*, 2003). This urgent need is due to increased regulatory action and consumer concern about food composition and safety (Luong *et al.*, 1997).

Milk has been considered as a human's most nearly perfect food as far as nutritional properties are concerned and its consumption depends on strict sanitary control employed by the dairy industry (Potter and Hotchkiss, 1995). Urea is present as an adulterant in milk since it is not a natural constituent of milk which has originated increasing concern from the public as the consumer. The presence of urea in milk may be due to excessive nitrogen uptake whose concentration is in the range of 1.66 – 4.16 mM and high urea concentrations are responsible for reduced fertility rates in dairy cattle (Butler *et al.*, 1996) There are several methods available for quantification of urea in food, industrial effluents and biological fluids. However, all these analytical and biosensor methods present some advantages and drawbacks (Koncki, R. (2007). Therefore, a biosensor development based on enzyme electrode could be useful for quantification of urea in food as well as in industrial effluents. Although purified enzymes exhibit very high specificity either for their substrates or inhibitors, their application in biosensor development may be limited due to time-consuming and costly enzyme purification, requirement of multiple enzymes or the need of cofactor/coenzyme. The use of whole cells containing the desired activity may provide an ideal alternative to overcome these problems. However, the presence of many enzymes and co-factors that are present in whole cells may catalyse undesirable reactions which can compromise the biosensor selectivity (Lei *et. al*., 2006).

The present work involves the development of an enzyme inhibition-based biosensor by using amidase from *Pseudomonas aeruginosa* (Amine et. al, 2006). This biosensor is based on ion-selective electrode (ISE) for assay of urea in milk by using a novel enzymatic method. Urea is a powerful time-dependent active-site directed inhibitor for aliphatic amidase (acylamide amidohydrolase EC 3.5.1.4) from *Pseudomonas aeruginosa* which catalyses the hydrolysis of a small number of aliphatic amides producing the corresponding acid and ammonia. Increasing concentrations of urea were found to inhibit proportionally amidase activity which was detected by the hydrolase reaction. Therefore, urea concentration in samples was inversely proportional to amidase activity which was measured with acetamide as substrate by using ISE for ammonium ions. The bio-component consists of cell-free extract containing amidase activity from *Pseudomonas aeruginosa* which was immobilized on several types of membranes and they could be re-used several times.

Materials and Methods

Materials

Glutaraldehyde was obtained from Sigma Chemical Co. (St. Louis, MO, USA). Modified polyethersulfone (PES) membranes (Ultrabind, US450 0,45 µm) were purchased from Gelman (USA) and Porablot® nylon (NY) plus was supplied by Macherey-Nagel, Germany. Milk (Mimosa brand) was purchased from a local supermarket. A

constitutive mutant strain L10 of *Pseudomonas aeruginosa* was isolated in our laboratory. All other reagents used were of analytical grade.

Methods

Bacterial strain, media and growth conditions for enzyme production

A constitutive mutant strain L10 of *Pseudomonas aeruginosa* was used as the source of amidase. Microbial strain (L10) was grown overnight in minimal salt medium as described previously (Brown and Clarke, 1972).

Enzyme extraction from P. aeruginosa

The cultures were harvested by centrifugation at 7000 x g for 10 min, the pellet was washed twice with saline, centrifuged and the resulting pellets stored at -20 ºC as described previously (Martins *et.al*., 2006).

Protein assay

Protein concentration was determined by the Coomassie blue dye binding method (Bradford 1976).

Immobilization of cell-free extract containing amidase activity

The immobilization of cell-free extract of *P. aeruginosa* was based on covalent bonding of cellular proteins to polyethersulfone membrane. Membrane discs were cut with 20mm of diameter and a mixture was prepared in an eppendorf tube containing 65 μl of cell-free extract in 50 mM Tris-HCl buffer pH 7.2 containing 1 mM β-mercaptoethanol, 1 mM EDTA, 10 % (v/v) glycerol and 1mM benzamidine (TMEGB buffer), 10 l gelatin (25%) and 5 μl of glutaraldehyde (5%, v/v). This mixture was immediately transferred to the center of membrane disc which was incubated at room temperature for 30 min. Subsequently, the membrane discs were washed three times with 3 ml of TMEGB buffer to remove unbound proteins of *Pseudomonas aeruginosa* to the membrane and were kept at 4ºC in a final volume of 3ml of TMEGB buffer.

Transducer

The transducer was a potentiometer with ammonium-ion selective electrode (ELIT) as described previously (Martins et. al, 2006) which was run in a personal computer (Fig. 1). Amidase catalyses the hydrolysis of acetamide forming acetic acid and ammonium ions as described above. The enzyme electrode consisted of immobilized cell-free extract containing amidase activity on several membranes and the side containing the cells was in contact with the surface of an ISE for ammonium ions through an O-ring as shown in Fig. 1. The calibration curve of NH_4Cl as a function of mV reading was carried out in 20 mM Tris buffer pH 7.2 containing 1 mM EDTA and 1mM -mercaptoethanol (TME buffer). The mV readings were plotted against the log of ammonium chloride concentration to provide the calibration data (Martins *et. al.* 2006). All potentiometric measurements were carried out in a final volume of 4 mL containing 0.1M acetamide in an appropriate buffer at room temperature in a magnetic stirrer. The enzyme electrode was placed in the reaction mixture and the biosensor response was determined from the steady state of the voltamogram obtained. All measurements were carried out in triplicates .

Urea assay

The biosensor response was determined by using a reaction mixture containing 0.1M acetamide in 20mM Tris buffer pH 7.2 in the absence of urea. Subsequently, the same membrane disc was washed with the same buffer several times and it was incubated with different concentrations of urea solutions either in Tris buffer or in milk for 30 min. The membrane discs were washed with buffer and used to determine biosensor response by using 0. 1M acetamide in the reaction mixture. There is a linear decrease

in biosensor response with increasing concentrations of urea solutions either in buffer or in milk. All experiments were carried out in triplicates. The biosensor response was measured as the difference between the slopes of the reaction with and without urea incubation (i.e ∆mV/min) of the membrane disc.

Enzyme assay by potentiometry

Amidase activity in free and immobilized cell-free extracts of *P. aeruginosa* was determined by using ISE for ammonium ions. The assays were carried out by using 0.1 M acetamide as a substrate in appropriate buffer, the progress curve of the reaction was followed and recorded for a few minutes and the values of ppm of NH_4^+ were converted in E (mV/min) as the biosensor response. Therefore, the increase in the ammonium ions formation was measured as a function of time in order to monitor the rate of amide hydrolysis in the presence of amidase which was present in cell-free extracts. One enzyme unit was defined as the amount of enzyme required to produce a change of 1 mV per minute in E at 25ºC and in aTris buffer.

Effect of [glutaraldehyde] for immobilization of cell-free extract.

A mixture was prepared containing 65 µL of cell-free extract, 10 µL of gelatin (25%) and final concentrations of glutaraldehyde solution in the range of 0 – 2.5% (v/v) in a final volume of 85 µL of the reaction mixture. The mixture was applied to a PES membrane disc with 20mm diameter with a surface area of 3.14 cm^2 and the biosensor response was obtained by using a reaction mixture containing 0.1 M acetamide in Tris buffer .

Performance of the biosensor for urea.

After optimization of the biosensor response, the analytical characteristics of the biosensor with polyethersulfone membrane were obtained by potentiometry for urea concentrations in the range of 0.02 – 1.0 x 10^{-3} M in Tris buffer. The biosensor response was measured as difference between the slopes of the reaction with and without urea incubation (i.e ∆mV/min) of the membrane disc.

Biosensor regeneration

Membrane discs previously used for assay of urea in milk were regenerated by reactivation with 20 mM hydroxylamine for 30 min and the regenerated membrane discs were used to measure the biosensor response in the reaction mixture described above. The biosensor response was measured in triplicates as a rate of reaction in mV/min in a final volume of reaction mixture of 4 ml.

Biosensor stability

In order to optimize the best storage conditions of the biosensor as well as its stability, different membranes containing immobilized cell-free extract of *P. aeruginosa* were stored in TMEGB buffer at 4ºC.

Determination of [urea] in milk

Urea recovery experiments were carried out by using commercial milk as well as in Tris buffer which were spiked with known amounts of urea. Biosensor response was measured in triplicates as a function of [urea] by using a Porablot NY Plus containing immobilized cell-free extract of *P. aeruginosa* which exhibited amidase activity as described above. The biosensor response was measured as the difference between the slopes of the reaction with and without urea incubation (i.e ∆mV/min) of the membrane disc.

Results and discussion

A typical sensogram is presented in Fig. 2 which reveals the hydrolysis of acetamide in the presence of immobilized cell-free extract of *P. aeruginosa* containing amidase activity since the values of NH_4^+ (ppm) were converted in E (mV) as the biosensor response. This figure also exhibits the progress curve of the reaction after incubation of the biosesnsor with urea solution which inhibited the rate of the reaction. Therefore, it represents a progress curve for the reaction catalysed by amidase which shows that there is an increase in the formation of ammonium ions as a function of time due to the hydrolysis of acrylamide producing acrylic acid and ammonia. From this data, the initial rate (mV/min) was determined from the initial linear part of the progress curve.

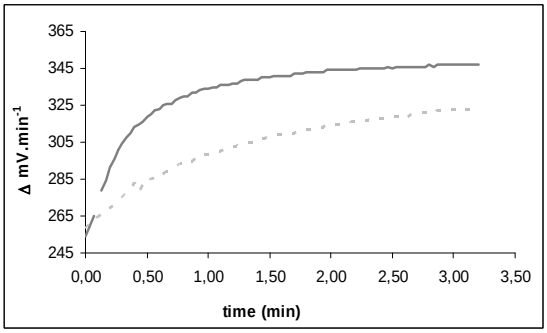

Figure 2 – Biosensor response as a function of time by using immobilized cell-free extract containing amidase activity on PES membrane. Measurements were carried out in a reaction mixture containing 0.1M acetamide in Tris buffer as described in Materials and Methods : - - - - - Incubation in 0.01mM Urea in TME buffer; —— No urea incubation .

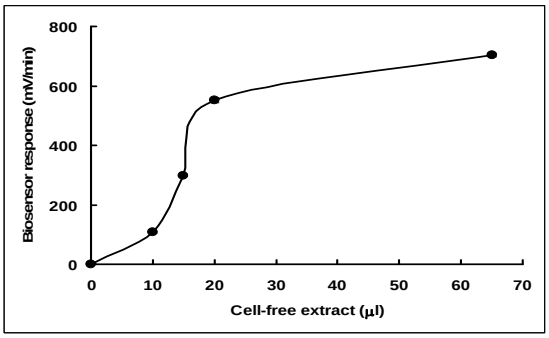

Figure 3 – Effect of immobilization of increasing concentration of cell-free extract on biosensor response with polyethersulfone(PES) membrane

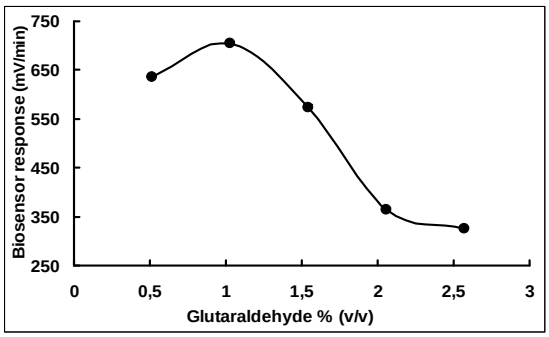

Figure 4 – Effect of glutaraldehyde concentration on biosensor response with polyethersulfone (PES) membrane.

The effect of immobilization of increasing concentration of cell-free extract of *P. aeruginosa* on biosensor response was also investigated which revealed a linear response in mV/min as a function of cell-free extract concentration up to 700 mV/min . The maximum biosensor response was obtained at a glutaraldehyde concentration of 1.0 % (v/v) by using PES membrane as the immobilization support as shown in Fig. 4.

Once the biosensor response was optimized, a calibration curve of the biosensor response in ΔmV/min was carried out as a function of urea concentration in the range of 0.02 – 1.0 x 10^{-3} M in TME buffer (Fig. 5).

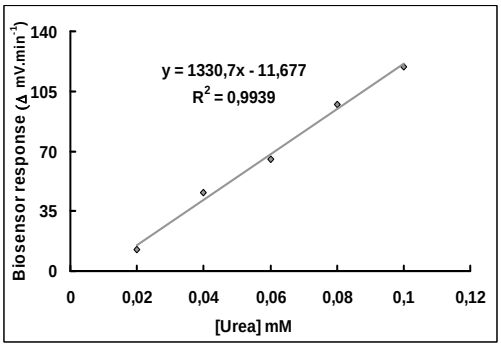

Figure 5- Calibration curve for urea by using the biosensor.

Linear response of the biosensor in ΔmV/min in the range of 0.02 _ 0.1 x 10^{-3} M which was carried out in Tris buffer.

The application of the present method to the detection and determination of urea was investigated by recovery experiments (Andreou and Clonis 2002) by using a sample of milk which was spiked with a known amount of urea (Fig. 6). Control experiments using urea-free milk samples were made in Tris buffer in order to investigate the matrix effects of the recovery in milk and an average substrate recovery of about 93.3% was obtained. As far as the biosensor stability is concerned, Porablot NY Plus membranes containing immobilized cell-free extracts were stored in TMEGB

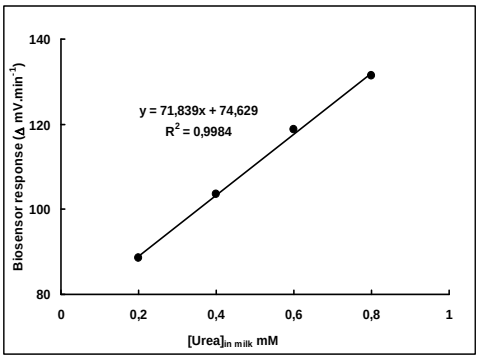

Figure 6 – Determination of urea in milk. Acrylamide recovery experiments were carried out by using milk and Tris buffer which were spiked with known amounts of urea

buffer at 4ºC which revealed that they were stable for over 70 days without any loss of amidase activity (Fig. 7). The membrane discs used for urea assay could be regenerated by incubation with hydroxylamine which resulted in about 80% recovery of biosensor activity as shown in Fig. 8

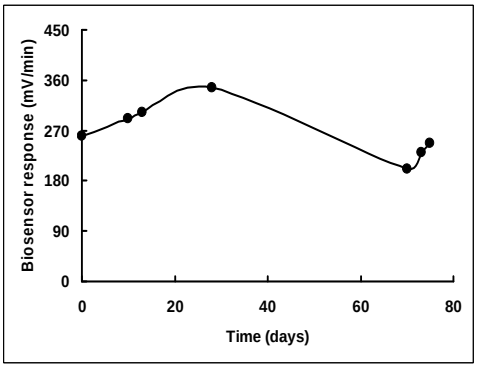

Figure 7 – Stability of biosensor response with PES membrane as a function of time which was stored at 4ºC in TMEGB buffer

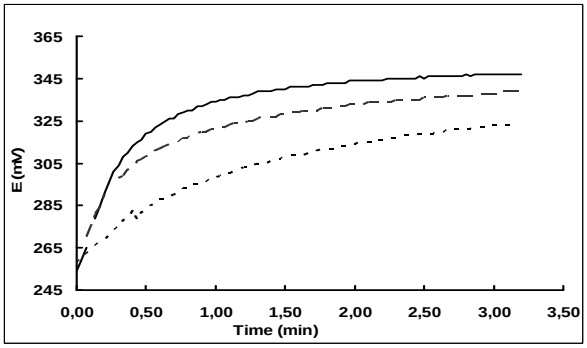

Figure 8 – Regeneration of the biosensor containing PES membrane which was incubated with urea. : ……. Incubation in 0.01mM Urea in TME buffer; - - - - - Reactivation with hydroxylamine and —— No urea incubation

The data presented suggest a potential use of this biosensor for urea assay in milk.

Keywords: tyrosinase, *Agaricus bisporus*, fungi, phenol
Topic: Sustainable process-product development through green chemistry

Abstract

Phenols are pollutant toxics found in several industrial effluents, being its determination of extreme environmental importance. In order to make possible an analytic methodology for a monitoring *in-situ*, this work intends to study the application of tissue of Paris mushroom as a source of the enzyme tyrosinase and its best reaction conditions seeking to develop a biosensor to phenols. Such enzyme is one poliphenol oxidase that transforms the phenolic composites into a lesser soluble product in water. This work aimed to characterize the fungi tissue for its future use as bio-component of a biosensor for the determination of phenolic compounds It was carried out an experimental process of successive extractions of tyrosinase and measurement of its activity. Additionally, the existence of phenol adsorption in the mushroom tissue and presence of phenol in the mushroom tissue had been verified. Obtained results showed that a significant amount of the enzyme remained in the paste of mushrooms even though extracting the first one. Finally, phenol is present in the composition of mushrooms, and the average concentration is 0.307 ppm and the hypothesis of adsorption of the phenol in the pieces of tissue of *Agaricus bisporus* can be eliminated.

1. Introduction

Phenolic compounds are extremely diverse. Although they may have hazardous adverse effects, they are a major pollutant present in the wastewaters from several industrial activities: coalmining, petrol refining, pharmaceutical production, founding and steel and iron manufacture, and the tanning and finishing of leather (Atlow et al., 1984).

Phenolic compounds are produced as secondary metabolites by most plants, in which they probably act as natural antimicrobial agents, as natural deterrents to grazing animals or as inhibitors of pre-harvested seed germination. Furthermore, these compounds are also formed during the natural decomposition of humic substances, tannins, and lignins.

Several procedures have been developed for the determination of phenolic compounds, such as chromatographic techniques, fluorimetric, and spectrophotometric methods. However, these techniques do not easily allow continuous monitoring in actual samples. They are expensive, time-consuming, need skilful operators, and sometimes require preconcentration and extraction steps that increase the risk of sample loss.

Biosensors are generally defined as an analytical device, incorporating a biological or biologically derived sensing element, such enzymes, either intimately associated with or integrated within a physicochemical transducer. They represent promising tools to supplement already existing techniques, due to their intrinsic characteristics such as

* Corresponding author. Tel + 55-21-25627629. E-mail:silva.livia@gmail.com

selectivity, low cost, potential for miniaturization and for the construction of simple flow devices for fast continuous monitoring. Among biosensors for phenols there is the enzyme tyrosinase as a bio-component, which is isolated from mushrooms due to economic reasons.

Tyrosinases (monophenol, o-diphenol:oxygen oxidoreductase, EC 1.14.18.1) belong to a larger group of proteins named type-3 copper proteins. Tyrosinase has been found widely distributed throughout the phylogenetic scale (van Gelder et al., 1997), which catalyses the *o*-hydroxylation of monophenols (cresolase activity or monophenolase) and the subsequent oxidation of the resulting *o*-diphenols into reactive *o*-quinones (catecholase activity or diphenolase), both reactions using molecular oxygen. Subsequently, the *o*-quinones undergo non-enzymatic reactions with various nucleophiles, producing intermediates, which associate spontaneously in dark brown pigments (Topçu et al., 2004; Marin - Zamora et al., 2006).

This work aimed to study the possibility of using tyrosinase naturally present in the tissue of the mushroom *Agaricus bisporus* to quantify phenol contained in standardized samples to finally, in future works, quantify phenol present in samples taken directly from the environment. Some works were met in literature using tyrosinase of this mushroom as biological component of a biosensor (Topçu et al., 2004; Marin-Zamora et al., 2006), however they do not use it in the immobilized form of the natural tissue, that is, immobilization *in-natura* (main objective of this work).

2. Materials and Methods

2.1. Studied Material

Fruit bodies of mushrooms (*Agaricus bisporus*), usually known as champignon Paris mushrooms, used throughout this work, were obtained from a two local dealers. They are Cadeg and Cobal Humaitá (Rio de Janeiro – RJ, Brazil). In both dealers, the lots of mushrooms were always bought on the same retail customer. Validation dates to consume the mushrooms were equally taken into account.

2.2. Source of Tyrosinase

Fruit bodies of mushrooms were triturated in 1750 ml of a pre-cooled acetone for enzymatic extraction. The pulp was then frozen by 24 hours, and then suspended in 300 ml of distilled water, and left overnight in a freezer. The resultant suspension was centrifuged or filtered to produce the first extract (Kameda et al., 2006). The steps of water addition and centrifugation were repeated once or twice to obtain more extracts.

2.3. Tyrosinase Activity

Tyrosinase activity was measured spectrophotometrically according to Campos et al. (1996). A diluted sample (ratio 1:10) of enzyme was added to a L-tyrosine solution (0.2M) in a phosphate buffer (0.2M and pH 6.0). The resulted mixture was homogenized and the changes of the absorbance were monitored at 280 nm in a DR/4000UV spectrophotometer at a regular interval of 30 seconds during 999 seconds.

One unit of enzymatic activity (U) was defined as the amount of enzyme that increased absorbance 0.001 (λ=280 nm) per minute. The enzymatic activity was calculated using the following formula:

$$A = \frac{(Abs_2 - Abs_1) \times 1000 \times D_E}{(t_2 - t_1) \times V_E} \text{ (U/mL)}$$

,

where: Abs_1 and Abs_2 are the absorbances in times t_1 and t_2 at the linear increase; V_E is the volume of the enzymatic solution (1 ml), and D_E is the dilution of the enzymatic solution.

2.4. Verification and quantification of the presence of phenol in mushroom tissue

In this research the enzymatic reactions due to the presence of phenol in the mushroom tissue had been carried out following the conditions: 5 g of mushroom tissue in two different sizes (0.5 and 1.0 cm^3); erlenmeyer with 250 ml of distilled water free of phenol and chlorine; the agitation was rated at 200 rpm in a shaker (agitator orbital Tecnal TE - 420), and the temperature was kept constant in 30 °C.

2.5. Phenol Determination

Phenol analysis was done according to the direct colorimetric method per Standard Methods (Apha, 1996). 250 milliliters of ammonium hydroxide (0.5N) was mixed to 10 ml of samples or blank and pH was adjusted to 7.9 ± 0.1 with potassium phosphate buffer. 100 µl of 4-amino-antipyrine solution (2% w/v) was added additionally. The final step was to mix a 100 µl of potassium ferricyanide solution (8% w/v) to obtain the final mixture. Fifteen minutes later, the absorbance was read at 500 nm. It is Important to clarify that each sample was previously filtered in a C18 PR-COLA cartridge for the interference removal.

3. Results and Discussion

3.1. Extraction and Determination of the Enzymatic Activity of Tyrosinase

The effect of the re-extraction of the enzyme in the enzymatic activity retained on different extracts was studied. With the obtained results (Figure 1) it could be observed that a significant amount of the enzyme remained in the paste of mushrooms even though extracting the first one. That result is corroborated by the literature; see Papa et al. (1994) and Kameda (2003). From the obtained results it could be observed that in function of the different lots, diverse activities were obtained. They varied from 20.2 U/ml to 980.36 U/ml.

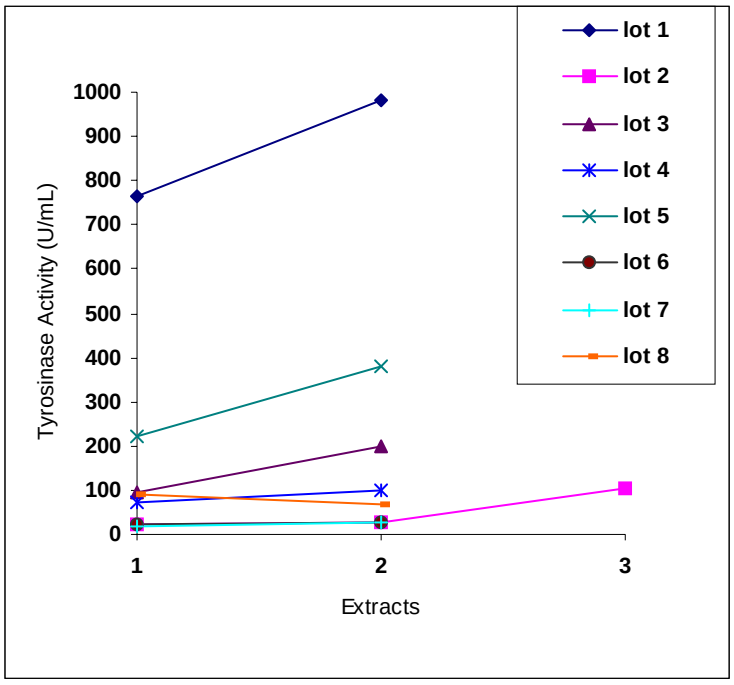

Figure 1: Effect of the re-extraction on the enzymatic activity of tyrosinase.

