PROCEEDINGS OF THE
10TH INTERNATIONAL CHEMICAL AND
BIOLOGICAL ENGINEERING CONFERENCE
CHEMPOR 2008

PROCEEDINGS OF THE
10TH INTERNATIONAL CHEMICAL AND BIOLOGICAL ENGINEERING CONFERENCE - CHEMPOR 2008

4-6 SEPTEMBER 2008, BRAGA, PORTUGAL

ORGANIZED BY

UNIVERSIDADE DO MINHO

ORDEM DOS ENGENHEIROS

INSTITUTE FOR BIOTECHNOLOGY AND BIOENGINEERING

SUPPORT

SOCIEDADE PORTUGUESA DE QUÍMICA

SOCIEDADE PORTUGUESA DE BIOTECNOLOGIA

EDITED BY

EUGÉNIO C. FERREIRA

MANUEL MOTA

UNIVERSIDADE DO MINHO, DEPARTAMENT OF BIOLOGICAL ENGINEERING

BRAGA, PORTUGAL

This volume contains full papers presented at the 10th International Chemical and Biological Engineering Conference - CHEMPOR 2008, held in Braga, Portugal, between September 4th and 6th, 2008.

Title: **Proceedings of the 10th International Chemical and Biological Engineering Conference - CHEMPOR 2008 (CD-ROM)**

Edited by **Eugénio C. Ferreira** and **Manuel Mota**

First edition August 2008

ISBN: 978-972-97810-3-2

Tiragem: 1000 exemplares

CD-ROM cover design: Helena Martins www. helenamartinsdesign.com

Publisher:

Universidade do Minho, Departamento de Engenharia Biológica

Campus de Gualtar, 4700 Braga, Portugal

Printed by:

MediaPromo - www.mediapromo.com

This publication was sponsored by:

FCT Fundação para a Ciência e a Tecnologia

MINISTÉRIO DA CIÊNCIA, TECNOLOGIA E ENSINO SUPERIOR

Foreword

This digital book contains the full papers presented at the 10th International Chemical and Biological Engineering Conference - CHEMPOR 2008, held in Braga, Portugal, over 3 days, from the 4th to the 6th of September, 2008. Previous editions took place in Lisboa (1975, 1889, 1998), Braga (1978), Póvoa de Varzim (1981), Coimbra (1985, 2005), Porto (1993), and Aveiro (2001).

The conference was jointly organized by the University of Minho, "Ordem dos Engenheiros", and the IBB - Institute for Biotechnology and Bioengineering with the usual support of the "Sociedade Portuguesa de Química" and, by the first time, of the "Sociedade Portuguesa de Biotecnologia".

Thirty years elapsed since CHEMPOR was held at the University of Minho, organized by T.R. Bott, D. Allen, A. Bridgwater, J.J.B. Romero, L.J.S. Soares and J.D.R.S. Pinheiro. We are fortunate to have Profs. Bott, Soares and Pinheiro in the Honor Committee of this 10th edition, under the high Patronage of his Excellency the President of the Portuguese Republic, Prof. Aníbal Cavaco Silva. The opening ceremony will confer Prof. Bott with a "Long Term Achievement" award acknowledging the important contribution Prof. Bott brought along more than 30 years to the development of the Chemical Engineering Science, to the launch of CHEMPOR series and specially to the University of Minho. Prof. Bott's inaugural lecture will address the importance of effective energy management in processing operations, particularly in the effectiveness of heat recovery and the associated reduction in greenhouse gas emission from combustion processes.
The CHEMPOR series traditionally brings together both young and established researchers and end users to discuss recent developments in different areas of Chemical Engineering. The scope of this edition is broadening out by including the Biological Engineering research. One of the major core areas of the conference program is life quality, due to the importance that Chemical and Biological Engineering plays in this area. "Integration of Life Sciences & Engineering" and "Sustainable Process-Product Development through Green Chemistry" are two of the leading themes with papers addressing such important issues. This is complemented with additional leading themes including "Advancing the Chemical and Biological Engineering Fundamentals", "Multi-Scale and/or Multi-Disciplinary Approach to Process-Product Innovation", "Systematic Methods and Tools for Managing the Complexity", and "Educating Chemical and Biological Engineers for Coming Challenges" which define the full papers arrangements along this book.