The tyrosinase present in the tissue mushroom, as in case of *Agaricus bisporus*, most likely comes from the cytoplasm of the cell (van Gelder et al., 1997). Therefore, a larger activity in the second (or third) enzymatic extract in relation to the first one may be due to the largest cellular breaking during the re-extraction process. This one makes the diffusion of the enzyme inside the cells towards the enzymatic extract.

Although the mushrooms were visually quite similar, an enormous difference was observed among the enzymatic activities of the lots under evaluation. And where they were bought is not an issue. Nevertheless, Ingebrigtsen et al. (1989), identified the degree of maturation of the mushrooms as the weight factor to interfere with the activity of the tyrosinase in the extract. In fact, Bevilaqua (2000) equally reported such variation in the extract caused by aged mushrooms. These ones contributed to an increase of 48% in the enzymatic activity in relation to the controlled lot. He concluded, "The aging of the mushroom is responsible for the activation in latent ways of the enzyme ". The presence of isoforms of tyrosinase of *Agaricus bisporus* was already mentioned in the literature by (Whichers et al., 1996; Espín and Whichers, 1999). According to van Leeuwen and Whichers (1999), the mushroom tyrosinase was present as a latent form in ~98-99% of the total tyrosinase activity.

Finally, phenol is present in the composition of mushrooms, and the average concentration is 0.307 ppm and the hypothesis of adsorption of the phenol in the pieces of tissue of *Agaricus bisporus* can be eliminated based on the satisfactory results of experiments that were performed during this work and results of Kameda (2003).

4. Conclusions

The tissue of mushroom *Agaricus bisporus* has showed to be an excellent source of the enzyme tyrosinase for the construction of a biosensor to phenol in the future. Throughout this work the results showed that a significant amount of the enzyme remained in the paste of mushrooms even though extracting the first one. Additionally, phenol is present in the composition of mushrooms, and the average concentration is 0.307 ppm and the hypothesis of adsorption of the phenol in the pieces of tissue of *Agaricus bisporus* can be eliminated.

Keywords: Whey Protein, Locust Bean Gum, Gelation, Hydrolysis, Rheology
Topic: Multi-scale and/or multi-disciplinary approach to process-product innovation.

Abstract

The gelling ability of whey proteins can be changed by limited hydrolysis and by the presence of other components such as polysaccharides; depending on the environmental conditions it can either be improved or impaired.

In this work the effect of LBG on the heat-set gelation of aqueous whey protein hydrolysates (10 % w/w) from pepsin was assessed at pH 7.0 by small deformation rheology. Whey protein concentrate (WPC) and hydrolysates with a degree of hydrolysis (DH) of 1.5, 2.5 and 4.9 % were used. Different LBG concentrations were tested: 0, 0.1, 0.3 and 0.55 % (w/w).

The behaviour of gels from whey proteins or whey protein hydrolysates towards the presence of LBG was very similar. The evolution of the viscous and storage moduli followed the general behaviour reported for many biopolymer heat-set gelation processes including whey proteins gelation. The increase in the LBG concentration generally led to a decrease in the gel strength. However, for whey proteins a small amount of LBG (0.1 %) leads to a big enhancement in the gel strength probably due to an increase in the protein concentration of the protein enriched phase. Further increases in the LBG concentration led to a decrease in the gel strength.

The gelation process is very sensible to environmental conditions and to processing and often leads to rather coarse data. The factorial planning used allowed validating conclusions using fewer experiments than those needed if no planning had been used, while still getting statistical significance out of the results. However, as many factors are involved, the modelling of the process was not straightforward.

1 Introduction

The gelling ability of whey proteins can be changed by limited hydrolysis; depending on the environmental conditions it can either be improved or impaired.

The functionality of whey proteins can also be changed by the presence of other components. For instance, protein-polysaccharide complexes exhibit many functional properties able to provide new food texturization and stabilization methods (Schmitt and others, 1998).

Synergistic effects have been found between whey proteins and several polysaccharides such as galactomannans, xanthan or carrageenan (Croguennoc et al.,

* Corresponding author. Tel + 351-258-819700. E-mail:crocha@deb.uminho.pt

2001; Turgeon and Beaulieu, 2001; and many others). The effect of limited proteolysis in the interaction with polysaccharides is hardly ever mentioned.

Locust bean gum (LBG) is a galactomannan (non gelling neutral polysaccharides found in the endosperm of *Leguminosae*) widely used in the food industry as a thickening agent (Pollard and Fischer, 2006).

Rheological studies are useful to evaluate the gelling ability of biological macromolecules; in particular, they allow accessing the structure of the gel, evaluating its texture, controlling the gelling behavior or complementing the information provided by sensory methods. In fact, as gelation is essentially a phase transition from liquid to solid, monitoring the changes in mechanical properties is important. Small amplitude oscillatory shear techniques can be used to monitor continuously the evolution of the viscoelastic properties, avoiding any modification of the molecular structure caused by shear. This is an advantage over other rheological tests.

In this work the effect of LBG on the gelation of aqueous whey protein hydrolysates (10 % w/w) from pepsin was assessed at pH 7.0.

2 Materials and methods

All chemicals used were of analytical grade and supplied by Sigma, Co (St. Louis MO, USA). Pepsin from hog stomach with an activity of 2540 units/mg $_{protein}$ (one unit will produce a ΔA_{280} of 0.001 per min at pH 2.0 at 37 °C, measured as TCA-soluble products using hemoglobin as substrate in a reaction final volume of 16 mL and 1 cm light path) was obtained from Sigma Chemical Co.

A commercial whey protein concentrate (WPC) powder (Lacprodan 80, batch Q500246) kindly supplied by Arla Food Ingredients (Viby, Denmark) was used for the experiments. According to the suppliers, the WPC dry basis protein content was 82 % (5.5 % moisture), the ash content was 3.5 % max., the lactose content was 7 %, and fat content was 8 %. max. Locust bean gum (> 75 % galoctomanan content) was kindly supplied by Danisco Portugal (Faro, Portugal).

Locust bean gum was purified by precipitation with isopropanol as described by da Silva and Gonçalves (1990).

Whey protein concentrate (WPC) and hydrolysates with a degree of hydrolysis (DH) of 1.5 (P1.5), 2.5 (P2.5) and 4.9 % (P4.9) were used. Different LBG concentrations were tested: 0, 0.1, 0.3 and 0.55 % (w/w).

Dynamic oscillatory tests were performed in a controlled stress rheometer AR2000 (TA Instruments, Delaware, USA) fitted with a parallel plate geometry (40 mm diameter, gap 800 μm). Each sample was equilibrated during 5 min; this step was followed by a frequency sweep ("mechanical spectrum") from 100 to 0.1 Hz at a strain of 5 %. Then a temperature ramp from 20 to 80 ºC was applied, at a rate of 2 º C.min^{-1}, after which the temperature was maintained at 80 ºC for 3 h. At the end of this time sweep the sample was cooled back to 20 ºC, at the same constant rate (2 ºC.min^{-1}). The mechanical properties of the resulting gel were monitored at 20 ºC for 1 h.

A full factorial design was used considering two factors (LBG concentration and degree of hydrolysis) and three levels for each factor and a quadratic model was adjusted with Design Expert 6.0.6 (Stat-Ease, Inc. Minneapolis). Two replicates of the experiments with WPC (DH = 0) were used to estimate errors and determine if the lack of fit of the chosen model was significant. Further refinement of the empirical model was made by excluding the factors that were found to be insignificant, one at a time, as the exclusion of one factor may influence the other.

3 Results and discussion

The evolution of rheological parameters follows the general behaviour reported for

many biopolymer heat-set gelation processes including whey proteins gelation (see for instance Paulsson et al., 1990; Gosal and Ross-Murphy, 2000). Initially *G"* is slightly higher than *G'* because of the liquid nature of the sample and the absence of pre-aggregated protein molecules (Figure 1).

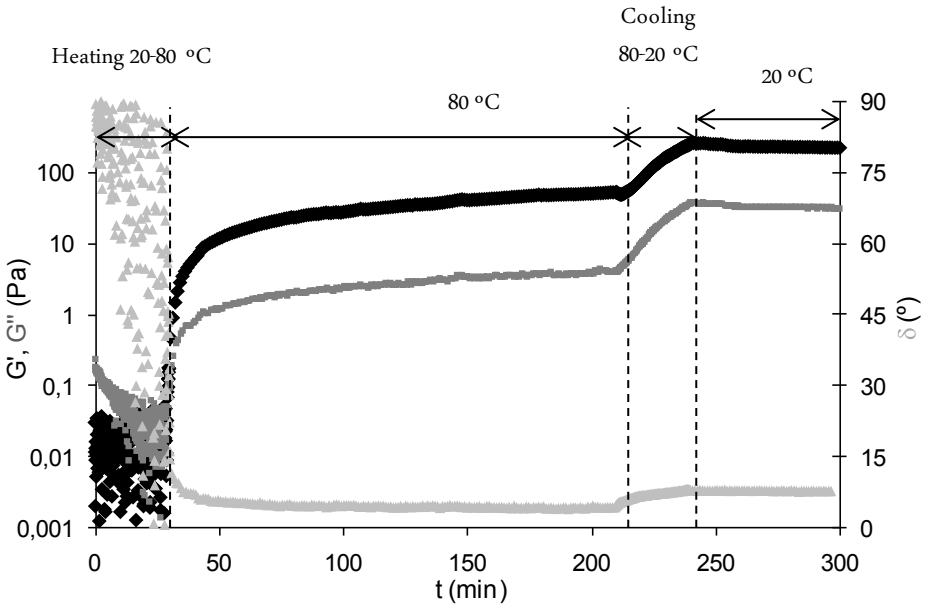

Figure 1 Gelling ability of whey protein concentrate (10 % w/w): black – *G'*; dark grey – *G"*; light grey – δ

As the temperature rises both moduli decrease until the gelation treshold is achieved (either before the end of the temperature ramp or during the time sweep step). As this point approaches, a sudden increase in the values of *G'* and *G"* is observable. However *G'* rises much faster and the crossover *G'-G"* point was considered the gelling point. By the same time the values of the loss angle decrease even more markedly, sign of the increase of the elastic behaviour.

Table 1 Influence of the LBG concentration and hydrolysis degree on the gelling ability of whey protein hydrolysates

Hydrolysate (% w/w)		LBG (% w/w)	*DH* (%)	*G'* (Pa)	*G"* (Pa)	*tan* δ	*Tg* (ºC)	*tg** (s)

WPC	10	0.80	0	108	39.0	0.36	80	326
P1.5	10	0	1.5	657	92.8	0.14	80.0	36.0
P1.5	10	0.1	1.5	588	105	0.18	77.6	-
P1.5	10	0.3	1.5	118	19.4	0.17	77.9	-
P2.5	10	0	2.5	138	24.8	0.18	73.7	-
P2.5	10	0.1	2.5	107	16.2	0.15	72.6	-
P2.5	10	0.3	2.5	27.8	5.00	0.18	72.4	-
P2.5	10	0.55	2.5	29.5	11.4	0.39	78.7	-
P2.5	10	0.8	2.5	31.5	13.0	0.41	80	745
P4.9	16.5	0	4.9	18.4±18.4	3.35±3.04	0.20±0.04	80.0±0.0	0.0±0.0
P4.9	16.5	0.1	4.9	284	43.2	0.15	74.9	-
P4.9	16.5	0.3	4.9	207	37.3	0.18	72.8	-
P4.9	16.5	0.55	4.9	76.0±17.1	23.8±2.3	0.32±0.04	80.0	35.9±0.1

The increase in the storage modulus and the reduced phase angle indicate the formation of viscoelastic gels. *G'* continues to increase after the gel point as more and more protein reinforces the weak tridimensional network initially formed, enhancing its elasticity.

Although the overall gelation patterns were similar for all tested samples the corresponding gelling parameters (*G'*, *G''*, δ, *Tg*, *tg*) were quite different (Figure 2 and Table 1).

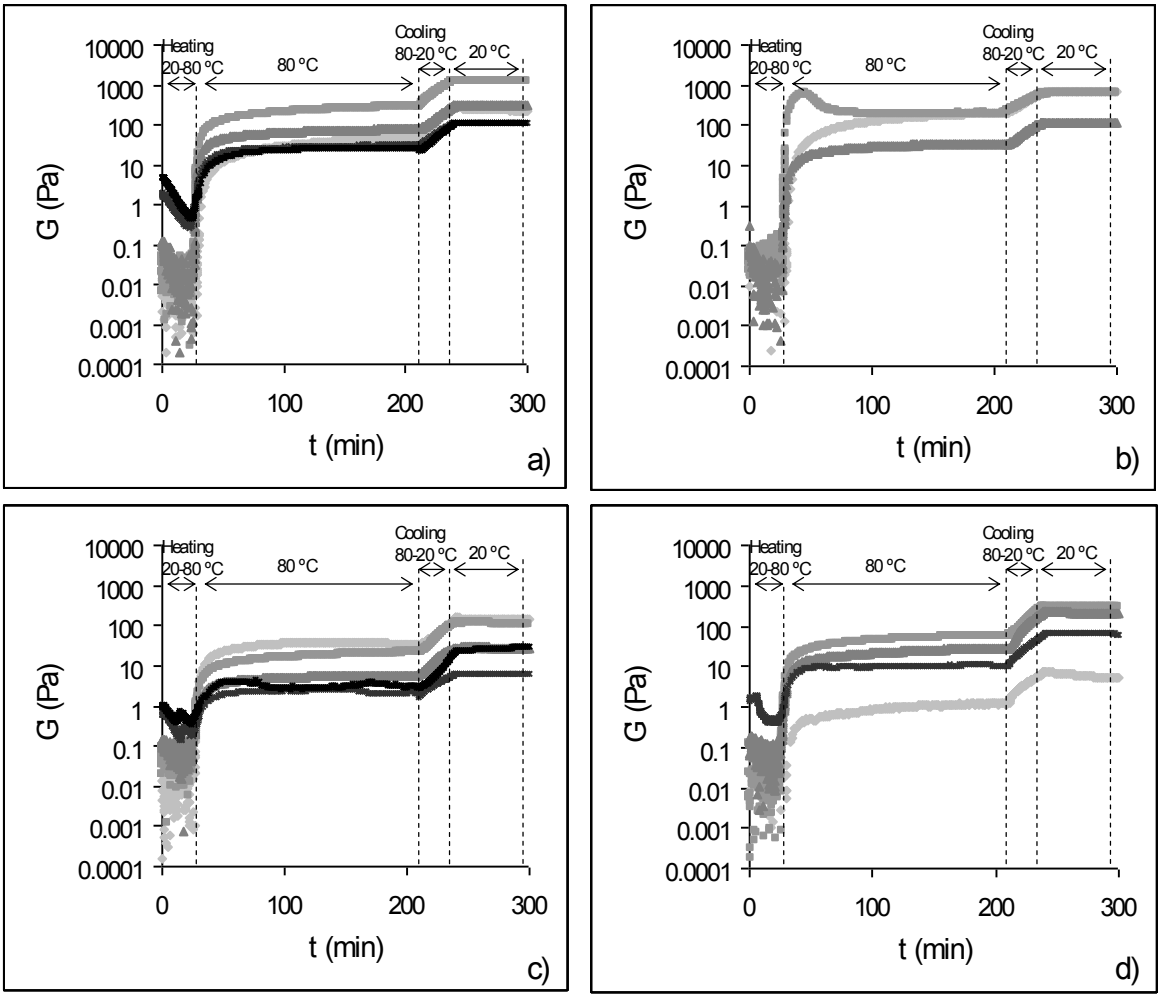

Figure 2 Influence of the LBG concentration on the gelling ability of whey peptic hydrolysates: the darker the colour the higher the LBG amount (0, 0.1, 0.3, 0.55, 0.8): a) WPC 10 % (w/w); b) P1.5 10 % (w/w); c) P2.5 10 % (w/w); d) P4.9 16.5 % (w/w)

In the case of hydrolysates alone, *G'* was higher for P1.5 (657 Pa) followed by P2.5 (138 Pa). These two were stronger than WPC at this concentration (*G'* = 204 Pa) indicating that they were stiffer. They were also more elastic as the loss angle was smaller. Apparently pepsin is effective in improving the gelling ability of whey protein gels for low degree of hydrolysis, possibly because β-Lg (the main gelling protein) is resistant to pepsin. In fact, P1.5 still has all the β-Lg intact and P2.5 still has 96 % of intact β-Lg. This improvement might be due either to the presence of low molecular weight hydrophilic peptides which can reduce electrostatic repulsions between intact β-Lg molecules enhancing protein-protein interaction or to the partial unfolding of α-La and BSA exposing their hydrophobic residues, therefore improving their individual gelling ability and/or allowing for a better interaction with the intact β-Lg.

LBG alters the microstructure of whey protein gels by modifying the equilibrium between aggregation and segregation. The gelation time was also decreased. The behaviour of gels from whey proteins or whey protein hydrolystates towards the presence of LBG was very similar. The increase in the LBG concentration generally led

to a decrease in the gel strength. However, for whey proteins a small amount of LBG (0.1 %) leads to a big enhancement in the gel strength probably due to an increase in the protein concentration of the protein enriched phase. Further increases in the LBG concentration led to a decrease in the gel strength.

When analysing the influence of the concentration of LBG on gelling properties (*G'*, *G''*, tan δ and temperature of gelation), the differences between the hydrolysates and WPC with no polysaccharide and the hydrolysates with 0.1 % of LBG were usually sharp (an example is presented in Figure 3); this difficults modelling with a simple quadratic function.

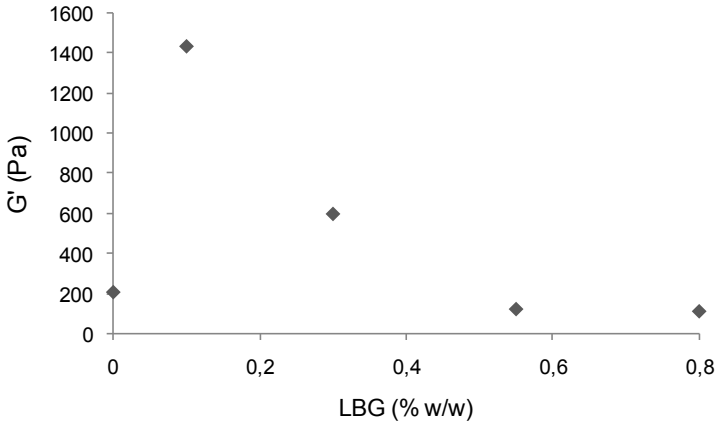

Figure 3 Influence of the LBG concentration on the final storage modulus of whey protein gels (10 % w/w)

Therefore the statistical analyses and empirical modelling were performed only with the data from mixed systems for the LBG range of 0.1 – 0.55 %. A quadratic model as described by Eq. 1 was used.

$$y = b_0 + b_1 x_1 + b_2 x_2 + b_{11} x_1^2 + b_{22} x_2^2 + b_{12} x_1 x_2 + residual \qquad \text{Eq. 1}$$

By means of an analysis of variance it was concluded that all the adjusted models are significant. The effect of LGB concentration and of the degree of hydrolysis on peptic hydrolysates gelation was negative for *G'* and *G''*, though an interaction factor has also to be considered. For tan δ and the temperature of gelation a minimum value exists in the studied range of LBG concentration, while a maximum exists in the studied range of *DH* for the temperature of gelation.

Table 2 Statistical analysis of the influence of the LBG concentration and hydrolysis degree on the gelling ability of 10.0 % (w/w) whey peptic hydrolysates

Variable	Regression coefficients						Regression quality	
	b0	*b1*	*b2*	*b11*	*b22*	*b12*	*PF* (%)	Lack-of-fit
G' (Pa)	1619	**-2886**	-618	-	-	1086	0.20	Not significant
G'' (Pa)	235	**-393**	-87.3	-	-	146	0.31	Not significant
$tan\ \delta$ (º)	0.193	-0.470	-0.012	1.09	-	0.102	0.05	Not-significant
T_g (ºC)	75.8	-10.4	5.40	31.3	-2.50	-	0.51	Not-significant

Items in **bold** correspond to non significant model terms that could not be withdrawn from the model because they were required to support hierarchy.

The gelation process is very sensible to environmental conditions and to processing and often leads to rather coarse data. The factorial planning used allowed validating conclusions using fewer experiments than those needed if no planning had been used, while still getting statistical significance out of the results. However, as many factors are involved, the modelling of the process was not straightforward. A simple quadratic function was generally not enough to accurately describe the system behaviour.

4 Conclusion

WPC mild hydrolysis (up to 2.5%) ameliorates the gelling ability, but affects the WPC synergism with LBG (no max found in the G' dependence on LBG content).

As a general conclusion, it can be stated that it is possible to make all kinds of different gels (fast gelling, slow gelling, hard and stiff, or weak gel) by manipulating the protein concentration, the degree of hydrolysis and the amount of LBG. It is important though to master the mechanism of phase separation in order to be able to design the adequate conditions for the desired texture.

Enzymatic Agent from Red King Crab Hepatopancreas and Its Applications

V. A. Mukhin, V. Yu. Novikov, K. S. Rysakova
Knipovich Polar Research Institute of Marine Fisheries and Oceanography (PINRO),
Murmansk, Russia.

Keywords: King crab hepatopancreas, enzyme, hydrolysis, enzymatic hydrolysates.
Topic: Integration of life sciences & engineering.

Abstract

In this review, the results of the investigation of proteolytic and chitinolytic activity of enzyme systems of invertebrates, in particular, the enzymatic agent preparing from the Red King crab (*Paralithodes camtschaticus*) hepatopancreas are described.

Enzymatic agent from Red King crab hepatopancreas was shown to be capable of producing protein hydrolysates. Properties and characteristics of enzymatic agents and protein hydrolyzates are investigated in detail.

1 Introduction

Currently, biochemists in different countries are aimed at the development and improvement of enzymatic processes that are used in the production of enzymatic protein hydrolysates and modification of natural polysaccharides.

Special attention to this direction is determined by the high specificity of enzymatic reactions, which makes it possible to obtain unique compounds of a certain structure, and environmental friendliness of biochemical manufacture, in contrast to purely chemical manufacture, which is expressed in renunciation of large volumes of aggressive chemicals and absence of contaminated chemical discharges. Peptides and chitooligosaccharides are interesting as substancts, whose biological activity is higher than that of natural protein and chitin.

Studies performed at the Polar Research Institute of Marine Fisheries and Oceanography demonstrated that invertebrates occurring in the Barents Sea contain proteins whose content of essential amino acids is competitive with common sources of nutrient proteins. The invertebrates of the Barents Sea have the great importance for development of a fishery of Northwest region of Russia. Except for food industry these objects have interest as sources of enzymes with various substrate activities.

The research of enzyme properties is actual for an evaluation of a physiological state of trade objects, for extraction high-activity enzymes, and also to prepare with the its help the enzymatic protein hydrolysates.

The alimentary systems of some marine invertebrates contain diverse and highly active proteases. In particular, Red King crab (*Paralithodes camtschaticus*) hepatopancreas can be used as a source of protease preparations. Their high activity was demonstrated on common protein substrates, including collagen.

The waste of Red King crab processing includes hepatopancreas, which is of interest as a source of various enzymes, including proteolytic ones (Kupina et al., 1999). Total proteolytic and collagenolytic activity of enzyme system of crab is greatly higher that activities in digestive organs of Vertebrates (Chen et al., 1991).

It is expedient to use the internals of sea invertebrates being waste products of a catch, as a source of proteinases. In particular, the hepatopancreas of the Red King crab is most perspective for extraction of highly active complex enzymatic agents of proteolytic action.

2 Experimental Methods

We have studied some ways of enzymatic agent (EA) preparing: fat extraction from hepatopancreas by organic solvents (acetone and n-butanol), fractionation by ultrafiltration and degreasing by the chitosan solution (Mukhin and Novikov, 2001a). EA, obtained on the

first method, (“Acetonic powder”) had smaller specific proteolytic activity, but the yield of product was higher and its cost was much lower. These factors have made its most suitable for wide practical use.

For the most objective reflectance of depth and degree of protein and chitin degradation we simultaneously took into account the data obtained with use of gravimetric, spectral analysises, exclusion chromatography, determination of the contents of the total and amine nitrogen, free amino acids, total reducing sugars and carbohydrates – D-glucosamine and N-acetyl-D-glucosamine.

Anson method with several modifications was used to estimate proteolytic activity of the EA using hydrolysis of 1 % haemoglobin solution (pH 3.6) and 1 % sodium caseinate solution (pH 7.0). Proteolytic activity was expressed in mmol Tyr (280 nm) per 1 g EA after 30 min of incubation 37 °C.

Chitinolytic (exochitinase) activity was determined by the formation of N-acetyl-D-glucosamine as a result of chitin hydrolysis; total glycolytic activity, by the total content of N-acetyl-D-glucosamine, D(+)-glucosamine and other reducing sugars in hydrolysis products. Colloidal chitin and chitosans with different deacetylation degrees were used as substrates. The concentration of N-acetyl-D-glucosamine was determined by the reaction with 4-dimethylaminobenzaldehyde (Reissig et al., 1955). The total concentration of reducing sugars was determined by the reaction with potassium hexacyanoferrate (Imoto and Yagishita, 1971).

Fractionation of protein was carried out by exclusion HPLC on system LC-10AVP (Shimadzu Corp., Japan) with columns TSK-gel Alpha-4000 (30 x 0,78 cm) and TSK-gel guardcolumn Alpha (6 x 0,4 sm) (TOSOH, Japan). Eluent - 0,3 M NaCl, eluent rate - 1 ml/min, UV-detector SPD-10AVP. Determination of D-glucosamine as OPA derivative was carried out also by HPLC on column Supelkosil LC-18 (30 cm x 4 mm). Binary eluent - acetonitrile:CH_3COONa, eluent rate - 1 ml/min, refractometric detector RF-10 AXL.

UV spectrum analysis of solutions (240-320 nm) was carried out with spectrophotometer UV-3101PC (Shimadzu Corp., Japan).

3 Results and Discussion

The proteolytic and chitinolytic activity of enzymatic agents from different taxons of the Barents Sea invertebrates, such as mollusks (*Serripes groenlandicus*, *Biccinum undatum*), crustaceans (*Paralithodes camtschaticus*, *Pandalus borealis*) and echinoderms (*Cucumaria frondosa*, *Asterias rubens*), was studied. The choice of them was conditioned by essential stocks of these animal species in the Barents Sea and insufficient development of rational technologies to process them.

Table 1. Proteolytic (A_{280}) and chitinolytic activity (U_{endo}, U_{exo}) of enzymes from different Invertebrates

Hepatopancreas or entrails	A_{280}	U_{endo}	U_{exo}	U_{exo}/U_{endo}
Serripes groenlandicus	7.6	0.836	0.198	0.237
Buccinum undatum	10.9	0.409	0.352	0.861
Cucumaria frondosa	-	0.346	0.077	0.223
Asterias rubens	30.3	14.544	0.091	0.0063
Paralithodes camtschaticus	100.9	4.324	1.825	0.422
Enzymatic agent from *Paralithodes camtschaticus*	284.0	9.277	3.866	0.417

Proteolytic activity in the hepatopancreas of crab and sea star was found to be an order higher than in other study objects. High protease activity in crab hepatopancreas is an evolutionary mechanism compensating for a poor differentiation of digestive system, low substrate specificity of enzymes, and cold environment.

The greatest chitinolytic activity was observed in the hepatopancreas and enzymatic agents extracted from the Invertebrates. Correlation between proteolytic and chitinolytic

activity exists in most cases. Exception is observed for the hepatopancreas from a starfish in which anomalously high endochitinolytic activity is found.

Properties of Enzymatic agent from Red King crab hepatopancreas

Enzymatic agent from Red King crab hepatopancreas has the greatest proteolytic activity and it can be yielded in great volumes. Therefore it is the most suitable for practical use in various fields of the industry, medicine, an agriculture, etc.

The EA contained over 90 % protein and was active under neutral conditions with respect to sodium caseinate (200-250 mmol Tyr/g for “Acetone powder” and 450-500 mmol Tyr/g for EA, preparing by ultrafiltration).

We studied the temperature, pH, and time dependence of proteolytic activity of enzymatic agent obtained from Red King crab hepatopancreas (Mukhin et al, 2001a).

It is established, that a temperature optimum of activity in relation to casein is 50°C, and in relation to a haemoglobin - 55°C. According to other researchers maximal activity against a collagen is also at 50-55°C (Chen et al., 1991; Sakharov, 1992; Litvin, 1993).

Reaction of proteolytic cleavage of proteins reaches a saturation about 3-4 hours of incubation. The linear part on the kinetic curve was observed within the first hour of incubation (Mukhin and Novikov, 2001a).

The highest digesting ability of EA was shown in relation to tissues of Icelandic scallop and Nothern shrimp which enter into a diet of the Red Ring crab, and also in relation to own tissues (Mukhin et al., 2001b, Mukhin and Novikov, 2001). To a lesser degree EA digests other protein products (meat of the hen, a beef, pork, etc.).

It has been shown, that proteolytic activity of crab hepatopancreas is subject to significant seasonal fluctuations. Apparently, these fluctuations are concerned with stages of sexual cycle of development gonads, larval stage of a chitinous shell, and also with trophic activity. Maximal proteolytic activity is found out in adults in November-March, and in the spring-and-summer season conforming to the season of molting and spawning it drops in two and more times.

It was discovered also a chitin-degrading activity of EA (Novikov and Mukhin, 2003).

Our study confirms the presence of chitinolytic and chitosanolytic activities in the hepatopancreas of the red king crab, related to the specific diet of this species (Novikov and Mukhin, 2003; 2005).

The maximum rate of chitin/chitosan hydrolysis by EA from crab hepatopancreas occurs at 36.5–37.0°C.

The optimal temperature of glycolytic (45°C) and exochitinase (35°C) activities are shifted towards lower temperatures relative to the optimum for the proteolytic activity (55°C) (Rysakova et al., 2008). This finding confirms the conclusion that glycolytic and proteolytic activities are exhibited by different enzymes contained in the enzyme preparation from the red king crab hepatopancreas.

Two pH optimums have been found for the enzymatic reaction under mildly alkaline and acidic conditions for both exo- and endochitinase activities. The optimum pH values for exochitinase and total glycolytic activities coincided and were found to be 4.5. The second maximum of exochitinase activity, which was absent in the case of glycolytic activity, was recorded at pH 8.0. The pH value at which the proteolytic activity of the enzyme preparation was maximum (pH 8.5) did not coincide with the pH corresponding to the maximum glycolytic activity but was close to the pH at which the exochitinase activity was maximum.

The enzyme preparation is most affine to partly deacetylated chitin with an acetylation degree within 40–50 % (Novikov et al., 2007).

By HPLC we have not found the formation of D-glucosamine during enzymatic hydrolysis of chitin and chitosan. It can be concluded that EA exhibits only chitinase activity since it does not cleave single D-glucosamine molecules.

We have confirmed the presence and quantified the exochitinase, endochitinase, and deacetylase activity of the enzymatic agent as well as demonstrated the absence of exochitosanase, and N-acetylglucosamine deacetylase activities. We assumed that the

chitinase and protease activities of the enzyme preparation are apparently exhibited by different enzymes.

It was studied the distribution of specific activities in various fractions of EA from hepatopancreas of the Red King crab.

The data obtained at fractionating of EA by ultrafiltration, a gel-filtration and preparing exclusion HPLC (Table 2) show, that maximal chitinolytic activity is concentrated in fractions with the greater molecular weight (more than 100 kD) in comparison with proteases (50-100 kD).

Table 2. Distribution of exochitinolytic and proteolytic activity of EA on fractions with different molecular weight

Fraction	U_{exo}, μmol AcGlcN/g	A_{prot}, μmol Tyr/g
> 100 kD	**1.53**	33.16
50-100 kD	0.13	**119.90**
10-50 kD	0.70	83.20
< 1 kD	1.96	0.99

Observable increase of exochitinolytic activity in 4-th fraction explains by predominance of amino acids, namely tryptophan which reacts with 4-dimethylaminobenzaldehyde giving a coloured complex.

Obtained results are suggested, that different enzymes are responsible for exochitinolytic and proteolytic activities.

Production and properties of enzymatic protein hydrolysates

Enzymatic agent from Red King crab hepatopancreas was shown to be capable of producing protein hydrolysates. Hydrolysis of protein-containing waste of Northern shrimp, King crab and Iceland scallop occurs most successfully at pH about 8 and 50-55°C for 5-6 h in presence of 3-6 g enzyme per kg substrate (Mukhin and Novikov, 2001; 2001a).

It is demonstrated that the hydrolysates can be used for growing test cultures (Mukhin et al., 2001b; Mukhin and Novikov, 2005), and feed supplement for chickens and fishes (Mukhin and Novikov, 2001a).

The maximum hydrolysis rate was observed at 55°C and pH 7.5. The degree proteolysis also depended on the incubation duration, concentration of the enzymatic agent, and concentration of the substrate. The reaction is described by a set of exponential curves whose steepness depends on the listed factors.

Dry hydrolysate was prepared from protein-containing waste of Icelandic scallop and Northen shrimp processing by means of EA from Red King crab hepatopancreas. The resulting product contains no less than 80 % free amino acids and oligopeptides. Predominant are aspartic acid, leucine, isoleucine, arginine, and lysine, which account for more than 50 % of the free amino acids.

Various types of protein hydrolysates are used in microbiology, medicine, and the food industry. Production of nutrient media requires high-quality inexpensive protein hydrolysates.

1. The potential of using the protein hydrolysate as a nutrient for microorganism cultivation is estimated. It is demonstrated that the hydrolysate can be used for growing test cultures.

Microbiological studies demonstrated that the test cultures satisfactorily grew on a nutrient agar containing enzymatic protein hydrolysates. The colonies demonstrated no morphological deviations.

The biological properties of protein hydrolysates from Icelandic scallop and Northen shrimp were evaluated on the test strains *Shigella flexnerila* 8516, *Shigella sonnei* “S form”, *Pseudomonas aeruginosa* 27/99, *Serratia marcescens* 1, *Corynebacterium xerosis* 1911, *Escherichia coli* 3941/12 (055:K59), *Staphylococcus aureus* Wood-46, *Klebsiella pneumoniae* 3534/51, *Salmonella typhi* II-901, *Salmonella typhimurium* 79, and *Citrobacter freundii* 101/57 grown on the following model media: fish-meal hydrolysate (FMH) No. 1, FMH agar, FMH broth, Endo-FMH agar, and Levin FMH.

Microbiological studies demonstrated that these enzymatic protein hydrolysates can be used as a protein component in nutrient media.

2. We have shown an opportunity of application of hydrolysates as additives in feed of chichens and young fish *Salmo salar* (Mukhin and Novikov, 2002; Mukhin et al., 2003).

For example, the results of experimental feeding of chickens (age 47 day) have shown, that additives of enzymatic protein hydrolysates in feed had led to increase of safety (from 88 to 91 %), average daily weight increment (from 30 to 34 u) and average mass of one specimen (from 1,4 to 1,6 kg).

3. As a result of the researches carried out in our laboratory optimal technologies of preparing of enzymatic agents from digestive organs of sea invertebrates, the enzymatic protein hydrolyzates intended for enteral tube feeding of people have been developed.

For preparing of food hydrolysate the enzymatic agent from hepatopancreas of the Red King crab was used as the proteolytic agent. The sub-standard muscle of the Icelandic scallop was applied as a source of protein.

Protein hydrolyzate for for enteral tube feeding of the postoperative patients, obtained on the developed technology, possesses the increased biological value due to the high contents of low molecular weight protein components. It is capable to run through a probe with a diameter 5 mm without padding pressure that facilitates its uptake in a gastrointestinal path of the patient. The ready form of a drug is characterized by the high contents of high-grade protein products and corresponds to the demands showed to products of a children's food on Hygienic norms of FAO (1991).

Clinical approbation of protein hydrolyzate for medical purpose has shown harmlessness of the given drug. Allergic and toxic reactions at the surveyed patients are not marked. Biochemical analysis of a blood testify to enriching of parameters of a nitrogen metabolism.

4. The developed enzymatic agents allow to make salty delicacy production with good organoleptic properties from fishes and invertebrates: the perch, henfish, sea cock, common whelk and other. The muscle tissue of these organisms is unable to ripen self-contained under influence of own proteolytic enzymes. Processing of muscle tissue of these objects by solution of EA from hepatopancreas of the Red King crab (concentration of 0,025-0,05 %) results in its particulate hydrolysis, a ramollissement and enriching of gustatory advantages of finished goods.

Enzymatic processing of low-grade meat semifinished products at the presence of 0,01-0,1 % of enzymatic agent from hepatopancreas allows to modify a complex of physical and chemical and consumer properties of meat products. Analysis of aminoacid composition has shown, that total composition of amino acids has not changed during enzymatic processing of beef forcemeat. The contents of free amino acids has grown almost in 2 times.

The practical significance of our results is that they demonstrated that crab hepatopancreas can be used as a source of enzymes exhibiting chitinolytic and chitosanolytic activities for industrial modification of chitin and chitosan. This enables maximum utilization of all components of commercial aquatic organisms and increases the efficiency of sea fishery owing to utilization of its processing waste. The study of the glycolytic activity of the enzyme preparation from the red king crab hepatopancreas is of practical interest in terms of designing chitinase preparations for fighting against pests and treating fungal infections.

Keywords: chitin, chitosan, deacetylation, crystallinity
Topic: Advancing the chemical engineering fundamental.

Abstract

In this work process of alkaline hydrolysis of chitin and chitosan was studied. Structural properties of initial and reprecipitation samples of chitin and chitosan in dry and wet condition are investigated. It is established, that degree of crystallinity of the investigated samples renders considerably smaller influence on deacetylation rate, than an opportunity of formation of hydrated environment around macromolecules of polysaccharide. This interferes with nucleophilic attack by hydroxyl ion and retards reaction rate.

1 Introduction

Chitin is unique natural polysaccharide occupying the second place after cellulose. In the initial state it does not find wide application because of power solubility and small reactivity. Usually chitin is exposed to modification by various ways for reception of derivatives, in particular chitosan (Muzzarelli, 1977).

The alkaline hydrolysis of chitin and chitosan results to cleavage mainly acetamido linkages with formation of free amino groups and conservation polysaccharide chain. In result well soluble high molecular weight polysaccharide is formed. Chitosan is widely applied in medicine, cosmetics, agriculture and other (Goosen, 1997).

In this work we have studied a process of alkaline hydrolysis of chitin and chitosan. The basic purpose has consisted in an establishment of the mechanisms responsible for cleavage of amide linkage in an alkaline condition.

2 Experimental Methods

Deacetylation of chitin and chitosan, obtained on known technology (No and Meyers, 1995) from shells of crabs and shrimps, has been investigated with the help of chemical methods, IR-spectophotometry, X-ray crystallographic analysis.

Degree of deacetylation (DD) of chitin/chitosan was determined by potentiometric titration of 0.1% chitosan solution in 0.1N HCl by 0.1N NaOH. DD of chitin and chitosan was determined also by IR-spectophotometry. For estimation of degree of crystallinity we used X-ray analysis.

IR-absorption spectra in IR wrote down on infra-red spectrophotometer IR-420 ("Shimadzu", Japan) from 4000 to 400 cm_{-1}.

Researches of structural properties of chitin and chitosan samples have been carried out in the Kola Science Centre of the Russian Academy of Science on the X-ray diffractometer DRON-2 (NPO “Burevestnik”, USSR) by a method of X-ray phase analysis on CuKα radiation with Ni-filter in range of angles 2θ = 6-36°.

3 Results and Discussion

Research of alkaline deacetylation of chitin has shown, that at single-pass continuous carrying out of reaction DD does not achieve maximal value of 100 %. In the beginning there is fast increasing of DD, then the reaction rate falls and on the kinetic curve the flat plateau with DD 70-80 % is observed. After washing, drying and repeated alkaline processing recurrence of primary kinetics is observed: fast rise of DD and then formation of a flat plateau.

Features of deacetylation kinetics of chitin and chitosan are considered in works (Kurita et al., 1977; Mima et al., 1983; Tsaih and Chen, 2003).

Several possible explanations of decreasing of deacetylation rate during alkali treatment of chitin are offered: influence of heterogeneity of chitin crystalline structure, formation of solvate complexes of chitin or alkali, change of reagent concentrations during reaction, etc.

Authors of work (Kurita et al., 1977) explain deacetylation process specificity, first of all, by crystalline structure of natural chitin. This explanation is most recognized now.

The first fast field of the kinetic curve is caused by deacetylation of more available for alkali chitin moleculas in amorphous regions of a sample. The flat field describes kinetics of deacetylation of more dense crystalline regions. After washing there is a further amorphicity of a sample due to change of DD that results to recurrence of deacetylation kinetics.

Authors of work (Ottoy et al., 1996) investigated distribution of various fractions on DD in party deacetylated chitosan, having various acid solubility. Results obtained by them testify for the benefit of the diffusive mechanism of deacetylation reaction in which the rate of alkali diffusion inside of solids plays a basic role, and not division of polysaccharide on amorphous and crystalline regions.

In work (Chang et al., 1997) it is shown, that deacetylation rate depends on concentration of alkali: the constant of deacetylation rate increased with increase of NaOH concentration. Authors of this article assume, that rate of heterogenous deacetylation can be supervised both a chemical reaction, and a diffusion of a reagent and reaction product inside particles of polysaccharide.

Other idea consists in change of reactivity of reagents.

1. The form of the kinetic curve directs at the assumption of existence of reverse reaction of acetylation. But experimental results have not confirmed existence of such reaction in conditions of alkaline deacetylation.

2. It is suggested the change of alkaline reactivity due to the formation of solvate (hydrated) complexes. For example, in (Percot et al., 2004) a formation of hydrates of NaOH which are less active in chitin deacetylation reaction in comparison with unhydrated molecules is supposed.

3. A formation of low-activity solvate (hydrated) complexes of chitin which can be destroyed after washing and drying of deacetylated polysaccharide. In our early work we have assumed a formation of complexes OH^- with chitin (Novikov et al., 1990; Novikov, 2003; Novikov et al., 2005) and have shown, that reaction of deacetylation is described by two simultaneous reactions of the pseudo-first order, one of which consists in deacetylation, and another - in formation of chitin complex with hydroxyls ions:

deacetylation:

$$A_n + OH^- \rightarrow D_n + AcO^-,$$

formation of low-activity intermediate:

$$A_n + OH^- \rightarrow A_n \cdot OH^-_m.$$

where A_n - acetylated polysaccharide, D_n - deacetylated polysaccharide.

We have carried out a studying of alkaline deacetylation kinetics, variating crystalline structure of polysaccharide and a condition of hydration (Chebotok et al., 2007)
Crystallinity of different samples of chitin and chitosan are shown on fig. 1 and tab. 1.

The results in Table 1 and Figure 1a show that at reprecipitation the crystalline structure of chitin and chitosan is practically completely recovered. In samples of chitin, reprecipitated from NaOH X-ray diffraction patterns of restored structure have wider peaks, than a diffraction pattern of initial chitin, but positions of peaks practically coincide (not shown).

Obtained results are coordinated with data given in works (Kurita et al., 1977; Rege and Block, 1999).

Table 1. Degree of crystallinity ($\chi_{кр}$, %) of chitin and chitosan samples

Sample	$\chi_{кр}$, %
Chitin initial, dry	61.1
reprecipitated from NaOH solution, dry	55.5
reprecipitated from HCl solution, dry	60.7
reprecipitated from NaOH solution, wet	8.8
reprecipitated from HCl solution, wet	8.5
Chitosan initial, DD 82 %, dry	35.8
reprecipitated from HCl solution, DD 82 %, dry	37.5
reprecipitated from HCl solution, DD 82 %, wet	3.8

It is considered (Kurita et al., 1977), that after crystalline modification there is partially regeneration of structure of α-chitin, partially formation of other crystalline forms and amorphicity of chitin.

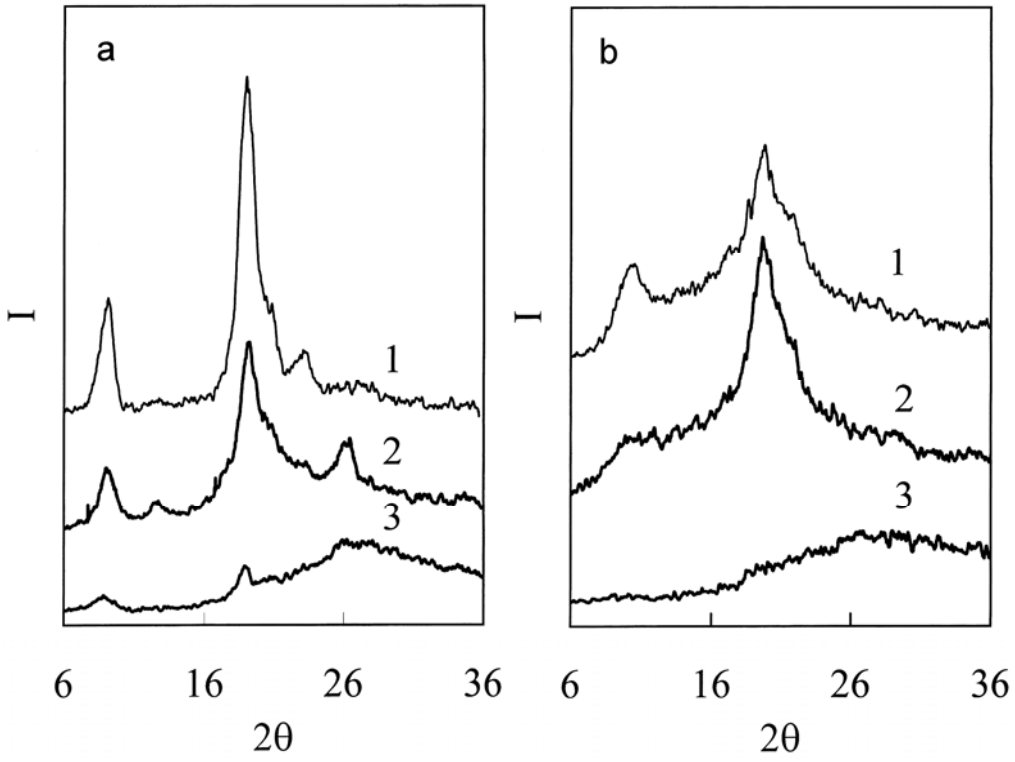

Fig. 1. X-ray diffraction pattern of chitin (a) and chitosan (b). Initial (1) and reprecipitation samples: dry (2) and wet (3).

In chitosan samples we also observed regeneration of crystalline structure (Fig. 1b) with some differences from initial structure of chitin. The positions of maximums of two basic peaks in chitosan sample is displaced concerning a positions of these peaks in a sample of α-chitin. In X-ray diffraction patterns of chitin with DD less than 71 % two peaks at 2θ 9.2° and 19.1° are observed. In chitosan (DD 95 %) these peaks are displaced and settle down at 2θ 11.2° and 20.1-20.4° accordingly. Our results d'not contradict the data of other researchers (Kurita et al., 1977; Gorbacheva et al., 1988; Rege and Block, 1999; Focher et al, 1992; Nud'ga et al., 1971).

We obtain X-ray diffraction patterns practically amorphous solids for reprecipitated wet samples of chitin and chitosan (fig. 1a, 1b).