A total of 516 extended abstracts are included in the Abstract Book, consisting of 7 invited lecturers, 15 keynote, 105 short oral presentations given in 5 parallel sessions, along with 6 slots for viewing 389 poster presentations. This companion CD-ROM contains the Proceedings with 384 full papers. All extended abstracts have been reviewed and we are grateful to the members of scientific and organizing committees for their evaluations. It was an intensive task since 610 submitted abstracts from 45 countries were received.

It has been an honor for us to contribute to setting up CHEMPOR 2008 during almost two years. We wish to thank the authors who have contributed to yield a high scientific standard to the program. We are thankful to the sponsors who have contributed decisively to this event. We also extend our gratefulness to all those who, through their dedicated efforts, have assisted us in this task.

On behalf of the Scientific and Organizing Committees we wish you that together with an interesting reading, the scientific program and the social moments organized will be memorable for all.

Braga, September 2008

Eugénio C. Ferreira

Manuel Mota

Committee Members

Honor Committee:
Under the high Patronage of his Excellency the President of the Portuguese Republic, Prof. Aníbal Cavaco Silva.

Members:
Ministro da Ciência, Tecnologia e Ensino Superior, Prof. Doutor José Mariano Gago
Secretário de Estado Adjunto, da Indústria e da Inovação, Prof. Doutor António Castro Guerra
Bastonário da Ordem dos Engenheiros, Engº Fernando Santo
Reitor da Universidade do Minho, Prof. Doutor António Guimarães Rodrigues
Presidente da Câmara Municipal de Braga, Engº Francisco Mesquita Machado
Governador Civil do Distrito de Braga, Dr. Fernando Moniz
Presidente da Fundação para a Ciência e a Tecnologia, Prof. Doutor João Sentieiro
Presidente da Sociedade Portuguesa de Química, Prof. Doutor José Luís Figueiredo
Presidente da Sociedade Portuguesa de Biotecnologia, Prof. Doutor F. Xavier Malcata
Presidente da Escola de Engenharia da Universidade do Minho, Prof. Doutor António Cunha
Prof. Doutor T. Reg. Bott (Univ. Birmingham)
Prof. Doutor João de Deus Pinheiro (Univ. Minho)
Prof. Doutor Luís J. Soares (Univ. Minho)

Scientific Committee:
President: Manuel Mota (Univ. Minho)

Members:
C. Bernardo (Univ. Minho)
J.C. Bordado (IST-UTL)
M. Carrondo (UNL)
C. Costa (Univ. Porto)
J. Coutinho (Univ. Aveiro)
J. P. G. Crespo (UNL)
J. J. C. Cruz Pinto (Univ. Aveiro)
E. C. Ferreira (Univ. Minho)
S. Feyo de Azevedo (Univ. Porto)
M. M. Figueiredo (Univ. Coimbra)
M. H. Gil (Univ. Coimbra)
J. Lafuente (Univ. Aut. Barcelona)
J. Lema (Univ. Santiago de Compostela)
F. Lemos (IST-UTL)
L. Q. Lobo (Univ. Coimbra)
F.X. Malcata (Univ. Católica)
L. Melo (Univ. Porto)
A. Q. Novais (INETI)
M. Nunes da Ponte (UNL)
R. Oliveira (Univ. Minho)
C. Pedro Nunes (IST-UTL)
F. Ramôa Ribeiro (IST-UTL)
A. E. Rodrigues (Univ. Porto)
R. Salcedo (Univ. Porto)
J. Sampaio Cabral (IST-UTL)
P. Saraiva (Univ. Coimbra)
R. Simões (UBI)
L. Sousa Lobo (UNL)
J. A. Teixeira (Univ. Minho)

Organizing Committee:
President: Eugénio C. Ferreira (Univ. Minho & Ordem dos Engenheiros)