1. Change of DD results in change of crystalline structure of polysaccharide at transferring from chitin to chitosan.

It is known, that at increasing of DD crystallinity of chitin drops, and then (after 90-95 %) the new crystalline structure of chitosan starts to form (Kurita et al., 1977; Focher et al., 1992).

If this fact takes place, with increasing of initial DD of chitin rate and depth of deacetylation should rise due to increasing of amount of amorphous regions. Taking into account such change, it is possible to expect, that the deacetylation kinetics of chitin/chitosan samples with various DD will differ. We have investigated the deacetylation kinetics of samples with initial DD 12, 66, 88 and 92 % (Fig. 2).

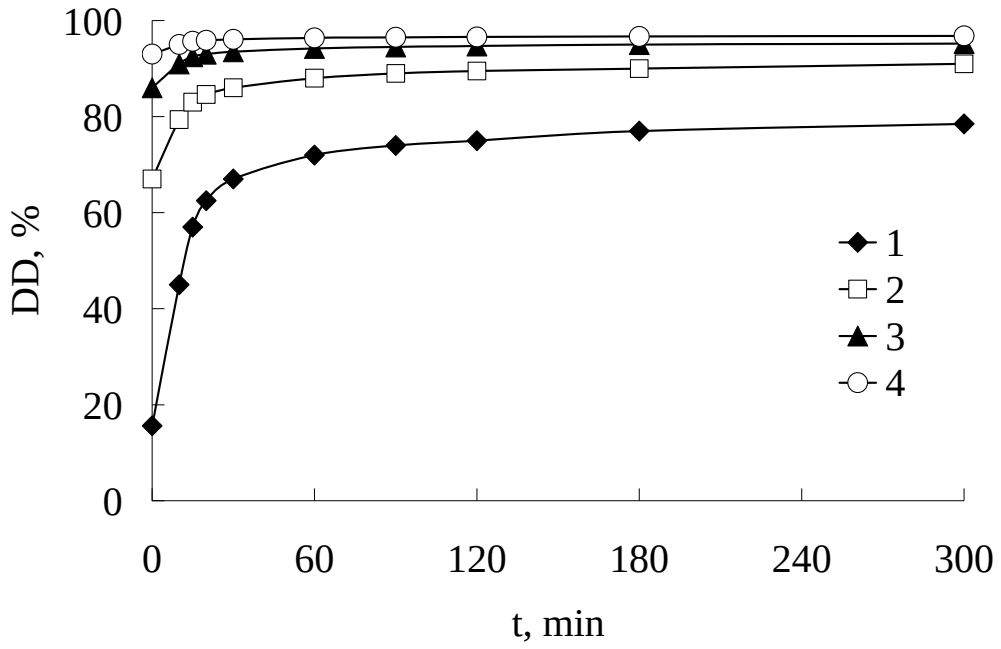

Fig. 2. Deacetylation kinetics curves of chitin/chitosan with initial DD 12 (1), 66 (2), 88 (3), and 92 % (4). Temperature 98 °C, 50 % NaOH.

Our results, have shown, that kinetic curves of deacetylation for normalized in relative values DD completely coincide. In other words, the deacetylation rate of chitin and chitosan does not depend on an initial DD. The form of kinetic curves appeared identical to chitin and chitosan with various initial DD, up to 95 % (Novikov et al., 1990; Novikov, 2003).

2. We have shown influence of crystallinity and a hydration of chitin molecules on deacetylation kinetics of dry and wet samples natural and reprecipitated chitin (Fig. 3) (Chebotok et al., 2007).

In our opinion, formation of solvated structures as a result of interaction of macromolecules of polysaccharides and low molecular weight electrolyte with solvent affects on deacetylation rate.

On Fig. 3 the kinetic curves of deacetylation of dry chitin (curve 1) and reprecipitated from solution NaOH of wet chitin (curve 2) are shown. From Fig. 3 it follows, that rate of deacetylation of wet reprecipitated sample ($\chi_{кр}$ = 4.0%) is much less than dry chitin ($\chi_{кр}$ = 59.0%). In NaOH solution, probably, the solvation (hydration) of chitin molecules takes place. Dipoles of water molecules are in appropriate way oriented around acetamidic and glycosidic linkages of macromolecules. According to the mechanism of reaction of deacetylation in an alkaline condition the hydrolysis of acetamidic linkage begins with nucleophilic attack by ions OH^- on carbonyl atom of acetamidic group. This hydrated environment complicates the nucleophilic attack that results in decrease of deacetylation rate.

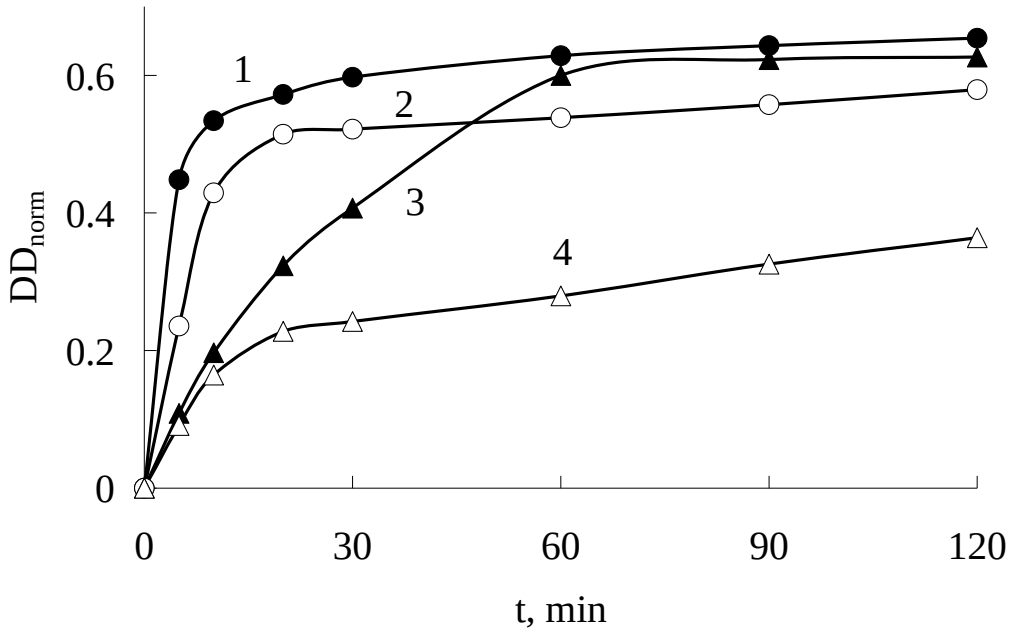

Fig. 3. Deacetylation kinetic curves of chitin: initial dry (1), initial wet (2), reprecipitated dry (3), and reprecipitated wet (4). Temperature 98 °C, 50 % NaOH. DD_{norm} – normalized DD, % (initial of each sample njrmalized to 0, upper DD - 100 %), t - time (min).

The decrease of reaction rate on the first part (0-30 mines) of deacetylation kinetics curve of reprecipitated dry chitin in comparison with dry and wet initial chitin can be explained by higher density of chitinous particles. In the initial samples obtained by consistent extraction of proteins and inorganic salts from the crab shell a particle of chitin are more porous. After crystallization of clear chitin from solution such pores are not formed for the account more density packing of molecules of polysaccharide.

Thus, obtained results allow to assume, that degree of crystallinity of the investigated samples renders considerably smaller influence on speed of deacetylation, than an opportunity of formation of a hydrated environment around of macromolecules of polysaccharide which interferes with nucleophilic attack of hydroxyl ion, retards reaction rate and stops reaction on fixed values of DD. The occurrence of two simultaneous reactions - deacetylations and formations of low-activity intermediate which is broken down at washing is possible.

Application of surfactants to membrane separation processes

Gryzelda Poźniak*, Ryszard Poźniak, Kazimiera A. Wilk
Department of Chemistry, Wrocław University of Technology, 50-370Wrocław, Poland

Keywords: modified polyethersulfone, ultrafiltration, bovine serum albumin, cadmium
Topic: Sustainable process-product development through green chemistry

1. Introduction

Membrane separation processes, which are more environmentally friendly than conventional separation techniques, have been enjoying considerable interest in biotechnology and metallurgical industry. Among membrane processes ultrafiltration has deserved special interest. However, wider application of ultrafiltration has been hindered so far due to a detrimental effect of fouling, i.e. an irreversible process caused by solute sorption. In biotechnology, ultrafiltration membranes are commonly used for concentration and purification of protein solutions. Very often protein molecules block membrane pores which results in a decline of membrane flux. Most thermo-resistant polymers have adequate chemical and biological stability suitable for membrane formations but their strongly hydrophobic character accelerates sorption of proteins on the membrane surface. Polyethersulfone (PES) - popular membrane material - belongs to such polymers. There are several methods to protect the membrane from fouling: physical modification by surfactants [Jönsson and Jönsson, 1991] and introduction of ionic groups to the membrane materials by plasma [Poźniak et al., 2002] or chemical treatment [Poźniak et al., 1995, 2007].

The metallurgical industry, especially the electroplating and metal finishing sectors generate huge amounts of water containing heavy metal ions such as Cd(II). Ultrafiltration (UF) has proved to be an efficient way to remove from water high molar substances (polymers, proteins) - particles of a size ranging from 2 to 100 nm and M larger than 500 Da. In consequence, the pore size of UF membranes is too large to reject small molecules, like metal ions.

Micellar enhanced ultrafiltration (MEUF) is a surfactant-based separation process that has been used to remove heavy metal ions from dilute streams [Scamehorn et al., 1994, Poźniak et al., 2005]. In this process, an anionic surfactant at a concentration higher than its critical micelle concentration (cmc) is added to the aqueous stream containing dissolved solutes. Negatively charged micelles force the cations to bond to the micelle interface. Micelles (size above 10 nm) with the bonding cations are then separated by UF using membrane of suitable porosity, capable of retaining micelles.

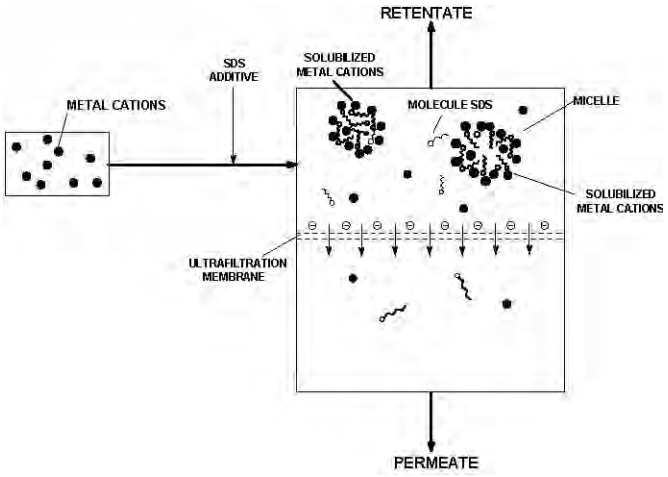

Fig. 1. Outline of metal cation separation by MEUF

To enhance selectivity in MEUF, ligand-modified micellar enhanced ultrafiltration (LM-MEUF) has been developed [Fillipi et al., 1997]. This method involves addition of an amphiphilic ligand and a surfactant to contaminated solution under conditions where most of the surfactant is present in the form of micelles. The ligand has a high degree of solubilization in the micelles and a tendency to selectively complexes the target metal on.

The goal of this paper is to show the effect of surfactant use for two membrane processes: ultrafiltration of protein and micellar enhanced ultrafiltration removal of Cd(II) ions. Polyethersulfone and sulfonated polyethersulfone UF membranes have been subjected to surfactant modification.

2. Experimental

2.1. Sulfonation of polyethersulfone and preparation of membranes

The polyethersulfone (PES ULTRASONE E-2020P from BASF) was sulfonated using a mixture of chlorosulfonic acid (CSA) and 1,2-dichloroethane (at room temperature, for 90 min). The initial molar ratio of CSA to PES was 3:1.

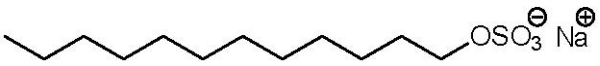
Three types of porous asymmetric membranes were formed by phase-inversion method from: (i) 13.5%-wt. solution of PES, (ii) mixture of 15%-wt. PES plus 10 %-wt. polyvinylpirrolidone (PVP 10 kDa) and (iii) 30%-wt. solution of sulfonated PSU in N,N-dimethylformamid (DMF). Water was used as coagulation medium.

2.2. Transport properties

The Amicon 8200 dead-end UF cell with membrane surface area of 19.6 cm^2 was used. The transmembrane pressure was set at 0.1 MPa.

Ultrafiltration of bovine serum albumin

The membranes formed from the mixture of PES and PVP were immersed in sodium dodecylsulfate, SDS (16.2 $mmol/dm^3$) or monoether dodecylpentaoxyethylene glycol, EDPEG (0.12 $mmol/dm^3$) solutions (24 hr). Additionally, the process was carried out in two cycles: the membrane was kept in SDS solution for 24 hr and then immersed in EDPEG solution for 5 min.



Sodium dodecylsulfate (SDS), cmc = 8.1 $mmol/dm^3$

Monoether dodecylpentaoxyethylene glycol (EDPEG), cmc = 0.06 $mmol/dm^3$

The performance of surfactant modified membranes was determined with buffer of pH 8 and 0.1 M buffered solution of bovine serum albumin (BSA). The concentration of protein in the permeate was detected at 280 nm (Specord M-40, Carl Zeiss). From the flux values before and after protein filtration the transport parameters: fouling index (FI), reduction of the flux in filtration (RF) and solute rejection (R) were calculated according to our procedure [Poźniak et al., 2006]:

$$FI = [1 - (J_f/J_o)] \times 100 \quad (1)$$

$$RF = [1 - (J_p/J_o)] \times 100 \quad (2)$$

$$R = [1 - (C_p/C_o)] \times 100 \quad (3)$$

where:

J_o – is the flux of buffer through the freshly mounted membrane,

J_p - is the flux of buffered BSA through the same membrane,

J_f – is the flux of buffer through the membrane after BSA filtration,

C_p and C_o are concentrations of protein in the permeate and in the feed solution, respectively.

Micellar enhanced ultrafiltration of cadmium

Mixtures of SDS (8.1, 40.5 and 81 mmol/dm^3) and $CdCl_2$ (1 mmol/dm^3) and mixtures of SDS (4.0, 8.1 and 40.5 mmol/dm^3) and $CdCl_2$ (1 mmol/dm^3) with ligand 8-hydroxiquinoline, 8-HQ (4 mmol/dm^3) were filtrated through PES and SPES membranes. The concentrations of metal ions and SDS in the permeate were determined with an atomic adsorption spectrophotometer (AAnalyst 100, Perkin-Elmer).

To evaluate the filtration efficiency in removing the cadmium cations from the feed solution, we used the flux of permeate (J) and rejection (R) expressed as:

$$J = V/A\ t \qquad (4)$$

where:
V – is the volume of permeate,
A – is the membrane area,
t – is the time of ultrafiltration

$$R = [1 - (C_p/C_o)]x\ 100 \qquad (5)$$

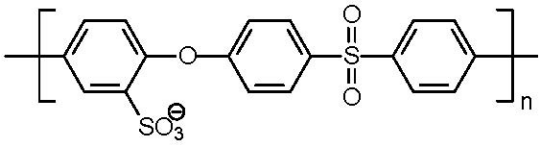
where:
C_p and C_o – are the cation concentrations in the permeate and in the initial feed, respectively.

3. Results

The two systems were used to obtain more permeable membranes from polyethersulfone (PES):

(i) adsorption of surfactants: anionic (sodium dodecyl sulfate) and nonionic (monoether dodecylpentaoxyethylene glycol),

(ii) chemical introduction of sulfonate groups to polymeric chains.



Three types of membranes were used in this study. Two of them we selected based on their similarities in physical structure; they differ in chemical composition only (PES and SPES, Table 1).

Membranes from PES+PVP system were used for hydrophilization by adsorption of surfactants. They have the greatest average pore diameter, because after physical modification of surfactants ultrafiltration of bovine serum albumin was performed.

Table 1. Characteristics of the used membranes

Membrane	Flux of water dm^3/m^{2}h	Total Porosity	Average pore diameter Nm	-SO_3 groups concentration mmol/g
PES+PVP	410	79	59	0.00
PES	53	72	13	0.00
SPES	76	79	18	0.79

Ultrafiltration of BSA

The effect of membrane hydrophilization by surfactants was monitored by evaluating the permeate fluxes and the resistance of the membrane to being fouled by bovine serum albumin. Hydrophilization was carried out according to different protocols: in one cycle by immersion in

surfactant solution and in two cycles by subsequent sorption of two surfactants - anionic and nonionic. It is well known that BSA molecules have negative charge at pH=8. Negative charge appeared also on a membrane modified with SDS, hence some repulsive effect was to be expected. With nonionic surfactant (EDPEG), the improvement in filtration indices was ascribed to the thick hydrophilic layer on the membrane surface which kept the protein molecules over the pore entrance [Chen et al., 1992]. The results of BSA ultrafiltration are shown in Table 2.

Table 2. Filtration indices of surfactant modified membrane PES+PVP

Surfactant	FI %	RF %	R %
SDS	21	33	95
EDPEG	15	28	96
SDS/EDPEG	6	15	98
NONE	58	77	91

In comparison with an unmodified PES membrane, the modified species show significant improvement of their performance in protein filtration. Fouling (FI) is less intensive and reduction of the flux in BSA filtration (RF) shows lower values. It is worth noting that the best results were obtained for BSA filtration through the membrane modified with consecutive sorption of SDS and EDPEG. That phenomenon can be explained by a combined effect of the nonionic surfactant that protects the membrane against deposition of BSA while the anionic surfactant reduces the fouling potential of BSA molecules which penetrate the first surfactant layer [Chen et al., 1992]. It is important to note here that the presence of surfactants on the membrane does not affect the separation properties of the membranes; the values of BSA rejection (R) are similar.

Micellar enhanced ultrafiltration of cadmium

The second reason for using surfactants in filtration processes is the phenomenon of enhanced removal of harmful species performed by micelles that are too large to penetrate the membrane pores. To check the effect of surfactant which is needed to remove Cd(II) ions, the MEUF processes were investigated. The results are shown in Tables 3 and 4.

Table 3. Cadmium flux and rejection in MEUF process

SDS concentration	PES membrane		SPES membrane	
mmol/dm^3	J dm^3/m^{2}h	R %	J dm^3/m^{2}h	R %
8.1	46	73	68	85
40.5	37	80	51	97
81.0	23	85	27	99

Table 4. Cadmium flux and rejection in LM-MEUF process

SDS concentration	PES membrane		SPES membrane	
mmol/dm^3	J dm^3/m^{2}h	R %	J dm^3/m^{2}h	R %
4.0	55	78	76	88
8.1	47	86	71	98
40.5	41	91	55	99

The highest rejection coefficient was observed for SDS concentration equal to 81 mmol/dm^3 in

MEUF and 40.5 mmol/dm^3 in LM-MEUF process. As usually, sulfonated polyethersulfone membrane worked more effectively that its off-charge analogue [Poźniak et al., 1995, Guan et al., 2005]. There is one more conclusion to be drawn from the presented data. The removal of divalent cations by means of MEUF and LM-MEUF hybrid systems is based on electrostatic binding of ions to oppositely charged micelles [Scamehorn et al. 1994]. After the addition of 8-HQ to SDS solution, the cmc is lower than without 8-HQ [Paulenová et al., 1996]. The evaluation of cmc for SDS in the investigated solution was about 10 times less than in distilled water (0.9 mmol/dm^3). Additionally, mixed micelles of ligand and surfactant with bound metal ions are more rigid and therefore the rejection of micelles is higher which is also favorable for cadmium recovery [Paulenová et al., 1996].

4. Conclusions

The hydrophilization of membranes from PES+PVP system by means of surfactant sorption improves membrane properties in the filtration of BSA. Polyethersulfone and sulfonated polyethersulfone membranes can be used for the separation of heavy metal ions by means of MEUF. However, charged membranes are more effective that their off-charge analogues. The best cadmium ions separations were observed for the LM-MEUF process.

Topic: Sustainable process-product development through green chemistry

Abstract

The present work suggests a new technological approach to minimize the use of antimicrobial agents, based on the principle of drug-delivery systems where the antimicrobial compounds are transported on nano-microparticles or in nano-micro-capsules. In this preliminary study, the efficacy of the method against biofilm of *Pseudomonas fluorescens* was assessed, using benzyldimethyldodecylammonium chloride (BDMDAC), which is a surfactant belonging to the family of benzalkonium chloride, as a biocide carried on microparticles (diameter: 4 μm). The latter were prepared using the layer-by-layer (LbL) self-assembly technique. The oppositely charged polyethyleneimine (PEI), sodium polystyrene sulfonate (PSS) and BDMDAC were assembled on polystyrene (PS) cores. The BDMDAC coated particles were observed by CryoSEM and their composition by X-ray microanalysis. Their size distribution (Coulter Particle Size Analyzer) and zeta potential (Nano Zetameter) were also determined. After nine days of the formation of biofilm, the coupons were collected and incubated for 30 min under two different conditions: i) saline solution; ii) solution of BDMDAC coated particles. In sterile saline solution (0.85% NaCl), the biofilm contained 1.6×10^7 CFU/mL. On the other hand, the biofilm exposed to the microparticles with biocide for 30 min contained no cultivable cells (determined by removing the biofilm from the coupon surface, diluting and spreading it on Plate Count Agar, followed by incubation at 30 ºC during 24 h).

Introduction

Layers of microorganisms and their extracellular polymers (“biofilms”) grow very easily on industrial cooling water tubes and heat exchanger channels, causing increased pressure drop and reduced heat transfer efficiency. These problems lead, ultimately, to an increase in the costs of the production and maintenance, as well as to public health problems and environmental impacts (Pereira et al, 2007). Often the layers build up in a non-uniform manner, with localized spots where thicker biofilms appear. Biofilm growth on surfaces is prevented by using biocides (e.g., chlorine) and detergents in the water stream in considerable large amounts. According to the E.U. Directive 98/8/EC, biocides are "chemicals with an active and in general toxic effect on living organisms, put up in the form in which they are supplied to the user, intended

to destroy, deter, render harmless, prevent the action of, or otherwise exert a controlling effect on any harmful organism" (Rasmussen et al, 1999). Such toxic chemicals are not totally consumed and their discharge into the environment or wastewater treatment plants is a source of serious problems.

Modern strategies to minimize fouling in industrial equipment (pipes, heat exchangers, etc.) focus on optimizing equipment design, developing new surfaces to reduce adhesion and applying efficient surface cleaning/disinfection methodologies, supported by on-line monitoring techniques. During the last 3 decades, a considerable amount of work has been reported on the effect of hydrodynamics on equipment performance and biofilm growth (Characklis *et al.*, 1990; Melo and Vieira, 1999) and although further advances are still possible on this aspect, the improvements will be generally marginal. High velocities have some drawbacks since, at the same time, they were shown to produce more compact deposits that are more difficult to remove from the surface (Melo and Vieira, 1999) both by mechanical actions and chemical methods (biocides find a higher resistance to diffusion in such compact structures). More recently, new low energy surfaces produced by surface bombardment to implant ions such as Mo and F, plasma sputtering and coatings with thin Ni-P-PTFE layers (Rosmaninho and Melo, 2006; Santos *et al.*, 2004) have been developed with an interesting potential for reducing deposit adhesion, but their application is much dependent on the relative costs of such expensive materials as compared to the costs associated to fouling. Applications to specific cases, such as tubing in medical purpose equipment, can be cost-effective, but this is not the case at industrial equipments. Additionally, it was shown that the major advantage of such surfaces is that they allow the production of deposits that are easier to clean (Santos *et al.*, 2004). Therefore, cleaning has increasingly become the crucial step in the optimization of these systems. There are, here, two interconnected issues: a) biofilms and other deposits do not attach uniformly along the surfaces; b) chemicals used to remove biofilms (such as biocides and dispersants) are carried as solutes by the bulk liquid and only a minor fraction does actually take part in the cleaning process, leaving a large amount in the discharge waters.

Nowadays, cleaning procedures are still highly inefficient processes that consume great amounts of water, chemicals and time. Large quantities of biocides are applied everyday to remove biofilms from power plant condensers (water flow rates above 2000 m^3/hour). Localized biofouling layers appear in different places of shell-and-tube heat exchangers and in plate heat exchangers, such as in the cooling section of milk pasteurizers (both in the process and in the water side). More efficient cleaning techniques are needed, that consume less water, fewer chemicals, less energy, less time and, simultaneously, are able to target the sites where the fouling layers develop. This will reduce the environmental burden (wastewater treatment) and minimize production losses caused by frequent stopping for cleaning.

The Layer-by-Layer (LbL) self-assembly of oppositely charged polyelectrolytes onto colloidal particles has been used to create novel nano- and microparticles with well controlled size and shape, finely tuned wall thickness and variable wall compositions (Decher, 1997; Donath *et al.*, 1998; Caruso *et al.*, 1998; Cordeiro *et al.* 2004). The original method was introduced in 1991 by Decher and co-workers for the construction of pure polymer multilayer

films on planar supports (Caruso, 2001).This technique uses electrostatic attraction and complex formation between polyanions and polycations to form supramolecular multilayer assemblies of polyelectrolytes. The first stage of shell fabrication involves step-wise deposition of polyelectrolytes from aqueous solutions. The polyelectrolyte multilayer film is formed by the alternate adsorption of oppositely charged layers on to the particle. After each adsorption step, the non adsorbed polyelectrolyte in solution is removed by repeated centrifugation or filtration and washing (Donath *et al*., 1998).

The goal was to develop and characterize microparticles with functionalized surfaces that act as carriers of biocide molecules. This will probably reduce the use of toxic chemicals and will minimize health and environmental risks of biocides.

The biocide benzyldimethyldodecylammonium chloride (BDMDAC) used in this work is a quaternary ammonium compound (QAC) and a component of benzalkonium chloride (BAC) that is normally used in re-circulating cooling water systems. BAC consists of a mixture of three alkyldimethylbenzlylammonium chlorides which differ only in the length of the alkyl side chains (C_{12}, C_{14} or C_{16}) (Bull *et al.,* 1998). BACs are surfactants with detergent and antimicrobial properties that are produced as industrial cleaners (Ferrer and Furlong, 2002) and are useful antiseptics and disinfectants. Quaternary ammonium compounds such as BDMDAC act by disrupting cell membranes and, depending on the their concentration, they can be either bacteriostactic or bactericidal (Ferrer and Furlog, 2001).

Materials and Methods

Particles Production Process

Polyethyleneimine (PEI – M_w 750 000) 50% (w/v) in water, Poly(sodium 4-styrenesulfonate) (PSS – M_w 70 000) and boric acid (SigmaUltra minimum 99.5%) were obtained from Sigma-Aldrich.
Benzyldimethyldodecylammonium chloride (BDMDAC – M_w 339.9) was obtained from Fluka. All chemicals were used without further purification.

Poly(styrene) (PS)-research particles 4.37 μm ± 0.07 μm 10% w/v aqueous solution were obtained from Microparticles GmbH.

The particles were prepared using the layer-by-layer (LbL) self-assembly technique as state above. The oppositely charged polyelectrolytes, PEI, PSS and BDMDAC, were assembled on polystyrene cores, in a process that comprises the following 3 steps according Figure 1. Polystyrene particles were allowed to interact with the PEI solution (1.0 mg/mL in borate buffer solution) for 20 min, and then washed in borate buffer solution 0.10 M pH 9 to remove the excess polymer. After this procedure the core was positively charged and was used for the deposition of the polyanion PSS, followed by the cation BDMDAC, both solutions of 1.0 mg/mL in borate buffer pH 9. The adsorption steps were carried by adding the polymer solution to the cores for 20 min, centrifuging at 4000 rpm for 4 min and resuspending them in borate buffer pH 9. This step was repeated twice.

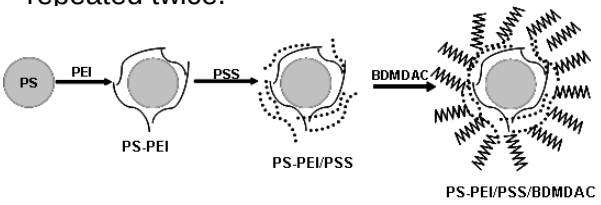

Figure 1: Schematic representation of the process of particles production.

The solvent used in the whole process

was borate buffer solution at pH 9. It was selected since the ionic strength of the solution as well as the pH value allows a better layer-by-layer process by promoting the right superficial charge for the different molecules intervening in the process.

Particle's Characterization

CryoSEM and X-ray Microanalysis The coated particle integrity was analysed by CryoSEM (model Gatan ALTO 2500) at CEMUP (Centro de Materiais da Universidade do Porto). Cryo preparation techniques for SEM have become essential for the observation of wet or "beam sensitive" sample. Using these techniques, the need for conventional preparation methods, such as critical point drying or freeze drying is removed. Besides, it allows observation of the sample in its natural hydrated state. CryoSEM is also a very rapid process, typically only a few minutes are needed. The X-ray microanalysis is an analytical technique for determination of the chemical composition of solid samples, thin layers or particles in electron microscopes like CryoSEM.

Size Distribution in Number and Volume. The size distribution of the particles was determined in a Coulter Particle Size Analyzer (model LS 230 – small volume module plus) by Laser Diffraction. The analysis of the particle size was considered as volume distribution and number distribution. A sample placed in the fluid module is circulated through a sample cell at a constant speed. A beam of laser light shone through the cell is diffracted by particles within the sample, and the forward scattered (or diffracted) light is collected by series of detectors. The distribution of light falling on the sensors enables the size distribution of the sample to be calculated.

Zeta Potential. The zeta potential of the particles was determined using a Nano Zetasizer (Malvern instruments, UK). Most particles dispersed in an aqueous system acquire a surface charge. These surface charges modify the distribution of surrounding ions, resulting in a layer around the particles that is different from the bulk solution. If the particle moves, this layer moves as part of the particle. The zeta potential is the potential at the point in this layer where it moves past the bulk solution. Zeta potential is a measure of one of the main forces that mediate interparticle interactions. Zeta potential is measured by applying an electric field across the dispersion. Particles within the dispersion with non-zero zeta potential will migrate toward the electrode of opposite charge with a velocity proportional to the magnitude of the zeta potential.

Microorganism and Growth Medium. Pseudomonas fluorescens was the microorganism used to produce biofilm. This microorganism is known to be a good biofilm producer (Melo and Vieira, 1999; Pereira et al. 2001; Simões et al., 2005). Their growth conditions were: T=27 ºC, pH=7 and glucose as carbon source. The optimum growth medium consisting in fifty milligram per litre glucose, 25 mg/L peptone, 12.5 mg/L yeast extract in phosphate buffer – pH 7. The medium was sterile (Pereira et al, 2007).

Biofilm Formation. A pure culture of *Pseudomonas fluorescens* was grown in a 4.0 L tank for 24 h, under optimal growth conditions (T = 27 ºC, pH = 7 and glucose as carbon source). After the incubation period, the suspension was diluted in 5.0 L of distilled and sterilized water that was put to recirculate between the fermenter and a flow cell where biofilm development on PVC coupons was monitored as the representation in Figure 2. The glucose concentration (determinated by

Dinitrosalicylic Colorimetric Method – DNS) was maintained at 20 ppm by pumping sterile medium into the system.

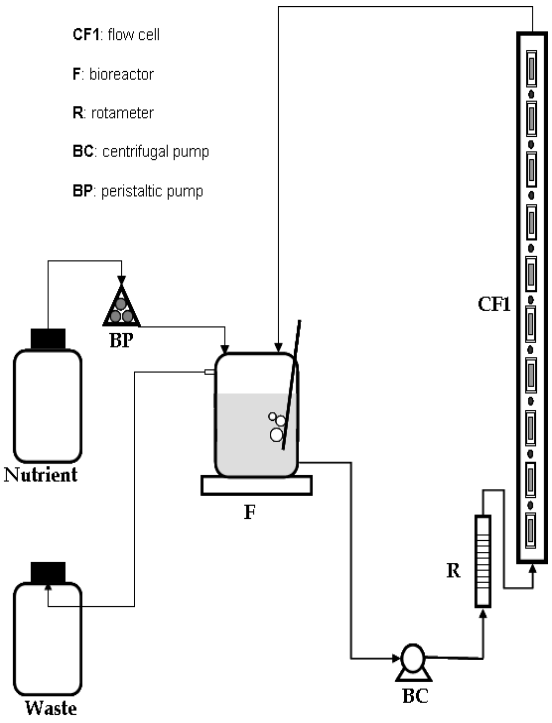

Figure 2: Schematic representation of the biofilm installation.

Biocidal properties of the BDMDAC coated particles. After nine days of the experience the coupons were collected, and incubated for 30 min at 27 ºC under different conditions: i) saline solution (0.85% NaCl); ii) solution of the BDMDAC coated particles. After this incubation time the biofilm was removed from the coupon surface, diluting and 100 μL of sample were spread on Plate Count Agar (PCA) with a sterilized glass rod and incubated for 24 h at 30 ºC. The viable cells were counted to assess the biocidal effect.

Results and Discussion

CryoSEM was used to visualize the morphology of the particles as well as the presence of the external layer (BDMDAC and/or PSS). The selection of this technique was mainly related to the fact that it allows the analysis of particles in the hydrated state. X-ray microanalysis coupled with CryoSEM was used to confirm the elemental constitution of the particles surface.

Cryo-SEM images of PS-PEI/PSS particles show that they are spherical and have a rough surface (see example in Figure 3).

The particles with an additional layer after contact with BDMDAC solution can be seen in Figure 3. X-ray microanalysis indicates that the external layer is mainly composed by C (carbon) and its content is considerably higher in PS-PEI/PSS/BDMDAC particles when compared with PS-PEI/PSS particles (Figures 3 and 4). This would be expected because BDMDAC has a very long carbon chain.

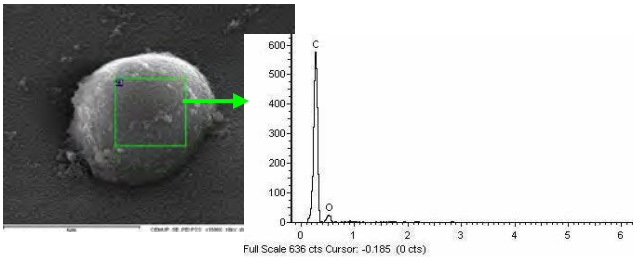

Figure 3: CryoSEM image (×15000, 10 kV) and X-ray microanalysis of PS-PEI/PSS particles.

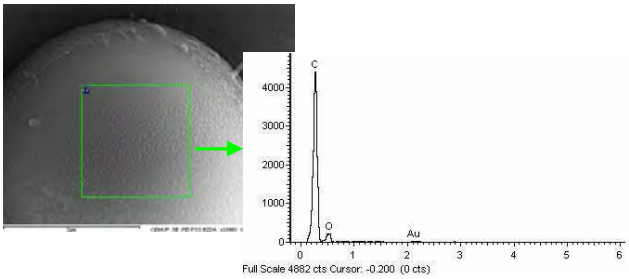

Figure 4: CryoSEM image (×30000, 10 kV) and X-ray microanalysis of PS-PEI/PSS/BDMDAC particles.

The size distribution of the particles is depicted in figure 5 and Figure 6. Three populations could be found for PS-PEI/PSS particles with an average size

of 3.0, 4.4 and 15.0 µm. In the case of PS-PEI/PSS/BDMDAC, again three populations were observed, but here two of them are well defined (3.0 and 4.4 µm), whereas a wider distribution could be seen between 6 µm and 20 µm (Figure 5). This can be related to particle aggregation due to the hydrophobic interactions between the carbon chains of BDMDAC. However, when considering the size distribution in number only the two populations of smaller diameters (3.0 and 4.4 µm) are observed, indicating that the number of particles of about 20 µm is not significant, for all type of particles (Figure 6).

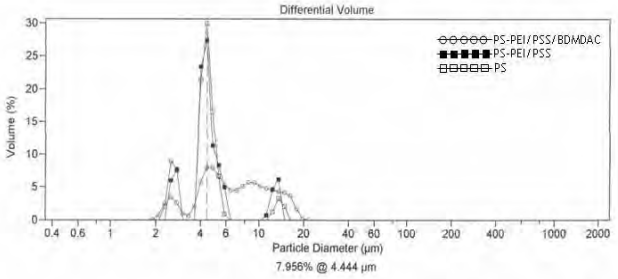

Figure 5: Volume distribution of the particles (PS, PS-PEI/PSS and PS-PEI/PSS/BDMDAC).

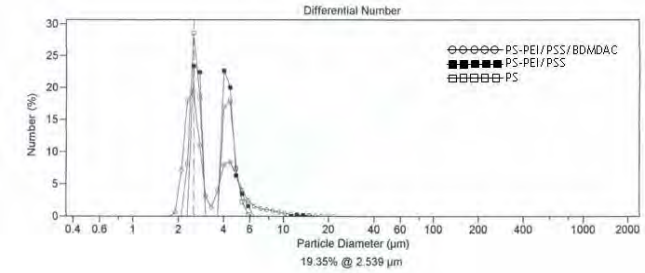

Figure 6: Size distribution of the particles in number (PS, PS-PEI/PSS and PS-PEI/PSS/BDMDAC).

The zeta potential of the particles PS-PEI/PSS at pH 9.0 in borate buffer solution is -34 ± 4 mV and the zeta potential of the particles PS-PEI/PSS/BDMDAC is -21 ± 5 mV.

After nine days, the coupons were collected and incubated for 30 min under two different conditions: i) saline solution; ii) solution of BDMDAC coated particles (2.3×10^8 particles/mL). In sterile saline solution (0.85% NaCl), the biofilm contained 1.6×10^7 CFU/mL. On the other hand, the biofilm exposed to the microparticles with biocide for 30 min contained no cultivable cells - see Figure 7.

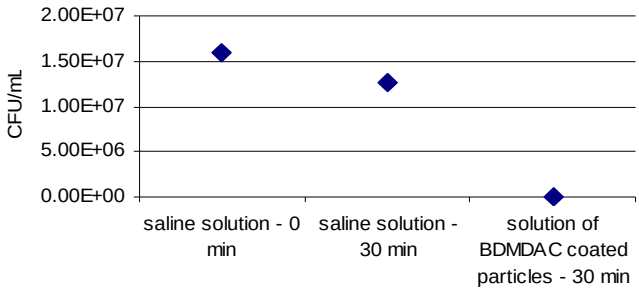

Figure 7: Number of bacteria colonies (CFU/mL) in biofilms subjected to different conditions.

We can see that the particles coated with biocide (BDMDAC) were effective against the biofilm formed by *P. fluorescens*.

Conclusions

The goal the work was to develop and characterize microparticles with functionalized surfaces that act as carriers of biocide molecules and test them against biofilm formed by *P. fluorescens*. The biocide used was benzyldimethyldodecylammonium chloride (BDMDAC) and the particle cores were polystyrene (PS, 4 µm). We can conclude that the particles coated with our biocide are active against biofilm of *P. fluorescens*.

The present work is the beginning of a study that will have, in the future, a potential impact in reducing environmental costs, a better control of the health risks associated with the use of biocides, a reduction in energy

consumption and a decrease in biocide costs in a large number of industrial plants.

Topic: Sustainable process-product development through green chemistry
Systematic methods and tools for managing the complexity

Introduction

Nanomaterials have a great importance in industrial applications due to their electronic, magnetic, optical [1] and catalyst [2] properties. Another important feature of nanoparticles is their large spectrum (range), an important characteristic in catalytic processes. Nanoparticle applications are found in communications, data storage [4,5], solar energy conversion [6]. It is well known that certain physical and mechanical properties of materials modify with the reduction of their particle size. Unfortunately, only a few synthesis methods of nanostructured powders are applicable at industrial scale.

Materials performance depend on their properties. Properties, in their turn, depend on the atomic structure, composition, microstructure, defects and interfaces, which are controlled by the synthesis kynetics and thermodynamics.

The synthesis of powders and their subsequent processing have a great influence over the final properties of the resulted materials. The selection of suitable processing methods determines, to a great extent, the results obtained for the final products.

At present, the obtaining of nanopowders for different practical applications uses nonconventional processing methiods, capable to offer better homogenity, increased purity, low sintherizing temperatures and a fine microstructure, with as small as possible grains.

Gold nanoparticles have raised the researchers' attention due to their numerous applications in catalytic processes [7] and in the DNA sequence determination [8].

Specialized literature presents a series of synthesis methods of different shapes [9] and size [10] gold nanoparticles which, by large, can be classified into two sections, function of their growth environment, i.e. polar (aqueous) or non-polar (organic) environment.

Generally, the gold hydrosols synthesis methods in aqueous phase suppose [1] the chloric-gold ions reduction with different reducing agents, such as: the citric acid [11], the sodium borohydride [12], the gold ion reduction by irradiation [13,14] and the sono-chemical reduction [15].

The synthesis of gold nanoparticles in nonpolar environments are based on the research performed by Burst &co. [16] who have managed to transfer the chloroaurate ions from the aqueous phase into the organic phase by using the tetraoctil ammonium bromide. After the phase transfer, the gold ions have been reduced and covered with alcanethiols[16]-alkylamines[17], thus obtaining stable monodispersed gold nanoparticles.

This paper presents the synthesis and characteristics of gold nanoparticles obtained in the organic phase with the use of sodium citrate. The gold nanoparticles characteristics were determined by in UV - visible spectoscopy (UV-Vis) and by electronic transmission microscopy (TEM).

Experimental

1. Materials and devices

Experiments were performed by using: the tetra-octilammonia, toluene, MERCK produced de-ionised water, Aldrich tetrachloroauric acid ($HAuCl_4$). Stirring was performed with a magnetic device.

2. Gold nanoparticles synthesis in the organic phase with sodium citrate

The aqueous solution of 0.011M tetrachloroauric acid was mixed with a 0.05M tetraoctil ammonium bromide solution in toluene for 10 minutes, to a 1:2.5 volume ratio at which the solution becomes orange. In order to obtain the desired size gold nanoparticles, a 10^{-2}M (1) and respectively $5x10^{-3}$M (2) sodium citrate solution was added by dripping under strong agitation, to a volume ratio between the mixed solution and the sodium citrate of 4:1. Stirring was maintained for 30 minutes at the environment temperature, the mixture being then transferred into a separating funnel. The reduction of gold metallic ions and the formation of nanoparticles has been evidenced by the modification of the solution colour, from orange to ruby red. After the phases separation, the organic ruby red phase which contains gold nanoparticles has been first washed with 2% hydrochloric acid for neutralization and several times with distilled water. After washing and phases separation, the organic phase has been kept into a dark colour glass bottle.

3. UV-Vis spectroscopic studies

The optical properties of gold colloidal solutions (1) and (2) have been characterized through UV-Vis spectrometry, by using a CECIL spectrophotometer within a wave length between 400 and 700 nm.

4. Electronic transmission microscopic measurements

The electronic transmission microscopy analysis (TEM) was made by using a CM12 Philips electronic microscope, with a 2Å resolution. The sample were prepared by placing a drop of gold colloidal solution on copper grid that has been covered with a very thin amorphous carbon layer. The examination has been made by electronic transmission microscopy in light fascicle (TEM-BF) and electron diffraction (SAED).

Results and discussions

The nanoparticle transfer mechanism from the aqueous solution into the organic solvent involves their hydrophobization. The aqueous solution containing the tetrachloroauric ions is mixed with the organic solvent which contains the coverage molecules (the tetraoctil ammonium bromide). Upon the mixture of the two phases, the coverage molecules will „wrap” the gold metallic nanoparticles, making them hydrophobic and thus facilitating their transfer into the organic solvent. The nanoparticle transfer from an aqueous environment into an organic one can be observed also by the change in the colour (from pale yellow to orange).

Figure 1 presents the UV-Vis spectra of gold colloidal solutions in the first experiment (10^{-2}M) and in the second experiment ($5x10^{-3}$M) respectively. Curve 3 corresponds to the $Oct_4N^+AuCl_4^-$ complex resulted from the mixture of the tetracloroauric acid with the tetraoctil ammonium bromide solution in toluene.

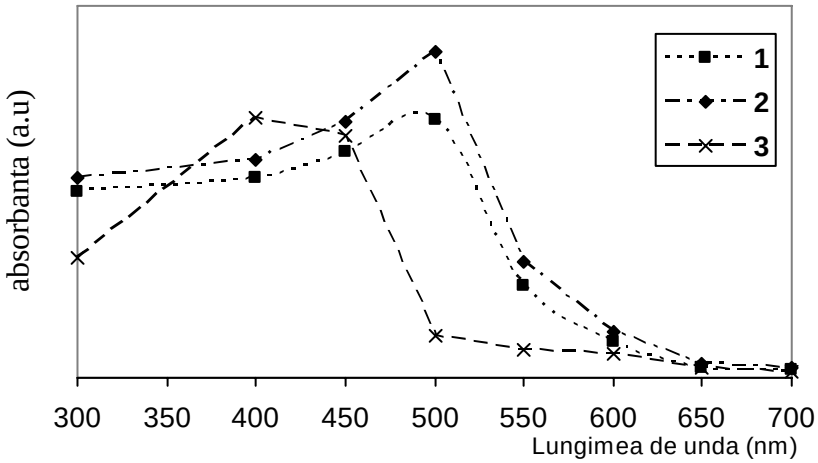

Figure 1. UV-Vis Spectrum of 10^{-2}M (curve 1), $5x10^{-3}$M (curve 2) gold colloidal solutions and of $Oct_4N^+AuCl_4^-$ complex (curve 3).

A strong absorbtion can be noticed in case of curve 3, around the 347nm value of the $Oct_4N^+AuCl_4^-$ complex resulted from the mixture of the tetracloroauric acid with the tetraoctil ammonium bromide solution in toluene. The absorbtion band is characteristic for the $AuCl_4^{6-}$ transfer band between the metal and the ligand.

The reduction of the $Oct_4N^+AuCl_4^-$ complex with sodium citrate leads to the formation of gold nanoparticles covered with the citrate ions, as illustrated by spectra 1 and 2 which reached their maximum around 530 nm. One can also notice that the absorbtion spectrum for curve 1 is flatter, which indicates a certain degree of aggregation of the obtained nanoparticles, in contrast to the sharper absorbtion spectrum registered for curve 2.

In spite of the fact that the samples exhibit a certain degree of aggregation, the colloidal gold solutions obtained in the organic phase with the aid of sodium citrate are stable for about 2 months, if preserved in a dark, constat temperature environment. A certain nanoparticle agglomeration is evident with time.

The electronic transmission microscopy enables to obtain qualitative data on the nanoparticle dimensions and on their distribution by size, as well as information on their microstructural and microcompositional morphology. The electronic transmission microscopy results (TEM) for the two samples are presented in Figures 2 and 3.

Figure 2 A presents the image obtained by electronic transmission microscopy of gold nano-particles obtained by the reduction of 0.011M tetrachloroauric acid with 10^{-2} M sodium citrate (**1**). A uniform gold nanoparticle distribution may be noticed. Figure B presents the distribution curve of nanoparticles dimensions. The continuous line overlapping the histogram is a Gaussian curve which gives information on the mean particle size, found to be in the range of 5-7 nm.

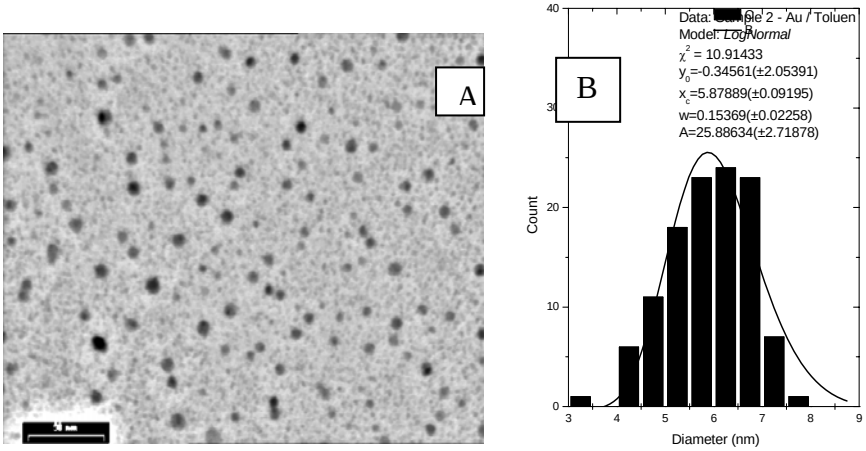

Figure 2. TEM image for A nano-particles obtained in the organic phase through 10^{-2} M sodium citrate reduction; B- Histogram of gold nanoparticle size distribution for the same sample.