Members:
M. Alves (Univ. Minho)
J. Azeredo (Univ. Minho)
I. Belo (Univ. Minho)
J. C. Bordado (Ordem dos Engenheiros)
J. M. Costa Reis (Soc. Portuguesa Química)
L. Domingues (Univ. Minho)
C. Gaudêncio (Ordem dos Engenheiros)
M. Henriques (Univ. Minho)
A. S. Pinheiro (Ordem dos Engenheiros)
I. Rocha (Univ. Minho)
L. Rodrigues (Univ. Minho)
T. Tavares (Univ. Minho)
A. Venâncio (Univ. Minho)
A. Vicente (Univ. Minho)

Keywords: Chemical Engineering, Food, Water, Waste, Energy, Biofuels, Hydrogen.
Topic: Invited Lecture

Abstract

The first Chempor Conference held in Lisbon in 1975 under the auspices of the Calouste Gulbenkian Foundation, heralded a regular wide-ranging review of research and development in Portugal and the U.K. Progressively in later years the Conferences have attracted contributions from other European countries and indeed further afield. There is an increasing awareness of the problems for the environment, notably global warming, brought about by human activities. Recent predictions about the future are dire, particularly regarding food and water for a rapidly growing world population. They represent a substantial challenge to the scientific and technical fraternity. In response to that challenge it is important to keep up to date with technical developments, to meet and keep in touch with co - workers in associated fields, and to cooperate wherever possible. The papers presented at the Chempor and other conferences have made and continue to make, a significant contribution to that objective of meeting the challenge.

1 Introduction

For thousands of years humanity has had to cope and come to terms with the challenges of starvation, disease and conflict. There have been some useful developments over the years in food production (particularly the so called “Green Revolution” in the ‘60s) and in medicine. Sadly though the establishment of universal peace seems as distant as ever. Despite the strides in agriculture and disease control, the basic needs have not been made for a large proportion of the world population. With the anticipated dramatic rise in the world population in the coming decades, estimated to be at around eleven billion in 2050, the problems of food production and medical care will become even more intense, unless effective action is taken. The provision of clean water for human consumption is also of vital importance in the suppression of disease. Technology has a responsive role to play in meeting this challenge.

In addition to these basic needs of humanity, energy has played an important part in the lives of many members of the human family since the Industrial Revolution, not least in food production but also in aspects of disease control and particularly in the field of transportation. In previous millennia, energy primarily required for food production, was provided either by human or animal power. The phenomenal growth in energy usage generally provided by the heat of combustion of fossil fuels (coal and oil) or other combustible, usually carbonaceous, material, has led to the discharge of vast quantities of products from the combustion process, notably carbon dioxide. Although there are dissenters, it is believed by the majority of the informed, that the random discharge of these so-called greenhouse gases to the atmosphere is leading to the phenomenon of global warming, bringing in turn changes to the climate. Additional problems associated with industrialisation and a higher standard of living is waste disposal and satisfactory sanitation.

In a U.K. government document (a summary of a White Paper) entitled, “This Common Inheritance” (HMSO, 1990) the following points were made; Mankind long believed that, whatever we did, the earth would remain much the same. We now know that this

is untrue. The ways we produce everything and the rate at which we multiply, use natural resources and produce waste, threatens to make fundamental changes in the world environment. Nature is under threat. We have a moral duty to look after our planet and hand it on in good order for future generations. That does not mean trying to halt economic growth. We need growth to give the opportunity to live better and healthier lives.

In recent years, though, the issue of climate change has been paramount in the United Nations, the European Union and individual nations, and various summit gatherings. The Kyoto agreement in 1997 pledged to cut the emission of greenhouse gases principally CO_2 by 12.5 % (based on 1990 levels) by 2010. At a recent G8 summit (July 2008) a target of achieving 50% reduction in global emissions by 2050 was suggested. In December, 2007, 15,000 people flew to Bali to discuss climate change (Campbell, 2008). It was the intention to build on the achievements of the Kyoto agreement and it was considered to be a success with a continuation of the dialogue begun at Kyoto.

The European Union environmental legislation (Integrated Pollution Prevention and Control – IPPC) applies separately to different aspects of the natural environment – air, water, waste and so on. Porteous (2008) states that the IPPC Directive, based mainly on U.K. law, requires major industrial installations to be licensed in an integrated way for controlling emissions to air and water and the management of waste to protect the environment as a whole. The approach encourages industrialists to think about the whole process adopting cleaner technology rather than just adding “end of pipe” controls

2 Food Production

One of the major problems of attempting to increase food production to satisfy the growing world population is land use, and land availability. Tropical rainforests are constantly burnt and wetlands drained to provide land for agriculture – growing crops and rearing animals as sources of food. The use of land for raising sheep and cattle for food however, is not considered by many as an efficient use of that land. The opportunity of growing two crops per year of edible foods is much more attractive in the light of the growing number of mouths to feed in the world. Together with pollution of water courses and overfishing, many species of wild plants and creatures are being driven to extinction. As a result valuable sources of food and medicine are lost. The alternative is to improve the output from existing agricultural land, which may be substantially achieved by the application of artificial fertilisers and use of herbicides and insecticides with special safeguards. A recent discourse (McClafferty and Islam, 2008) emphasised that billions of people worldwide suffer from “hidden hunger”, an insidious form of malnutrition, that can leave children stunted, immune systems compromised and adults unable to work effectively. The condition results from micronutrient malnutrition caused by their lack in the diet. The poor in developing countries who live mostly in rural areas, depend largely on locally grown staple foods like rice,wheat and corn to satisfy hunger but provide insufficient nutrition. A world wide organisation “Harvestplus” is dedicated to the development of micronutrient rich staple foods that rural populations can grow and consume. In order to provide the necessary content of iron, zinc and vitimin A suitable low cost fertilisers will be required on a large scale.

3 Water

As important as food if not more important in many ways, is the availability of clean water. Water supplies around the world are heading towards crisis point. Experts are predicting large-scale water shortages over the next 25 years. It is anticipated that two out of three people on the planet will face regular depletion of water supplies. Population increase and rising standards of living, together with pollution, are rapidly diminishing the availability of naturally occurring sources of clean water. Water related

diseases, such as diarrhoea, cholera, tachoma, hepatitis and intestinal worms afflict millions of people worldwide. Approximately 1.8 million people die each year from diarrhoeal diseases alone,90% of whom are children under the age of five (Laursen,W., 2007). Many pathogens excreted by humans and animals can cause these diseases when they are ingested via faeces-contaminated drinking water. These pathogens, and other contaminants can be physically removed by filtering, adsorption or sedimentation, and they can be rendered innocuous by chemical, heat or u.v treatment.

In developed countries the potable water supply is carefully protected from contamination. In the E.U. for instance,there are stringent requirements for water quality to safeguard the health of people in respect of micro organisms and toxic substances. The water origin is usually rivers or it may be obtained from boreholes in suitable locations tapping into aquifers. In addtion to serving the public, water has many industrial uses such as a medium for conveyance of wastes, slurries.and wood pulp, as a solvent and as a heat transfer medium principally through vapour (steam), or cooling

Where sea water is available, desalination becomes a possiblity. In multi-stage evaporation there are implications for energy use and its associations with global warming. An alternative is the application of reverse osmosis. Kowtsakos(2008) states that there are not enough chemical engineers employed in this industry.

The disposal of waste water from public sewage systems and industrial use, also requires stringent controls, since it is often returned to its source. It has been said that the water in the River Thames is used ten times over in its journey from its source to the sea! In the methods available for the treatment of water the application of physical forces predominate, (well known to chemical engineers). In general terms there are three stages. In the treatment of waste water particularly, the primary treatment involves physical operations such as screening and sedimentation that are used to remove the floating and settleable solids from the water. Secondary treatment involves biological and chemical processes to remove organic matter. A final treatment is applied to remove any trace constituants that still remain in the water.

Filtration is widely used for the preparation of public water supplies - including traditional sand filtration and membrane fitration, that have application outside the water industry such as solvent recovery and the production of potable water from sea water. Papers presented at the Chempor Conference in 1975, described the disinfection of water in the 1974 epidemic of cholera (Lobato de Faria) and water demineralisation (Rodriques and Tondeur).