Figure 3 A shows the image obtained through electronic transmission microscopy of gold nanoparticles obtained in the organic phase, using sodium citrate $5x10^{-3}$ M (2) solution as a reducing agent. An uneven distribution of gold nanoparticles is noticed; Figure B presents the nano-particle size distibution curve. The continuous line is a Gaussian fit to the histogram and gives information on the mean particles size, found to be in the range of 1-3 nm.

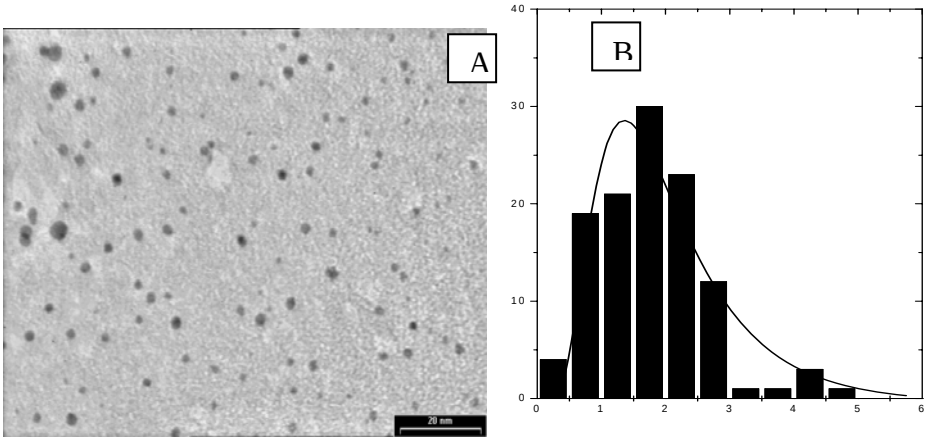

Figure 3. TEM image for A – nano-particles obtained in the organic phase by using a $5x10^{-3}$ M sodium citrate solution as a reducing agent; B - Histogram of gold nano-particle size distribution for the same sample.

The size of the obtained gold nanoparticles increases with the concentration of the sodium citrate solution. The results obtained through electronic transmission microscopy for these samples are consonant with those obtaine through UV spectroscopy.

Conclusions

This paper presented the organic phase synthesis of gold nanoparticles through the reduction of chloroauric ions with sodium citrate. In order to vary the nanoparticles dimensions, experiments were conducted with sodium citrate solutions of different concentrations: 10^{-2}M (1) and $5x10^{-3}$M (2). Following TEM investigations, the obtained nanoparticle sizes increased with the concentration of the reducing agent, all the other conditions remaining unchanged. Gold nanoparticle applications are found in solar energy conversion.

Keywords: sol-gel synthesis, silica based xerogel/aerogel, flexible nanomaterial.
Topic: Sustainable process-product development through green chemistry: Nanotechnology.

Abstract

Flexible silica based xerogels and aerogels were synthesized via sol-gel technology with methyltrimethoxysilane (MTMS) precursor. A two-step acid-base catalyzed sol-gel process was used, followed by Ambient Pressure Drying or Supercritical Fluid Drying to produce the xerogels or the aerogels, respectively. The obtained materials have shown promising properties for aerospace applications, namely low density (40-100 kg/m^3), high surface area (~ 400 m^2/g), small pore size (~ 30 Å), high hidrofobicity (> 130º) and moderate flexibility.

1 Introduction

In the last few years, new synthesis technologies for advanced materials were developed. Commercial demand and environmental and energy restrictions have been the driving force for research on this area. The sol-gel technology is a good example of this trend, offering competitive advantages over traditional techniques: high homogeneity and purity of the product, low temperature required, preparation of new crystalline and noncrystalline solids and special products such as films and aerogels. By sol-gel technology, materials with improved and tailored properties may be prepared, as the product microstructure can be controlled during the synthesis and drying stages. Mainly, it is a wet technology, which starts from a homogeneous solution, that gives rise to a colloidal solution – sol, and evolves gradually to an integrated solid network – gel. In the end, a xerogel or an aerogel is obtained, if the gel is dried at ambient pressure or in supercritical conditions, respectively.

Silica aerogels synthesized with $Si(OR)_4$ precursors exhibit a nanostructured three-dimensional solid network with low density (~ 40 Kg/m^3), high surface area (~ 1000 m^2/g), low thermal conductivity (0.02 W/mK) and high transparency (~ 90 %). These unique properties allow their use in several applications, namely as thermal or acoustic insulators, dielectric or optical materials, filters and catalysts (Pierre and Pajonk, 2002, Rao *et al.*, 2006). However, they are brittle, absorb moisture and deteriorate with time. Flexible and hydrophobic aerogels would allow improved performance of these materials in particular applications, namely aerospace applications. An aerogel for applications in space should meet the targets/properties indicated in Table 1. The key property to tailorable aerogels for space is porosity: a high porous structure gives aerogels very low thermal conductivity and density, making them competitive with current space insulation materials. Also, if the application involves insulation from water, especially for electric components insulation, it is fundamental to have a material with high hydrophobicity. Aerogels in space have a wide range of applications, such as: thermal and structural insulators for re-entry and Mars vehicles, spacecraft components and cryogenic tanks; protection coatings for solar panels and thermal blankets; semi-flexible coatings for cables, ribbon Printed Circuit Boards (PCB's) and Multi Layer Insulation Blankets (MLI's) in space suits and spacecrafts; collection of

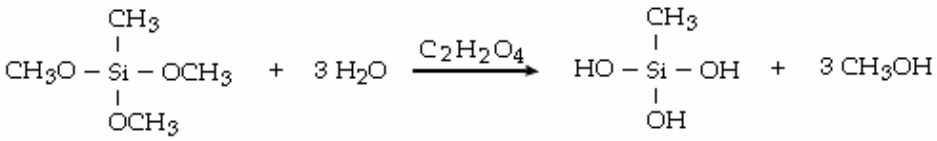
Using methyltrimethoxysilane (MTMS) as precursor in sol-gel chemistry, as proposed by Rao *et al.* (2006), the obtained silica based aerogels can fulfil the major part of the targets listed above. In MTMS, one OR group of $Si(OR)_4$ is replaced by R, being R=CH_3. This group does not suffer hydrolysis during the synthesis and remains in the aerogel structure, providing the hydrophobicity and flexibility required (Rao *et al.*, 2006, Baghat *et al.*, 2007). The density, the surface area and porosity are also controlled by the drying technique, being the xerogels denser and less porous than aerogels. However, both have very low density, very high surface area and porosity, and consequently very low thermal and electric conductivities.

In this work, flexible silica based xerogels and aerogels were obtained via sol-gel technology with MTMS precursor. The materials were chemically and physically characterized, for assessment of their suitability to aerospace applications.

2 Materials and Methods

The applied sol-gel technology to synthesize the silica based xerogels and aerogels includes the sol-gel synthesis, which consists of a two-step acid-base catalyzed sol-gel process, pursued by ageing and drying stages. The overall experimental procedure followed the description of Rao, Baghat *et al.* (2006, 2007).

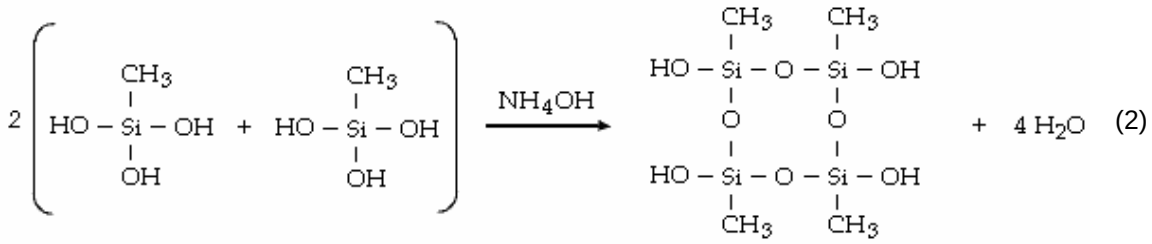
MTMS ($CH_3Si(OCH_3)_3$, 98 %, Aldrich), methanol (CH_3OH, 99.8 %, Riedel-de Haën), oxalic acid ($C_2O_2(OH)_2$, 99 %, Fluka) and ammonium hydroxide (NH_4OH, 25 % in water, Fluka) were used as precursor, solvent, acid and basic catalysts, respectively. At first, MTMS was diluted in methanol and then water was added, in the form of an oxalic acid solution (0.1 M), to promote the hydrolysis of MTMS (reaction 1) in acidic conditions (pH ≈ 2) – acid step.



(1)

After 24 h, an ammonium hydroxide solution (10 M) was added, drop by drop, and the condensation of monomers began (reaction 2), forming a sol – basic step. As the first drops

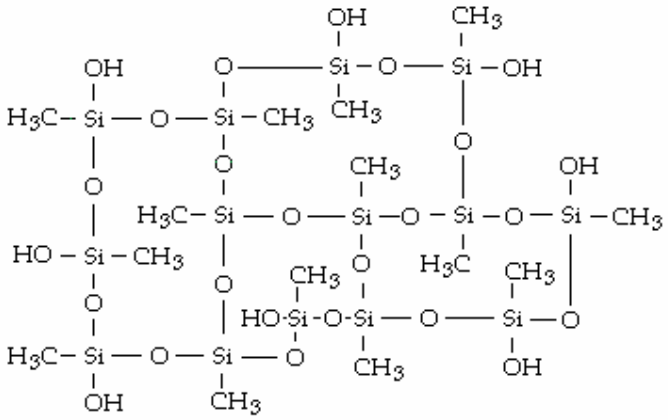
were added, the pH increases sharply and the medium became alkaline. The pH after the total addition of the basic catalyst solution was ~ 12.



The acid and basic steps were carrying out at controlled temperature – 25 ºC, by means of a glass jacket with water as cooling agent (Fig. 1). In this work, the molar ratio of MTMS:methanol:acidic water:basic water tested was 1:35:4:[1.8-9.4].

The obtained sol was placed in an oven at 27 ºC and left for gelation. After 4-8 h, a gel was formed. In this stage, the alkaline conditions favours polycondensation reactions, resulting in the building of a tri-dimensional network of Si-O-Si (*cf.* hypothetical structure 3). The water produced in this inorganic polymerization may act as reactant in the hydrolysis and condensation reactions, increasing their completeness.

Figure 1 Experimental set-up for the synthesis stage.



(3)

The resulting gel was aged for two days at 27 ºC. This ageing period promotes the cohesion of the solid network, because the polycondensation of monomers continues as long as neighbouring silanols are close enough to react. Besides this, syneresis and coarsening processes also occur during the ageing (Hench and Orefice, 1992).

To remove the liquid (methanol, water, catalysts), mainly methanol, entrapped in the solid network, the gel was dried in two different ways. Initially, Ambient Pressure Drying (APD) was used to produce xerogels. In this case, the gel was transferred to a ventilated oven, at atmospheric pressure, and submitted to a temperature cycle – 24 h at 60 ºC, followed by three stages, at 100 ºC, 150 ºC and 200 ºC, of one hour each – to evaporate the alcohol (T_b(methanol) = 65 ºC – Goodwin, 1987). This method leads to the shrinkage of the pores due to surface tension effects. Recently, aerogels have been produced using Supercritical Fluid Drying (SFD). To reach the supercritical point of the solvent (T_c(methanol) = 240 ºC and P_c = 80 bar – Goodwin, 1987), the gel was placed in an autoclave (Fig. 2), which was then filled up with methanol. After, the temperature of the autoclave was increased at constant volume, causing an increase in the pressure inside it. When the critical point of the methanol was exceeded, the liquid became a supercritical fluid and, from this condition, the gaseous solvent was released, at constant temperature, and, consequently, the pressure has decreased. Near the atmospheric pressure, the autoclave was flushed with nitrogen to remove the remaining solvent. In this process, the shrinkage is minimized because the liquid-gas saturation line is not crossed (Fig. 3).

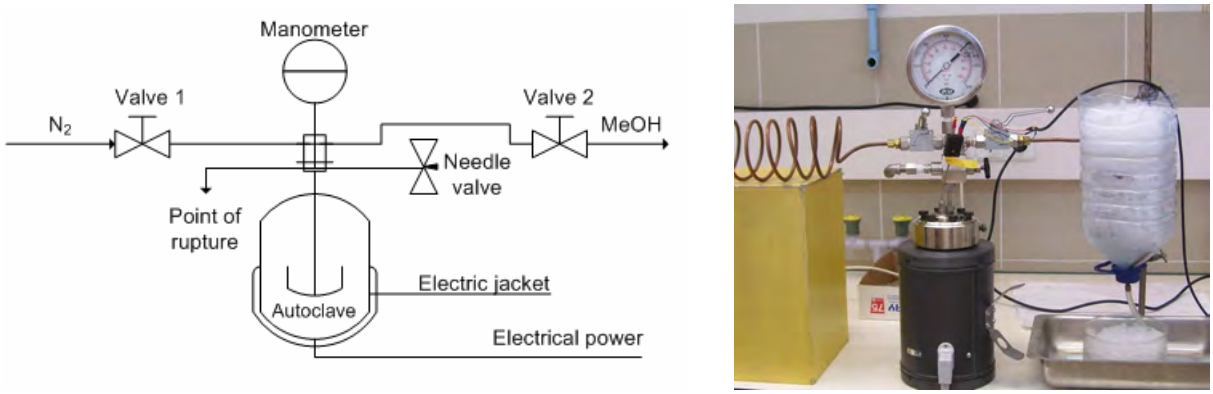


Figure 2 Experimental set-up for the SFD.

The elemental composition (C,H,N,O), chemical structure, surface area, density and contact angle of the xerogels and aerogels were accessed by elemental analysis (*EA 1108 CHNS-O*, *Fisons Instruments*), Fourier transform infrared spectroscopy (*Magna-IR™ System 750*, *Nicolet*), nitrogen gas adsorption (*ASAP 2000*, *Micromeritics*), weight-volume measurements and a contact angle technique (*Contact Angle System OCA 20*, *Dataphysics*), respectively.

3 Results and Discussion

During the basic step of the synthesis, a sharp pH increase from ~ 2 to ~ 9 was observed with the addition of the first 2-3 drops of the basic catalyst solution; then, the pH increased slowly towards its final value (pH = 10-11), depending this value on the total amount of the basic catalyst solution added (Fig. 4). The condensation reactions occurred extensively at the very beginning of the basic catalyst addition and the solution became cloudy and milky, proving that the main effect was achieved with a tiny amount of catalyst.

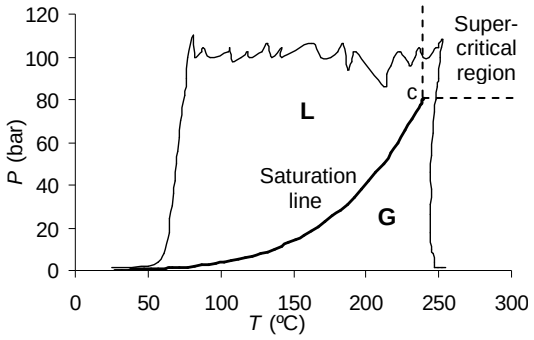

Figure 3 Typical *P-T* evolution in the SFD.

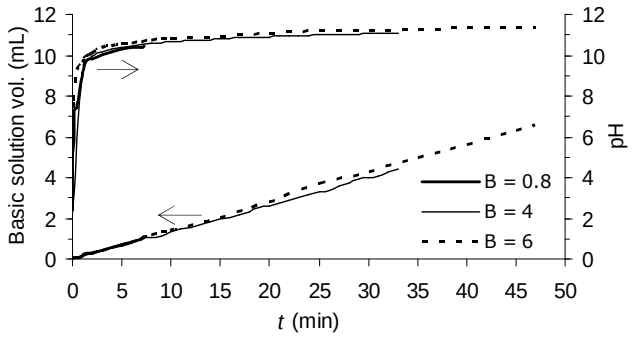

Figure 4 pH evolution during the basic catalysis step.

In a fully condensated material, the repetition units of the inorganic polymer have Si:O:C:H molar ratio of 1:~1.5:1:~3, neglecting the H atoms on the terminal groups (*cf.* structure 3). This corresponds to a theoretical C:O:H mass percent of 18.1:36.3:4.5. Comparing these values with the elemental analysis results – Table 2, it can be concluded that all the samples have only one CH_3 group per Si in its structural formula, since a good agreement for the % C is obtained. Therefore, the hydrolysis was complete. Also, the hypothesis of a fully condensed material is validated by this agreement, especially for samples in which B ≤ 6. This was expected, since the pH rise is accomplished by a small volume of the basic catalyst solution, as a consequence of its high concentration. The measured values for the % H are higher than 4.5 %, what can be explained by the contribution of H in OH terminal groups. The N content obtained in the experimental results proves the existence of impurity traces in the materials dried by APD or SFD, since only the basic catalyst had N atoms. The theoretical and experimental values for the % O in xerogels are very different, because the temperature used in the elemental analysis (1060 ºC) was not enough to break the Si-O bonds.

a) $B = (H_2O)_{Basic}/MTMS$; b) Based on desorption isotherms.

The FTIR results for the xerogel and aerogel, for B = 4, are shown in Fig. 5. Materials with different B ratios were also analyzed, but the obtained spectra were almost the same. This is also the case displayed in Fig. 5, being the little displacement between curves due to the intrinsic variability of the laser beam. The intense bands appearing around 760 cm^{-1} and between 1000 and 1100 cm^{-1} are due to symmetric and asymmetric stretching vibrations of Si-O-Si bonds, respectively (Hedge and Rao, 2007, Castro *et al.*, 2005). The band just after 500 cm^{-1} may possibly correspond to bending vibrations of the same bonds (Hedge and Rao, 2007). The bands at ~ 850 cm^{-1} and ~ 1270 cm^{-1} can be assigned to Si-C bonds (Hedge and Rao, 2007, Castro *et al.*, 2005). The little peaks observed at ~ 1400 cm^{-1} and near 3000 cm^{-1} are due to the bending and stretching of the C-H bonds, respectively (Becker *et al.*, 1997, Hedge and Rao, 2007). There are no significant bands between 1600 and 1700 cm^{-1} or after 3000 cm^{-1}, proving that the Si-OH bonds are not abundant, the solvent was properly removed and the adsorbed water is absent (Becker *et al.*, 1997, Hedge and Rao, 2007). These observations confirm that the condensation reactions were very extensive and the obtained materials have a silica based structure, with highly hydrophobic CH_3 groups inside.

A decrease in the density of the xerogels and aerogels with the increase of B is observed – Fig. 6. In the case of xerogels, this decrease is more pronounced up to the sample corresponding to B = 4. For higher B values, the variation is almost within the experimental uncertainty. As the xerogel became more powdery and weak with the increase of B (for B = 9.4, the xerogel was a powder), 4 was considered the optimum B value for the desired properties. Aerogels show considerably lower densities than xerogels. Furthermore, it seems that the stabilizing B value for density is now 3.

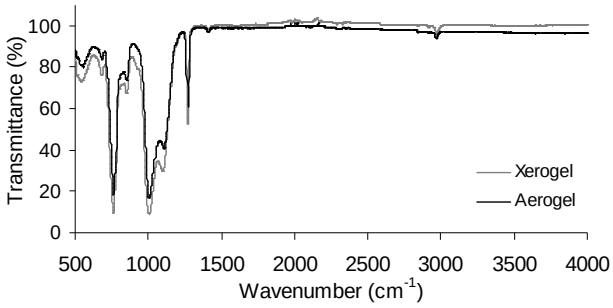

Figure 5 Typical FTIR results for the synthesized xerogels and aerogels.

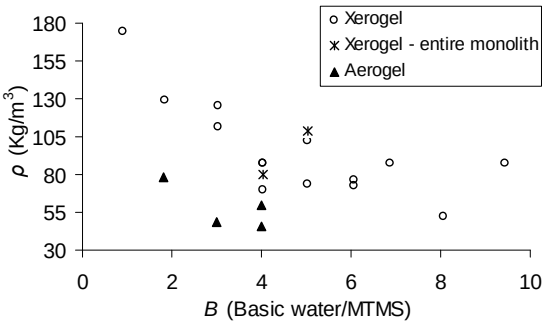

Figure 6 Densities of xerogels and aerogels for several B molar ratios.

Concerning the surface area results – Table 2, in the case of xerogels, the sample for B = 3 has lower surface area than the samples for B = 4-6. This was predictable, because the xerogels for B < 4 are more dense and rigid. The surface areas of the other three samples are comparable. For the aerogels, considering their density, higher BET surface area values were expected. For B = 4, the surface area value is lower then the one of the correspondent xerogel. This means that the results of surface area analysis should be completed and more replicas should be done. The pore sizes obtained for the xerogels and aerogels are consistent with a mesoporous structure, as they are in the interval 20-500 Å.

The contact angle values – Table 2 – confirm the high hydrophobicity of the obtained xerogels and aerogels and allow their classification as non wetting materials. Figures 7 and 8 show the flexibility characteristics of the synthesized xerogels and aerogels monoliths.

Figure 7 Xerogel monolith.

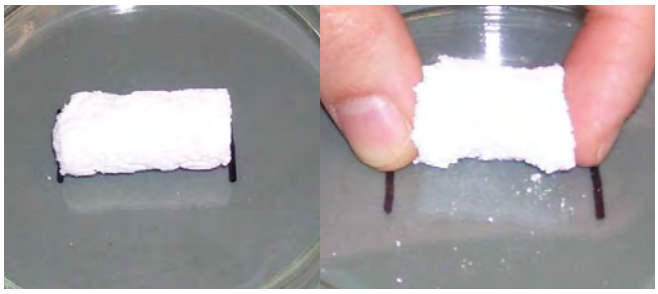

Figure 8 Aerogel monolith.

5 Conclusions

Flexible and hydrophobic silica based xerogels and aerogels were obtained, using MTMS as precursor in a two-step acid-base catalyzed sol-gel process, followed by drying at ambient pressure or at supercritical conditions. The synthesized materials showed suitable properties for aerospace applications, namely very low density (40-100 kg/m3), high surface area (~ 400 m2/g), small pore size (~ 30 Å), high hidrofobicity (> 130º) and moderate flexibility.

Effect of operating conditions on the extraction of β-glucans from barley

O. Benito, S. Lucas, E. Alonso
Departamento de Ingeniería Química y Tecnología del Medio Ambiente. Prado de la Magdalena s/n. Facultad de Ciencias. Universidad de Valladolid (Spain)

Keywords: β-glucan, barley, extraction
Topic: Sustainable process-product development through green chemistry

Abstract

The aim of this work is to analyze the effect of operating parameters on the extraction of β-glucans from different varieties of barley. Several experiences have been carried out in batch extractors, with a reference experiment, in order to check the influence of temperature, pH, time, solvent and flour:solvent ratio. Time and temperature showed to have a strongly marked influence: the higher temperature, the higher extraction rate. Higher temperatures led to improve the extraction yield, increasing the amount of starch co-extracted. Extraction time was a critical factor up to 3 hours. Longer times did not increase the amount extracted. The influence of pH was not very remarkable, just generating a slight increase in extraction yield up to 8; beginning to decrease from that value. The use of alcohols (methanol and ethanol) as solvents, did not improve the extraction rate. On the other hand, it was observed an important decrease on the β-glucan solubility, greater the higher concentration of alcohol employed and the longer carbon chain. Finally, a extraction yield of 40-50% was obtained when operating at solvent:flour ratio from 7 to 12, at 55ºC, in almost all range of pH, when lasting the extraction process more than 2,5 hours.