4 Waste Disposal

Substantial industrialisation and improved standards of living, have given rise to the production of waste materials of one sort or another, from manufacturing to domestic and retail outlets. It is usual to classify waste disposal into three categories; landfill. incineration and recycling. Landfill is subject to tight scrutiny because of the risks to public health.through the contamination of ground water.Disposal at sea, consisting of long term persistent noxious substances with a lowering of the amenity of an area due to smell visual degradation and possibly noise, is also not readily acceptable. Flamable waste incineration particularly domestic waste, has been practiced for many years. Because of the problem of emissions notably CO_2 , the technique has come under critical assessment.

The best option is to recycle but this is no easy option because there is likely to be a mixture of components that may need separation,which can be labour intensive.In order to overcome some of these difficulties it might be possible to recycle in a different way; by the incorporation of say,plastics and broken bottles in building materials for

instance. At the first Chempor Conference in 1975, Bridgewater presented a paper entitled “Plastic waste-disposal or recovery?”

5 Energy

Increased industrialisation and improved living standards that have been achieved in many parts of the world have been largely based on the availability of energy, one sort or another.The traditional acquisation of energy going back over countless generations has been through combustion to provide heat. Combustion is still an important component in the scheme of things,and is likely to remain so, but the associated technology has become more complex, due to the concern for the effects of the associated emissions on the climate, already discussed.

The first priority in achieving minimum output of greenhouse gases is effective energy management. Chemical engineering technology is uniquely placed to make a substantial contribution to effective management to maximise energy efficiency. A basic requirement is effective design, not only in respect of the combustion process itself, but in achieving maximum heat transfer. A recent simplified study (Casanueva-Robles and Bott, 2005) of the water-cooled steam condensers on a 550 MW coal fired power station,demonstrated that a 1mm thick biofilm on the condensers resulted in an increase of the CO_2 .discharged to atmosphere of 6.2 tonnes/h. Although this may be considered to be a large additional CO_2 discharge, it represents only a relatively small proportion of the total emission. Nevertheless,if the biofilm formation could be reduced or even eliminated altogether, it would make a significant contribution to the aim of reducing the effects of emissions.

Effective control of the accumulation of microbial biofilms can be achieved by the use of biocides. Chlorine has been the preferred biocide for many years on account of its availability and relativly low cost. Chlorine however represents an environmentally unacceptable pollutant when the water is discharged back to its source. Cooling water is usually taken from a natural source such as a river, lake or the sea. Under these circumstances the residual chlorine is a danger to living plants and creatures in the water. Furthermore chlorine reacts with organic material to form carcinogenic compounds that are clearly a danger to humans who may come incontact with the water and particularly if it is used for drinking purposes. As a result, alternative, environmentally friendly biocides are available that are continually being improved. The method of dosing e.g. continuous or intermittent, may affect the overal effectiveness of biocide application

Similarly heat exchangers that recover the heat from hot combustion gases can become fouled with deposits of mineral matter originally contained in the fuel. If steps are not taken to reduce or eliminate these unwanted deposits,the efficiency of heat recovery will be jeopardised, so for a given heat requirement the fuel consumption will increase and the production of CO_2.will also increase.

The reduction of surface fouling in heat exchangers, by good design and suitable control techniques,can make a substantial contribution to a reduction of greenhouse gas discharged to atmosphere.from combustion based systems.Tackling the problem of heat exchanger surface fouling has been a top technological priority in recent years, particularly since the so called “oil crisis” in the early 1970s. Improvements to heat exchanger design in respect of fluid velocity and temperature distribution,have made significant contributions to energy conservation. The use of helical baffles in shell and tube heat exchangers (Boxma, 2000) and the use of inserts in the tubes (Wills et al, 2000), to improve the opportunity to remove deposits are examples of technical advances in design. The material from which a heat exchanger is made and its quality in terms of roughness, have also come under the designers’ scrutiny.

Attention to operational managemement to ensure that the design requirements such as flow velocity and temperature distribution, are maintained is also an effective tool in maximising energy transfer. The use of modified surfaces and coatings to prevent or reduce surface fouling is also a possibility, although cost and durability have to be carefully considered. The use of additives, as with cooling water, is an option but its presence may not be acceptable in certain products as it may be considered an impurity. This is of particular significance in the processing of food.

In addition to these aspects of energy management, it is possible to reduce emissions by capturing the CO_2 and storing it, usually below ground in deep disused mines and the like. An underground carbon storage facility has recently opened in Australia (Anon. 2008). The CO_2 originates from a natural gas well, not from a combustion process, but the principal is identical. The storage facility consists of rock formations 2km below the surface with an estimated capacity of 10,000 tonnes of greenhouse gas. Such a capacity would not be sufficient for a large 1,000 MW coal fired power station that could have around 8 Mt/year CO_2 emission.

The process is most cost effective when applied to large stationary sources of CO_2, such as power stations, refining furnaces and metal smelting, which account for more than half of all man-made CO_2 emissions. Techniques for capturing CO_2 include absorption,adsorption and membrane filtration. At the first Chempor Conference in1975, a paper was presented by Carter et al entitled " The adsorption of carbon dioxide by deep beds of molecular sieve adsorption". Although this paper was principally concerned with a gas coolant purification system for a high temperature nuclear power reactor, it did herald the concept of CO_2 capture for storage underground.

Fossil fuels particularly oil, are running out - with associated higher costs that have recently been in evidence, so that alternative sources of energy will be required. The combustion of waste, particularly domestic waste, can be a source of energy for power generation, but the emissions that include greenhouse gases, may also contain other unwanted compounds, that could be difficult to handle. Preliminary work on the use of hydrogen as an alternative source of energy is a possibility since it does not give rise to greenhouse gas emission from combustion. It may also be used in fuel cells that convert chemical energy directly into electrical energy without combustion. Research is being carried out to investigate their use for powering vehicles. The source of hydrogen in the quantities that will be needed and the fact that it is a gas at atmospheric pressure will create major problems. At the present time hydrogen is largely produced by the electrolysis of water; the source of that power may have come from a conventional power station! Research is being carried out on the posibility of using solar thermo-chemical cycles to produce hydrogen without producing CO_2 (Sattler et al 2007).There are however technical problems still to be overcome . An interesting application for industrially generated CO_2. resulting from hydrogen generation is for use in actual greenhouses, to encourage plant growth and capture of CO_2 (Anon 2007). Other sources of electrical energy that do not generate greenhouse gases include wind power, solar power, river and tidal barriers, sea wave motion and geothermal energy.

A developing industry, considered to be a replacement for the combustion of fossil fuels, is the production of "biofuel", It is a fuel as the name implies, which is biological in origin, such as methane, biogas and biodiesel, seen as sustainable supplements to petrol and diesel.These can be a means of reducing carbon emissions

Biodiesel refers to a diesel type fluid originating in biological sources such as vegetable oils or animal fats. The manufacturing process produces methyl esters (biodiesel) and a valuable biproduct - glycerine, that has many potential uses. Apart from use in vehicle engines there are other applications such as domestic heating oil to reduce or

eliminate the dependence on fossil fuel. Such an application would be of advatage in rural areas where there is no access to domestic gas supplies.

Although combustion generates greenhouse gas emissions, it is argued that since it is plant derived, the CO_2 produced is taken up in subsequent plant growth so that the actual pollution, when this is taken into account, is zero, i.e. carbon neutral. An alternative is biomass produced from organic materials directly from plants or from industrial processes. Woody biomass refers to wood type material or less dense material such as straw and tall grass. Non-woody biomass as the name implies, includes waste from industrial and food processes and specially grown crops such as sugar cane and maize.

Another alternative is biogas, formed by anaerobic digestion of organic materials, generally waste materials such as sewage sludge and waste from food production. The biogas produced is generally a mixture of methane and carbon dioxide with a ratio of approximately 2:1 respectively. It is possible, with suitable modification to use it in internal combustion engines or to generate electricity by the usual method of combustion to raise steam to operate turbines.

In an assessment of the potential for biofuels Bourne (2007) quoting a U.N. report, concludes that although the benefits from biofuels are large, an extensive use of biofuels could jeopodise the security of food supplies, with an increase in food prices. At the present time it is estimated that 25,000 people die from starvation each day! In the light of these kinds of data it is unfortunate that in some parts of the world rain forests and natural habitats are destroyed to provide areas for the production of crops, not for human consuption, but to provide biofuel of one sort or another. Sugar is a typical example. It is fermented to produce alcohol as a liquid fuel to replace petrol in specially adapted internal combustion engines.