1. Introduction

β-glucans are a kind of non-starchy polysaccharides (formed by the linkage of glucose units via β-(1→3) (approximately 30%) and β-(1→4)-glucosidic linkages) that can be found in several kinds of cereals, such as barley, oat or rye in concentrations from 2 to 12% in dry basis. In barley, β-glucans are minor components (up to 6-7%), located majoritary in the aleurone and endosperm cellwalls (Irakli *et al*, 2004) of the grain. They form part of the dietetic fibre (the same as other structural compounds of vegetals, such as cellulose and hemicelluloses), nevertheless β-glucans are soluble in water.

It is known that they have good properties for human health, if eaten. Among all these properties it is worth mentioning their implication in process of control of cholesterol and glucose concentration in blood (McIntosh *et al*, 1995; Bhatty, 1999; Brennan, 2005). These effects have been associated with the molecular weight of the polymers. Recently, FDA (Food and Drug Administration, USA) has included β-glucan in its list of products that contribute to lower the cholesterol level in blood, pointing out how to label the products that contain barley to remark its positive effect on health.

Extraction of β-glucans form cereals has to deal with several difficulties. A typical extraction process involves, at least, three stages (Bhatty, 1995; Laroche, 2007): inactivation of endogenous enzymes, extraction of β-glucans with a suitable solvent, and finally a purification-isolation stage, because other chemicals present in cereals (proteins, saccharides, or starch) can be co-extracted. All these stages increase the complexity of the overall process, increasing the economical costs, therefore. This is the most limiting factor for the extraction process.

When a solid-liquid extraction process is carried out, temperature, pH, extraction time and polarity of the solvent are some of the operating parameters that are to be taken into account. It is important to characterise the behaviour of the target compound when changing the operating variables, in order to improve the extraction process.

In this work a simple solid-liquid discontinuous extraction process from different waxy-type barley (H13-06 (hull-less) and D24-06) with hot water was proposed. The effect of most important operating parameters such as temperature, pH, extraction time and polarity of the solvent was checked in order to optimize the continuos extraction process. Moreover, a reference experience based on literature revision carried out at 55ºC, 3 hours, water as solvent, solid:liquid ratio 1:10 was chosen as a comparative tool (Papageorgiou *et al*., 2005).

2. Experimental section

Two different kinds of barley were used, both of them grown and harvested in Castilla y León (Spain): H13-06 and D24-06. These varieties correspond to the waxy-type barley, a specie of barley which has higher content in β-glucan and a lower in starch than common species. The main difference between those two kinds of barley is that grains of H13 are hulless, not presenting external hull covering the kernel. Barley was supplied by Instituto Tecnológico Agrario de Castilla y León (ITACYL). Table 1 summarizes the composition of both varieties:

Table 1. Chemical composition of the barley used as raw material

	H13-2006 (%)	D24-2006 (%)
Moisture	11,07	10,98
Fats	2,26	2,48
Ash	1,78	1,86
Proteines	4,9	4,3
Starch	52	44,8
Amilose/Amilopectine	10,22/89,78	9,05/90,95
β-Glucan	4,13	5,33
Dietic Fibre	13,85	18,7

Barley employed was milled and sieved through a 0,5mm sieve.

Initially, temperature, pH, time, solvent, flour:solvent ratio were defined as the factors that had to be tested. According to the literature, basic conditions (of temperature) for the initial experiments were selected: 55ºC, 3 hours, water as solvent, solid:liquid ratio 1:10 (these conditions constitue the basic experiment). In this reference experiment, pH of water was not modified, being around 6.

Barley flour was weighted and added to an erlenmeyer flask. Then water was added, being the flour suspended at high stirring rate. Temperature was kept constant in a water bath (Lauda Ecoline Staredition E100, Lauda, Germany). Stirring was obtained with a multistirrer plate (Fisher Scientific, USA), as shown in figure 1:

Once the extraction process was finished, solid:liquid separation was done by centrifugation (5500rpm, 10 minutes). Solid material was discarded and liquid (supernatant) was stored at 4ºC until the moment of being analysed.

All the experiments were conducted in duplicate.

Figure 1. Experimental set-up used for the extraction of β-glucans from barley

β-glucan determination was made at ITACYL, using the Megazyme Assay Kit for mixed linkage β-glucan analysis (*Megazyme*, Ireland). β-glucan concentration is expressed as % (weight) of the total sample.

Yield results shown in the following figures was calculated by dividing the amount of β-glucan in the extract generated and the total amount of β-glucans in the barley flour used in the extraction process.

3. Results

β-glucan extraction yield was 41,5±1,0% for D24 and 47,2±2,4% for H13 for the reference operating conditions This result, contrary to that expected, can be explained for the presence of interferences. H13 is a hulless barley, with a lower content in β-glucans. D24, despite of its higher content in this compound, is more difficult to extract them, probably due to the presence of the hull of the kernel. This problem can be solved by milling the barley in a industrial mill, that generates three milling fractions, with different compositions of β-glucans.

When the extraction process was divided in three stages (of one hour each), the amount of β-glucan extracted was around 60%, a 20% higher than when developing the process in one single stage.

Several experiments were carried out in order to check the influence of temperature, pH, time, solvent and flour:solvent ratio on β-glucans extraction, changing the study variable and keeping constant the remaining ones. The reference experiment was achieved at 55ºC, pH around neutrality (6), 3 hours of extraction time and with 1:10 solid:solvent ratio.

Temperature effect (35-75ºC): It was observed a costant increase in the extraction yield when increasing the temperature from 29% at 35ºC up to 56% at 75ºC. However when temperature is higher than 55ºC, operational problems connected with the higher suspension viscosity and the co-extraction of starch in the extract were observed (the amount of starch in the extract was increased dramatically, from 0,12% to 0,71%, which makes more difficult the subsequent purification, (Temelli, 1997)). For these reasons, the optimal extraction temperature was fixed in 55ºC (see Figure 2).

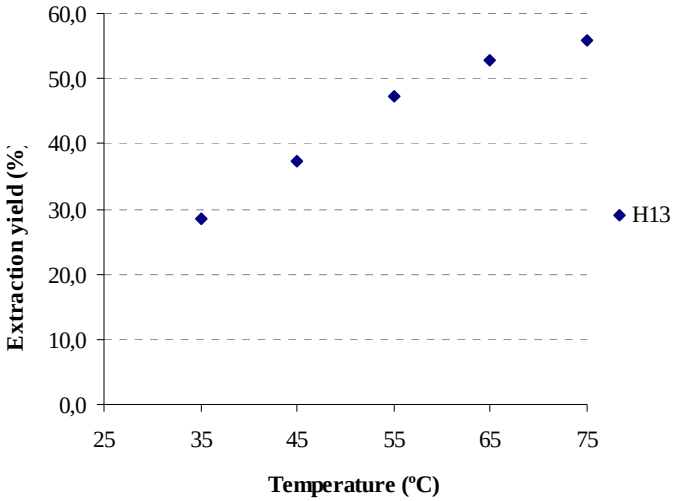

Figure 2. Temperature effect on the β-glucan extraction yield (H13 barley).

Extraction time effect (0.5-5 h). Times under 2,5 hours were found to be too short (yield fell down under 40%), but an extraction time of 5 hours did not entail a dramatic increase in the amount of β-glucan extracted, rather it kept constant (45-47%) after three hours of extraction. Extraction time of 3 hours is enough to ensure the equilibrium was reached and to get a high extraction yield (see Figure 3).

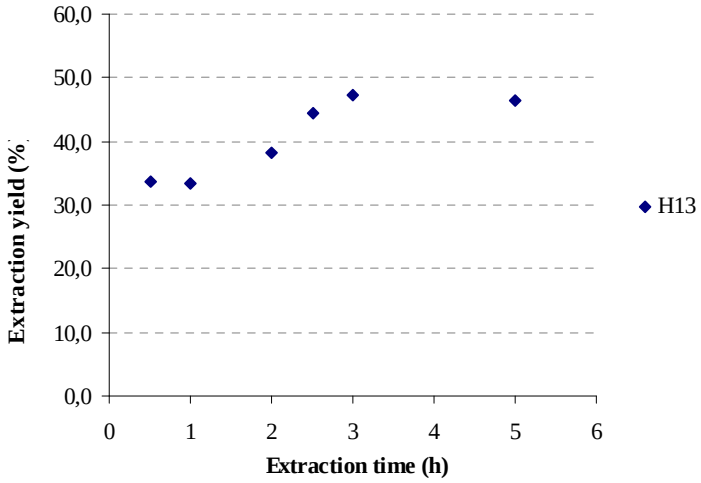

Figure 3. Effect of extraction time on the β-glucan extraction yield (H13 barley).

When the influence of pH (in the range 6-11) was studied (see Figure 4), a slight increase in extraction yield was produced. Water was weakly basified (pH 8) by addition of some drops of NaOH (6N). However, a further increase (pH 11), decreased the amount of β-glucans extracted. This decrease with pH was more marked in the case of H13 type. This could be due to the depolymerisation of our targed compounds. This result reveals that it is not necessary to increase the pH of the original water used as solvent (close to neutral pH).

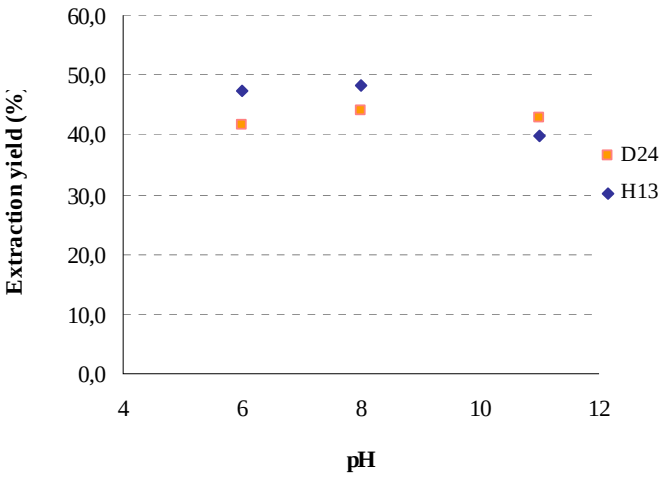

Figure 4. pH effect on β-glucan extraction yield (H13 and D24 varieties of barley).

Solid (flour):liquid ratio (in the range 5-15) was also tested for H13 variety. As it can be observed in Figure 5, an important change in extraction yield (over 50%) could be noticed when this ratio was shift from 5 to 10. The increase of this ratio to 15, did not produce a positive effect in the extraction of β-glucans. When using ratios of 8, 10 or even 12, it was observed a constant yield, around 47%. This result showed that it is possible to operate at lower solid:liquid rate (at 8), which is important taking into account a further purification step. Using less amount of solvent means simplifying the concentration of β-glucans.

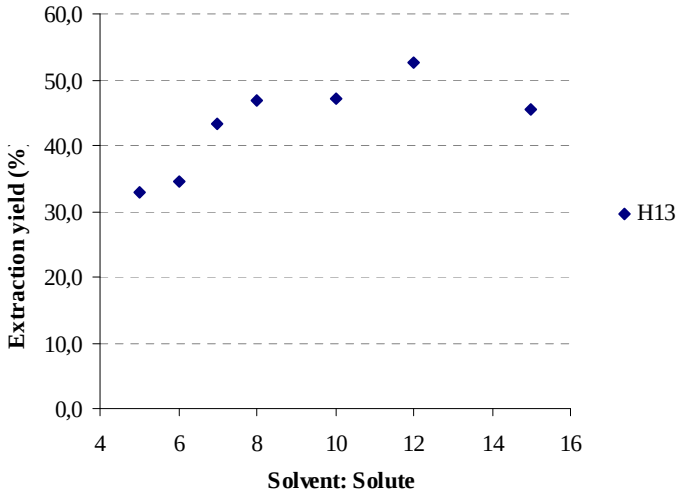

Figure 5. Effect of solvent:flour ratio on β-glucan extraction yield (H13 barley).

Polarity of the solvent can be classified as a critical parameter. This part of the study was developed using the D24 variety. The better results were obtained with water as solvent (yield was 41,5%). When an alcohol was used as solvent (5% in volume), the extraction yield decrease slightly to 41,4% in the case of the use of methanol and to 34,1% when ethanol was used. When the concentration of alcohol was increased (50% or 100%), it was not possible to extract β-glucans. The amount of polymer extracted in those cases was under the detection limit of the analysis method. According to this result, alcohols can not be used as co-solvents. This property would allow to the alcohols to be used to precipitate β-glucans, using the alcohols as anti-solvent.

4. Conclusions

Initial conditions fixed for discontinuous extraction of β-glucans from barley with water (55ºC, 3h and flour:solvent ratio of 8) are suitable to get extraction yields in the range 40-50% for both varieties of barley tested. Time and temperature showed to have a strongly marked influence: the higher temperature, the higher extraction rate. Longer times than 3 hours didn't increase the amount of β-glucans extracted. The influence of pH was not very remarkable, just generating a slight increase in extraction yield up to 8; beginning to decrease from that value. The use of alcohols (methanol and ethanol) as solvents, did not improve the extraction rate. The operation in 3 steps of one hour each one, allowed to increase the maximum amount of β-glucan up to 60%. This result shows that β-glucan extraction can be enhanced when increasing the number of extraction steps, which justifies the need to develop a continuos extraction process.

Abstract

In the present study the step-growth polymerization of lactic acid [HO−CH(CH_3)−COOH] in solution was studied. In order to attain a polymer with high molecular weight, the water formed during the polymerization reaction must be continuously removed. For that an organic solvent with high boiling point was added and the water was removed from the vapour phase with the help of drying agents. Moreover, higher molecular weights were achieved when pressure reduction in the reactor was implemented. This procedure allows to obtain poly(lactic acid) polymers (PLA) with a molecular weight up to 45 000 $g.mol^{-1}$ in a one single reaction stage. The polydispersity of the PLA polymers is satisfactory, nevertheless the results point out that, in the direct condensation of lactic acid, racemization reactions can be a limiting factor. Mainly, the small leaks in the reactor and the catalyst used are contributing for the racemization reactions. The specific rotation measurements, used in this work, showed to be a powerful technique to evaluate the racemization extent.

1 Introduction

An increasing effort in the development of sustainable alternatives to petrochemical origin materials has been recently registered, mainly due to environmental reasons (Bogaert and Coszack, 2000).

Poly(lactic acid), PLA, is an aliphatic polyester, biodegradable/compostable, biocompatible, and bioreabsorbable, obtained from a 100 % renewable raw material, the lactic acid. The possibility to tailor the lactic acid based polymers, with specific properties, allows to use them in many different aplications. Due to its hydrolytical instability and good biocompatibility, PLA can be used in biomedical, pharmaceutical and cosmetic industries, it is approved by the US Food and Drug Administration (FDA) (Garlotta, 2002). Moreover, PLA is also a promising substitute for conventional polymers, which leads to efforts to use PLA in large volume of applications. To be used as a commodity, lactic acid polymers need to have a high molecular weight and good mechanical properties. PLA, with high molecular weight, has mechanical properties similar to the conventional thermoplastics, like PET, and can find applications in important technological fields, as films for agriculture, fibers for the textile industry, packaging and composites (Bogaert and Coszack, 2000).

However, high molecular weights are difficult to reach, mainly due to the amount of water that is formed during the polymerization and its influence upon reactions´ equilibrium. High molecular weight PLA can be synthesized by two routes: ring opening polymerization (ROP)

* Corresponding author. Tel + 351-239-798793. E-mail:dinam3@eq.uc.pt

of the intermediate lactide or step-growth polymerization, also called polycondensation. The first mechanism is an effective and the most used method, but quite complex and an expensive process (Garlotta, 2002). The latter allows to obtain lactic acid polymers directly from the monomer. However, to obtain high molecular weight polymers, some weaknesses must be overcome. Due to the difficulty in removing water from a highly viscous medium, Ajioka *et al*., 1995*,* developed the polycondensation of lactic acid in solution*.* This method presents disadvantages for the environment, since it uses organic solvents with high boiling point as a reaction medium. However, it has proved to be effective allowing to achieve high molecular weight polymers by continuous removal of water. Nevertheless, other authors that used this technique for lactic acid polymerization were not able to achieve the results reported by Ajioka (Kim *et al*. 2002).

The limitations of the methods mentioned previously support the effort in developing new ways to obtain biodegradable lactic acid based polymers. In this study, the polymerization of lactic acid in solution by a step-growth mechanism has been investigated. Although, this technique is less developed, it is considered to be less complex, and there is room for improving the current reactions´ procedure, in order to reduce some of its disadvantages.

With the purpose to try to understand the relationship between the reaction conditions and the properties of the obtained polymers, these were subject to some characterization techniques: the molecular weight distribution was determined by size exclusion chromatography (SEC) and the stereoregularity was evaluated by optical rotation measurements and ^{1}H NMR spectroscopy.

2 Experimental Section

Reagents

All reagents were ordered from Sigma-Aldrich and used as received. L(+)-lactic acid aqueous solution 80 % was used as monomer and *m*-xylene (96%) was used as solvent. The catalysts tested were: tin (II) chloride dehydrate ($SnCl_2.2H_2O$) (98%), tin (II) octoate (Sn(II)Oct) (98%) and 4-dodecylbenzenesulfonic acid (DBSA) (90%). Molecular sieves, 3 Å beads, 8-12 mesh, absorption capacity of 21%, were used as drying agent.

Polycondensation of Lactic Acid Solution

The polymerization of L-lactic acid solution was carried out using an organic solvent with high boiling point, *m*-xylene, (Ajioka *et al.* 1995). The inicial concentration of monomer aqueous solution in the mixture was 20% (v/v). In a 2 L volume flask, equipped with a Dean-Stark trap and a mechanical stirrer, the reaction began with the distillation of the 80% L-lactic acid aqueous solution. Then, the catalyst was introduced (0.1% mol of catalyst) and the Dean-Stark trap was replaced by a tube packed with molecular sieves used as a drying agent. The polymerization was performed for several hours at the boiling point of the solvent, 140 ºC, using a bath to keep the temperature constant and under inert atmosphere (N_2). When the experiments were performed at reduced pressure, the pressure was decreased step by step till reaching the set-point. A cold trap was placed between the reactor and the vacuum pump to avoid the oil contamination. The final polymer is recovered as a white powder after dissolution in chloroform and precipitation in methanol. Table 1 summarizes the experimental conditions used in this study.

Characterization Techniques

The molecular weight distribution, average molecular weight (Mw) and polydispersity (PD) were determined using the SEC technique (Size Exclusion Chromatography), calibrated with

narrow polystyrene standards. The column set consists of a PL 5µm guard column (50x7.5mm) followed by one MIXED-D PL column (300x7.5mm, 10µm). The HPLC pump was set with a flow rate of 0.6 mL.min^{-1}. The eluent was chloroform and the experiments were carried out at 25 ºC with a sample concentration of ≈2 mg.mL^{-1}. Before the injection (≈100 µL) the samples were filtered through a PTFE membrane with a 0.45 µm pore. After column exclusion, the samples were analysed in a evaporative light scatttering detector, PL-EMD 960.

The ^{1}H NMR spectrum were recorded on a Varian 500-MHz spectrometer at 25 ºC, using CDCl3 as solvent containing 1% (v/v) of tetramethylsilane as an internal standard.

The specific rotation of lactic acid polymers $[\alpha]_{\lambda}^{T}$, was measured on a Optical Activity AA-5 electrical polarimeter at 25ºC, with a wavelenght of 589 nm and a concentration of 0.1 g.mL^{-1} in chloroform. The percentage of optical purity of lactic acid polymers (*OP%*) was calculated using the following relationship: $OP\% = [\alpha]_{589}^{25} / -156 \times 100$. Where -156 degree is the specific rotation of PLA with only L stereoisomer in its composition.

Table1: Operating conditions used in the experimental study and results.

Sample	Catalyst	Pres. set-point [bar]	Time [h]	Mw [g.mol^{-1}]	PD	OP [%]
PLA1	$SnCl_2.2H_2O$	1	30	3 163	1.5	83

3 Results and Discussion

Oligomerization

The reaction begins with the thermal dehydration of the initial 80% (v/v) lactic acid aqueous solution. At the end of the destillation the mixture has oligomers with a small polymerization degree. Fig. 1 shows a typical molecular weight distribution of the oligomers at the end of the destillation, oligomer4, and the final polymer at the end of polymerization, PLA4 (See Table 1 for polymer specifications). Unfortunately, due to the calibration restrictions, it is not feasible to use the SEC technique to determine the polymerization degree, neither the average molecular weight of these oligomers.

The initial lactic acid solution contains a carboxyl and an hydroxyl group resulting in a high polarity of the initial reaction mixture. The polarity of the medium decreases significantly with monomer convertion to the small oligomers during the initial thermal dehydration, which is self-catalysed by the carboxyl group of the monomer. The decrease in lactic acid concentration is followed by a decrease in the total amount of the carboxyl groups and a reduction on the reaction rate. As the self-catalysis by the carboxyl group does not allow reaching high molecular weight polymers a catalyst is added at the end of oligomerization. These results are confirmed by Moon *et al*. 2000, who reported that the polarity change can alter the catalyst activity.

Policondensation

The polymerization of lactic acid oligomers by step-growth was carried out under different reaction conditions and different strategies to remove the water from the reaction medium were explored. The polymerization was improved by screening catalyts and studying the influence of process variables on the quality of the final polymer. The results obtained are shown in Table 1. It is well-known that, for commodity aplications, PLA should have high molecular weight and high stereoregurarity (Garlotta, 2002). As these influence the mechanical properties, the crystallinity and the degradation rate, molecular weight and stereoregularity should be carefully controled to achieve polymers with required properties. Therefore, these two parameters were used for characterization.

Figure 2 shows the ^{1}H NMR spectrum of PLA1 (See Table 1 for polymer specifications). The bands at 1.6 and 5.2 ppm are due to the $-CH_3$ and $-CH$ groups present in PLA, thus confirming the synthesis of the desired polymer. The band at 7.3 ppm refers to the solvent used in the analysis, $CDCl_3$.

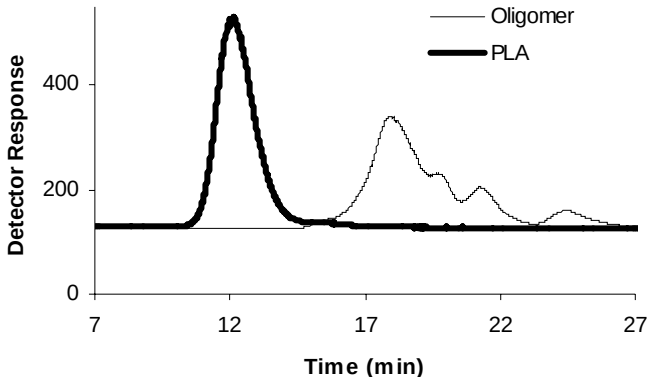

Figure 1: SEC curves for the oligomer4 and PLA4.

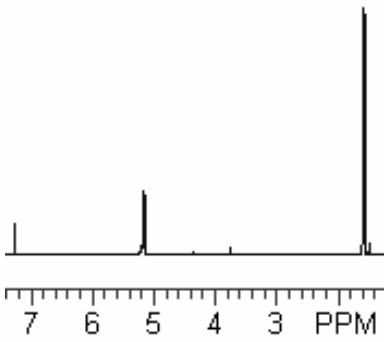

Figure 2: ^{1}H NMR spectrum for PLA1 in $CDCl_3$ at 500 MHz.

To control the water content in the reacting mixture, different procedures were applyied to the polymeric samples listed in Table 1. The water is a product of the esterification reaction (scheme A in Fig. 3). PLA1 was obtained at atmospheric pressure and during reaction the condensed water was not removed. The SEC curve (not here shown) indicates a low average molecular weight. In order to remove the water, in the second experiment, PLA2 (Table 1), a different approach was implemented. In this experiment, prior to condensation, the solvent vapour containing the condensed water passed through a tube packed with molecular sieves used as drying agent. This approach allowed a considerable increase on the final molecular weight, however, not reaching the target values. Thus, to facilitate water absorption by the drying agent, during the following experiments the pressure in the reactor was slowly decreased leading to high molecular weight polymers, PLA3, 4 and 5 (Table 1).