A compromise that might go some way to meeting this concern about biofuel and food, is to utilise the waste produced in food production and agriculture generally, rather than using the food substance itself for the production of biofuel. Sugar production from cane is a good example of this approach. For many years waste material from cane sugar refining (bagasse) has been used as a fuel for combustion to produce steam and electricity for the refining process, and the surplus electricity has been made available for the local community. In addtion there is waste associated with the harvesting of the cane on the plantation currently often burnt in situ. This could also be used as a source of energy.It is anticipated that improvements could make the whole process carbon neutral since the equivalent $C0_2$ emission will be absorbed by the next year's growth.

Green algae, waterborne micro organisms, imbibe CO_2 and provided there is sufficient light available they will rapidly multiply to form a substantial mass of growth. They have often been regarded as a nuisance in reservoirs and in places where there are leisure activities.The Chinese authorities for instance, had to clear vast amounts of algae in preparation for some of the boating competitions at the Olympic Games. It has been suggested that algae might be a good source of biofuel since it is easy to grow and removes greenhouse gas from the environment.

Boyle (2008) reports that a company (Ineos) in the U.K.is proposing to prodce bioethanol fuel from municipal solid waste, agricultural waste and organic commercial waste. It is claimed that 400 litres of ethanol could be produced from one tonne of waste. It is pointed out that unlike other biofuels there is no choice to be made between food or fuel with this technology.

6 Concluding remarks

Humanity is facing a huge challenge in respect of the provision of food and clean water to sustain a rapidly increasing world population. In addition there is the availability of energy to satisfy the needs of the growing population in terms of standard of living and manufacturing industry. The examples cited illustrate the tremendous unique opportunity and indeed the moral obligation for chemical engineers, to apply their skills to meeting this challenge. It is in a spirit of optimism and dedication and the cooperation of governments and industrial entrepreneurs, that will ensure success. The whole process will continue to be facilitated by the exchange of ideas that results from conferences such as Chempor.

Topic: Advancing the chemical engineering fundamentals.

Abstract

Gas-liquid mass transfer in an aerated stirred tank containing two liquid phases was investigated by measuring the saturation of an organic solute in the gas phase. The purpose of this work was to provide experimental evidence for the mechanisms at play. Gas-liquid-liquid mass transfer is studied by measuring evaporation of an organic liquid from an aerated stirred tank 0.232 m in diameter. The continuous liquid phase consisted of tap water, while the dispersed organic phase consisted of n-heptane, n-dodecane or solutions thereof. Exhaust air was sampled using 125 ml sampling bulbs and analysed by gas chromatography. Change in outlet gas saturation (saturation in the transferred organic solute) as a function of organic phase composition in this system unequivocally shows that organic phase spreading coefficient is an extremely important factor in mass transfer rate in gas-liquid-liquid systems. Once the spreading coefficient of the organic solution changes from negative to positive, the outlet gas becomes saturated, corresponding to a several-fold increase in mass transfer coefficient.

1 Introduction

Interest in gas-liquid-liquid systems has recently been increasing due to its application in homogeneous catalysis systems [Cents 2001, Dumont 2003] and in the bioprocess industry. Aerobic fermentations [Nielsen 2003, Galaction 2004], VOC biodegradation [Daugulis 2003] and biotransformations using a gaseous substrate [Tecelão 2001] are examples of such bioprocesses involving an organic liquid finely dispersed in the aqueous medium.

In all these processes, mass transfer of one or more gases/vapours into/from the liquid-liquid emulsion occurs and is often rate determining. It is known that the presence of the second liquid phase dispersed in the continuous aqueous phase affects the gas-liquid mass transfer rate. An extensive review [Dumont 2003] of gas-liquid mass transfer to “oil-in water” systems reveals that, while most authors have found mass transfer enhancement due to the presence of the organic phase, both the extent of this enhancement and the mechanism by which it is achieved are not agreed upon by researchers. Gaps and contradictions in the experimental data do not allow definite choice between mathematical (and/or conceptual) models proposed for the phenomena involved.