It is well known that esterifications are slow reactions and to increase the reaction rate a catalyst is required (Moon *et al*. 2000). Protonic acids, like H_2SO_4 or H_3PO_3, are usually used as catalysts. However, metal ions, as Lewis acids, can be more efficient for typical hydrogen ions (Roger and Long, 2003). The data in Table 1 show that the catalysts play a great influence on the molecular weight and optical purity of the final product. For the samples under analysis, the optical purity of the final product (polymer) decreased compared with that of the reagent (monomer), suggesting some racemization reactions. Moreover, the polymers obtained at reduced pressure show an optical purity that is drastically lower than those obtained at atmosferic pressure. Most probably, this is due to a small leak that disabled inertization, therefore allowing ester interchange reactions.

Tin (II) chloride dehydrate, $SnCl_2.2H_2O$, enabled achieving the highest molecular weight, near 45 000 $g.mol^{-1}$. It is a strong Lewis acid and largely used in direct polycondensation of lactic acid due to it high catalytic activity, although some ester interchange reactions have been reported (Hiltunen *et al.* 1997).

The mostly used catalyst in the lactide polymerization is tin (II) octoate, a strong Lewis acid, but the results show that it is not as efficient as tin (II) chloride dehydrate (Table 1). Concerning to the optical purity measured (0%) one can say that it proved to be a strong ester interchange catalyst promoting racemization reactions (Fig. 3 scheme C), *i.e.*, the PLA4 polymer has the same amount of L and D estereoisomers in the polymer chain.

The 4-dodecylbenzenesulfonic acid, DBSA, is a weak protonic acid with poor results in terms of molecular weight. However, it can be very efficient in terms of the polymer stereoregularity control (Table 1).

Other catalysts such as dibutyltin dilaurate, DBTL, and titanium (IV) butoxide were tested but the results were not encouraging.

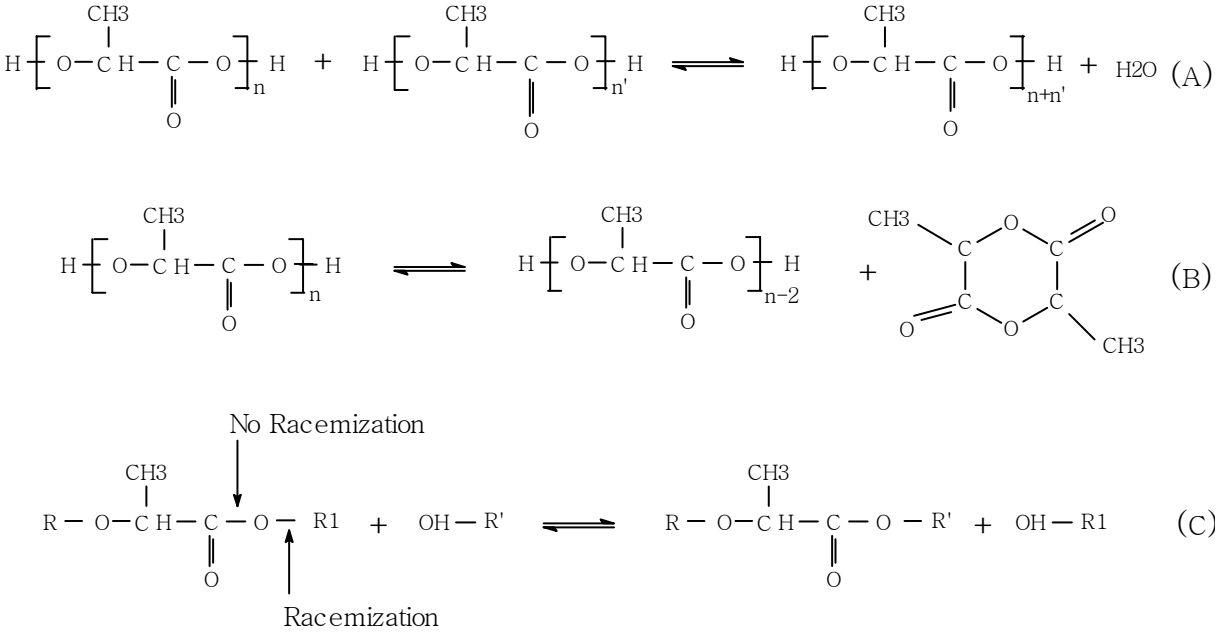

Figure 3: Reactions during lactic acid polycondensation: a) Dehydration, b) Ring-Chain c)Transesterification.

Reactions

The lactic acid polymerization by step-growth is an equilibrium system involving several reactions, the most important are represented in Fig. 3. Dehydration equilibrium, Fig. 3 A, is the most important reaction for attaining high molecular weight polymers. Lactic acid is an alpha-hydroxy acid, it has two functional groups, that reacts with himself by the condensation, realesing a water molecule. Efficient removal of the condensed water becomes the key point to obtaining high molecular weight polymers.

The ring-chain equilibrium, Fig. 3 B, involves the depolymerization of PLA into lactide. Under ideal reaction conditions, high temperature and high vacuum, the evaporation of lactide is favoured. However, with the use of organic solvents, the lactide is reintroduced into the reaction mixture and the depolymerization equilibrium is well controled.

Transesterification is a dynamic equilibrium of ester interchange reactions occurring between the polymer chains. These reactions can explain the introduction of D-lactyl units in the polymer chain. During the ester interchange reactions there are two ways in which ester linkage can cleave, Fig. 3 C. One is acyl-oxygen cleavage, which does not involve the chiral

carbon. The other is alkyl-oxygen cleavage, in which the covalent bond between oxygen and the chiral carbon breaks and subsequently reforms, this results in an inversion of the conformation and a decrease in optical purity (Hiltunen *et al*. 1997). The optical purity results, Table 1, indicate undoubtedly the racemization reactions occurence. According to the data analysis, racemization reactions are dependent on the reaction conditions and, mainly, on the catalyst used.

4 Conclusion

PLA polymer was successfully produced by direct condensation using a solvent with high boiling point to facilitate the continuous removal of water, a reaction side product, therefore increasing the extent of the polymerization reaction. The use of a drying agent combined with reduced pressure enabled to further improve the efficiency in water removal. This polymerization method allowed to obtain high molecular weight PLA in one single step, instead of the three steps required by the ROP method. From the economic point of view, it is of best interest to develop an efficient, effective and less expensive method to produce a promising polymer, Poly(lactic acid).

The change of L-lactyl units to D-lactyl units, suported by the optical results, is a major problem in PLA synthesis by polycondensation. Its control is essential and can be attained by a suitable catalyst. Protonic acids seem to be the best catalysts in order to avoid racemization reaction, therefore improving the optical purity of the polymer. More research work needs to be carried out to find the best catalyst to provide an enhanced molecular weight and a lower racemization extent.

Abstract

Plastics represent one of the most important contemporary materials. Their features, easy workability and price far exceed classicality of metal, wood, glass etc. However, the long decomposition period of some polymeric materials as well as growing scores of plastic waste make a considerable problem. One of the possible solutions is development and production of biodegradable polymers which are more rapidly decomposed in biotic environment and thereby eliminated. Good examples of biodegradable materials are wraps, compostable bio-waste bags, agricultural mulch foils and protective painting and others.

Poly (vinyl)alkohol (PVAL) is considered to be relatively well biodegradable polymer. Hydrophile feature of PVAL makes its decomposition easier by using microorganisms but limits its range for practice application and that is why the PVAL is modified. Polymeric materials of biologic origin (biopolymers), for example proteins (colagen, protein hydrolyzate), polysacharides (starch), polyesters (e.g. poly-3-hydroxybutyrate, PHB) are often used for the purpose of modification. It is possible to use additives of extracellular polysacharides type such as Dextran, Xanthan and Gellan which are the most remarkable agents. These polysacharides can be added to the mixed polymers for the purpose of the increasing and accelerating of their biodegradability. Required feature low price can be limited factors.

The aim of the study was to review the impact of different Xanthan and Gellan proportion to biodegradability in soil environment of their mixtures with polyvinylalcohol (PVAL) and glycerol, with regard to mechanical properties of the mixtures (tensile stengh, fracture strain). Tested mixed granulates containing 10.5 %, 21 % and 42 % of Xanthan or Gellan were prepared on twin-screw thread extruder LABtech.

The tensile strengh of the mixtures was decreasing with increasing polysacharides content, in the tested range within cca 20 %, whereas the Gellan mixtures constantly showed lower values than Xanthan ones. The strain decreasing was more evident - between first two samples at cca 30 %, by the last mixtures (containing 42 % of polysacharides) the values approximated to zero. Obviously, the reaching of aplicable physicomechanical features will be compromising but eventually hardly achieved.

Mixed granulates biodegradation in soil environment was tested under aerobic conditions in reaction flasks [1,2]. The CO_2 production via gas – chromatography together with O_2 usage for aerobic conditions keeping control was monitored during all tests.

According to DCO_{2max} level of biodegradation, all the polymeric mixtures appeared as hardly degradable in the soil environment. The mixed granulate N/68/107 containing 10.5 % of

Gellan degraded the worst of all the set, respectively only of 17.9 %. Mixed granulates N/68/108 (21 % of Gellan) and N/68/109 (42 % of Gellan) degraded of 35.9 % and 39.6 %. Granulates N/68/110 (10.5 % of Xanthan), N/68/111 (21 % of Xanthan) and N/68/112 (42 % of Xanthan) degraded of 21.2%, 45.2% and 47.3%. These results showed that the polymeric mixtures containing Xanthan were better degradable than mixtures containing Gellan. It means that the kind and amount of used polysacharide had a significant effect over the biodegradation of polymeric mixtures but the biodegradability of PVAL itself was not influenced. The level of biodegradation was approximately in relation with content of degradable components (PVAL and glycerol).

1 Introduction

Development of new biodegradable polymeric materials, materials of shortened life, is an alternative in preventing “contamination” of the environment with non-degradable synthetic substances. A convenient solution may be in combining synthetic polymers with natural degradable polymers, for example, poly (vinyl)alcohol (PVAL) with current bacterial polysaccharides Xanthan and Gellan, assuming, of course, that required useful properties of the blends are met. Biodegradability of the substances themselves are by and large known [3,4,5], however, properties of their blends have been studied but very sporadically.

The concept of biodegradability is highly relative, depending on a whole number of factors and conditions under which the breakdown is studied. Action of the mentioned conditions and factors depends on where the polymeric products are degraded, whether in soil, natural water, biological treatment plant or in compost. In biodegradation testing, therefore, environmental conditions, if possible, should be kept standard and comparable to secure reliability and reproducibility of measured results.

Laboratory tests in a soil environment under aerobic conditions are affected by a whole number of factors: composition and structure of soil, particle size, soil origin (affecting occurrence and type of micro-organism settlement), also temperature (optimum for growth of soil micro-organisms is 25 – 27 ^{o}C), pH (5.5 - 6.5), moisture (50 – 70 %), aeration, presence of nutrients (C/N ratio within limits 10:1-40:1). The ratio of sample to soil substrate is also important – ISO standard 17556 [6] recommends ratio 1:1000. Duration of soil tests is highly variable – from 45 days to 6 months. The biodegradation progress may be assessed through changes of gaseous phase in an enclosed testing system [7] or through decrements in weight of tested samples – so-called burial tests [8]. Microbiological analysis may be a complementary criterion to these tests.

2 Experimental

Biological material

Soil substrates – mixtures of three soils – two kinds of commercial soils (garden substrate and grave substrate by the AGRO CS Co) and natural soil (taken at Holešov, Czech), ratio 2:1:1 (related to dry matter). Preparation was performed in accordance with ISO 17556 [6]. Soil substrates were kept at constant temperature 5 ^{o}C. Prior to test, soil substrate was disposed of coarse impurities by sieving through screen of approx. 5 mm mesh, dry matter was determined and basic analyses performed – pH 6.20, ignition loss 79.52 %, N content 0.5 %, P content 0.11 - 0.22 %, and TC 32.9 %.

Inert material

Material employed as inert was a product under trade name AGROPERLIT (hereafter Perlit, by AGRO CS Co). Perlit is an expanded volcanic rock. The mixture dosed into test bottles was soil/Perlit in a 1:1 ratio (related to soil dry matter). Perlit properties declared by manufacturer: water content max. 2.0 %, pH 6.0 - 7.5, particle size < 0.3 mm content max. 15%, < 1 mm max. 25 %, 1.0-4.0 mm max. 75 %, bulk density 200 kg m^{-3}.

Tested samples

Preparation and composition of blends

Samples based on PVAL, glycerol and bacterial exopolysaccharides Gellan and Xanthan were prepared at the Department of Rubber and Plastics, Chemical and Technological Faculty of Slovak Technical University in Bratislava, Slovakia. Preparation of samples on a twin-screw LABtech extruder was performed under thermal profile (feed hopper-extrusion head) 120/130/140/150/160/170/180/190/160/150 ^{o}C and 300 rpm. Blends containing Xanthan displayed processing properties superior to Gellan. Blend composition is presented in Tab.I.

Tab I.: Characteristics of polymeric blends

Sample	PVAL [%]	Saccharide [%]	GLY [%]	GLY v TPS	GLY v PVAL	Type of saccharide
N/68/107	74,8	10,5	14,7	4,5%	10,2%	GELLAN
N/68/108	61,6	21	17,4	9%	8,4%	
N/68/109	32,8	42	25,2	18%	7,2%	
N/68/110	74,8	10,5	14,7	4,5%	10,2%	XANTHAN
N/68/111	61,6	21	17,4	9%	8,4%	
N/68/112	32,8	42	25,2	18%	7,2%

Determining biodegradability

Soil tests were conducted according to own procedure, but reflecting requirements of standard ISO 17556 [6]. Quantities investigated were produced CO_2 and decrease in O_2 by means of gas chromatography. The tested sample served as sole external source of carbon and energy for soil micro-organisms. Biodegradation tests in all cases were carried out in gas-tight reaction bottles of approx. 1140 ml total volume [2,9].

At beginning of test, actual gaseous volume V_g of test bottles (around 980 ml) was determined. In all cases, soil substrate + Perlit (1:1) was dosed into test bottles, solutions of ammonium sulphate and sodium hydrogen phosphate (ratio C:N:P approx. 100:10:1) were added, water content in mixture was adapted to 50 % and tested samples were added (thoroughly “mixed in”). Bottles were enclosed gas-tight and incubated at 25^{o}C without access of light. Aeration frequency was based on performed analyses so that oxygen concentration would not go below approx. 6 % volume (1 to 2 weekly). Air for aerating bottles was disposed of CO_2 by washing in NaOH solution. Water content in blends was checked by gravimetry (weighing whole bottles) and kept at an approx. 50 % level.

Analysis of CO_2 and O_2 by gas chromatography

Gas-chromatographic analysis of CO_2 and O_2 on gas chromatograph was described in our other work [2,9].

Processing results

Daily and cumulated production of CO_2 were calculated, together with percentage of substrate removal

DCO_2 (actually produced quantity of CO_2 as related to theoretically producible quantity). Biodegradation dependencies were calculated by applying 1st-order kinetics. Description given in [2,9].

3 Results and discussion

Mechanical properties of samples

Specimens for determining mechanical properties were cut from strips prepared on a single-screw extruder (see Preparation and composition of blends). Mechanical properties were measured on Metrotest 5kN apparatus according to STN ISO 527 at jaw speed 1 mm/min in strain range 0-3 %, and 50 mm/min in strain range > 3 %, at room temperature. The working part of specimen was 10mm.

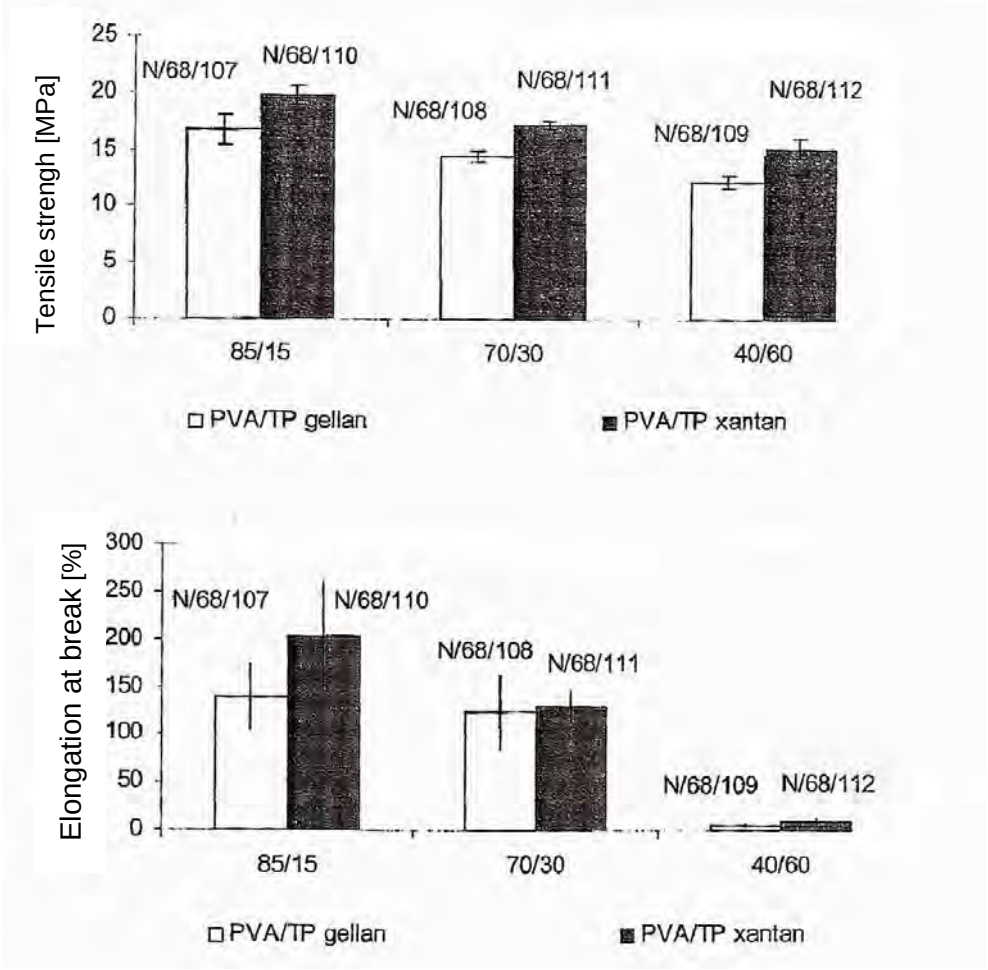

Fig. 1: Mechanical properties of samples

Blends containing Xanthan exhibited higher stress and strain values than blends containing Gellan. Tensile strength decreased with increasing concentration of polysaccharides, approx. 25 % for both sample series. The decrease in strain values was far more obvious, in the given series almost down to zero (blends with approx. 42 % Xanthan or Gellan), to practically inadmissible values.

Evaluation of soil test

Samples N/68/107 to N/68/109 contained polysaccharide Gellan and differed in percentual content of particular components in the blend, the same as samples N/68/110 to N/68/112 containing polysaccharide Xanthan. Duration of the test was 1145 hours (almost 48 days). Cumulative CO_2 production was calculated from read-off data together with percentage of substrate removal DCO_2. Dependencies were processed by formal 1st-order kinetics.

Figure 2 presents the biodegradation course of sample N/68/109 as an example.

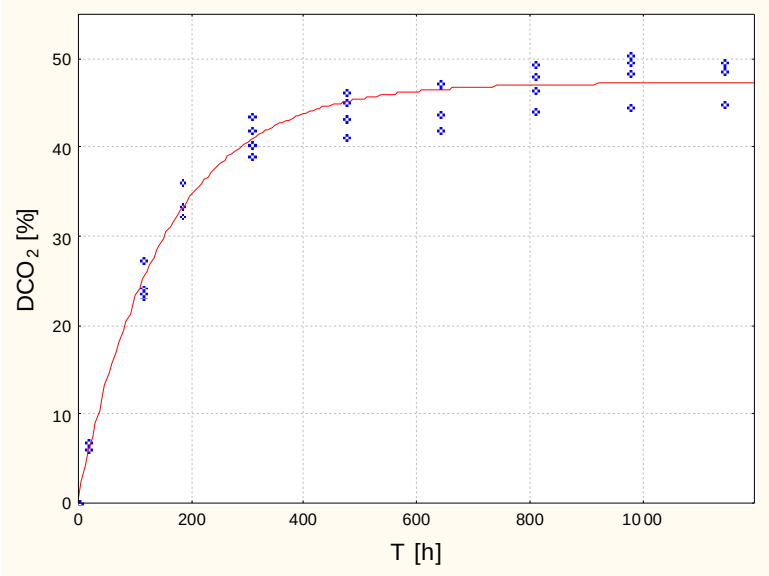

Fig.2: The biodegradation course of sample N/68/109

Viewed from CO_2 production, all tested samples appeared as poorly degradable, which followed from values of DCO_2max and from the graph spanning DCO_2max values (Fig.3). Sample N/68/107 with lowest Gellan content (10.5%) degraded worst and that by merely 17.86%. Sample N/68/109, containing four times more Gellan, degraded by 39.61%. The most readily degradable sample of the series, N/68/112 containing 42% Xanthan, degraded by 47.28%, sample N/68/110 containing 10.5% Xanthan degraded by only 21.21%. From the graphs above it is obvious that samples containing Xanthan were more readily degradable than samples containing Gellan.

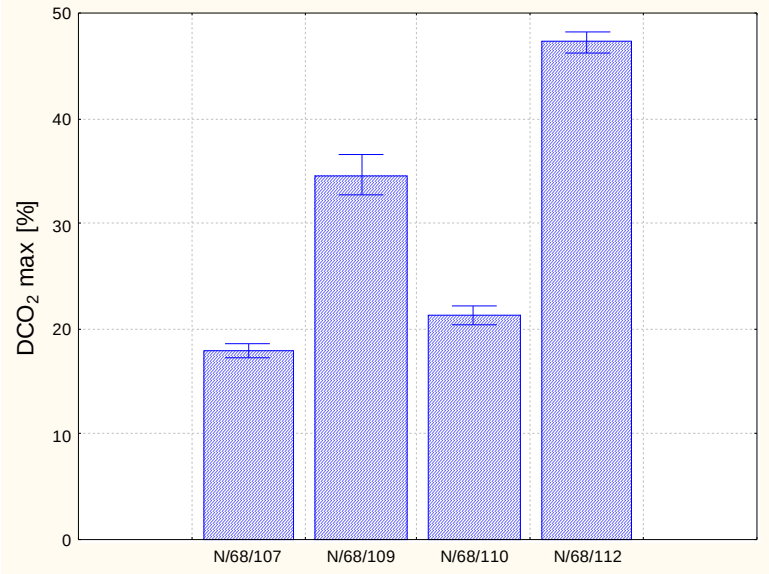

Fig.3: Blends DCO_2 values

The presented facts allow to admit that blends of given composition fail to meet the good biodegradability as required, levels of DCO_2max do not attain even 50 %. A greater addition of polysaccharide improves total degradability, which, however, is in no relation to addition volume.

4 Conclusion

The objective of this work was to evaluate biodegradability of a blend of poly (vinyl)alcohol (PVAL) with variable content of polysaccharides Xanthan and Gellan and glycerol in a soil environment, with respect to mechanical properties of the blend (tensile strength, elongation at break). Assessing biodegradability employed the so-called "bottle" test with a final determination employing gas chromatography for monitoring production of CO_2, which was designed and verified at our laboratory [2].

Based on test results, we may state the type as well as quantity of polysaccharide exerted significant influence on biodegradability and mechanical properties of investigated samples. Blends containing Xanthan exhibited superior mechanical properties and also degraded to greater extent than blends with Gellan. Despite that, from the viewpoint of CO_2 production, tested samples were poorly degradable in a soil environment and only the blend with highest Xanthan content approached 50% degradability. The "bottle" test turned out to be rather "comfortable" and offered credible results.