The pathways for mass transfer between dispersed organic and dispersed gas phases may involve either (i) direct gas/organic contact or (ii) indirect mass transfer through the

* Corresponding author. Tel + 351-218417188. E-mail: salves@alfa.ist.utl.pt

intermediate continuous aqueous phase. Both mechanisms may coexist leading to a series/parallel set of pathways.

The effect of adding a second liquid phase may thus be expected to be different depending on the spreading coefficient *S*, defined as:

$$S = \sigma_{WG} - (\sigma_{OG} + \sigma_{OW}) \quad (1)$$

where σ_{WG}, σ_{OG} and σ_{OW} are the water-gas, organic-gas and organic-water interfacial tensions, respectively. If the spreading coefficient is positive, the dispersed organic phase tends to spread on the bubbles. Direct contact is thus likely and very high mass transfer coefficients are expected.

If the spreading coefficient is negative, on the other hand, such an organic film is not thermodynamically stable. Even so, gas-liquid mass transfer enhancement may occur due to the presence of organic droplets (which are much smaller than the bubbles) in the bubble boundary layer: they may either improve the concentration gradient due to a shuttle effect [Rols 1991] or improve boundary layer mixing.

In this paper, gas-liquid mass transfer effectiveness is quantified in a gas-liquid-liquid system in an aerated stirred tank, with organic phases of variable spreading coefficients, to elucidate the effect of spreading coefficient on gas-liquid mass transfer.

2 Materials and methods

The experimental set-up consisted of a 0.232 m diameter, flat-bottomed, fully baffled glass vessel with steel bottom. Liquid level was kept equal to tank diameter. Agitation was provided by a 0.090 m diameter Rushton turbine placed 0.118 m above the tank base. Temperature was not controlled. It was measured both in the liquid and in the gas above.
The continuous liquid phase consisted of tap water, while the dispersed organic phase consisted of n-heptane (anhydrous, 99%, Aldrich), n-dodecane (Reagent Plus, > 99%, Aldrich), or solutions thereof.
Air was introduced through a ring distributor placed below the turbine. Air flow rate was measured using a rotameter.
Exhaust air was sampled using 125 mL sampling bulbs and analysed for the relevant organic compound(s) by gas chromatography in a Hewllet-Packard 8690 II, equipped with a HT5 capillary column.

3 Theory and calculations

A simple measure of mass transfer effectiveness is the approach to equilibrium of the exit gas, i.e. the Murphree efficiency, *E*. In the present work, since there are no volatile organics in the inlet air, this is given by

$$E = \frac{p_{Gout}}{p_G^*} \quad (2)$$

where p_{Gout} is the partial pressure of the relevant organic compound at gas outlet, and p_G^* is its equilibrium partial pressure, which may be calculated assuming Raoult's law for the liquid organic phase. The advantage of *E* is its simplicity and the fact that no gas phase mixing assumptions are required for its calculation. Thus, although mass transfer coefficients may be calculated from *E* under the aforementioned assumptions, the simpler concept of *E* is enough to draw conclusions from the data obtained in this work and will thus be used.
The relationship between *E* and mass transfer coefficients may be established through mass balance:

$$Q_V \cdot \rho_{mol} \cdot dy = Q_V \cdot \rho_{mol} \cdot \frac{dp_G}{P} = K_G a\left(p_G^* - p_G\right)dV \qquad (3)$$

where K_G is the gas overall mass transfer coefficient between the gas and the organic liquid, a is the specific gas-liquid interfacial area, V is the liquid volume, P is pressure, Q_V is the gas volumetric flow rate and ρ_{mol} is the gas molar density.

Integration depends on the degree of backmixing of the gas, which lies between the two limiting conditions of its being well mixed and following plug flow. Assuming plug flow:

$$K_G a = -\frac{Q_V \rho_{mol}}{VP} \ln\left(1 - E\right) \qquad (4)$$

And assuming a well-mixed gas phase:

$$K_G a = -\frac{Q_V \rho_{mol}}{VP} \left(\frac{E}{1 - E}\right) \qquad (5)$$

4 Results and discussion

Figures 1 and 2 present the % saturation (= E x 100) of heptane in the outlet gas as a function of heptane % mol fraction in the organic liquid for an organic holdup of 2%, 2 different gas flow rates.

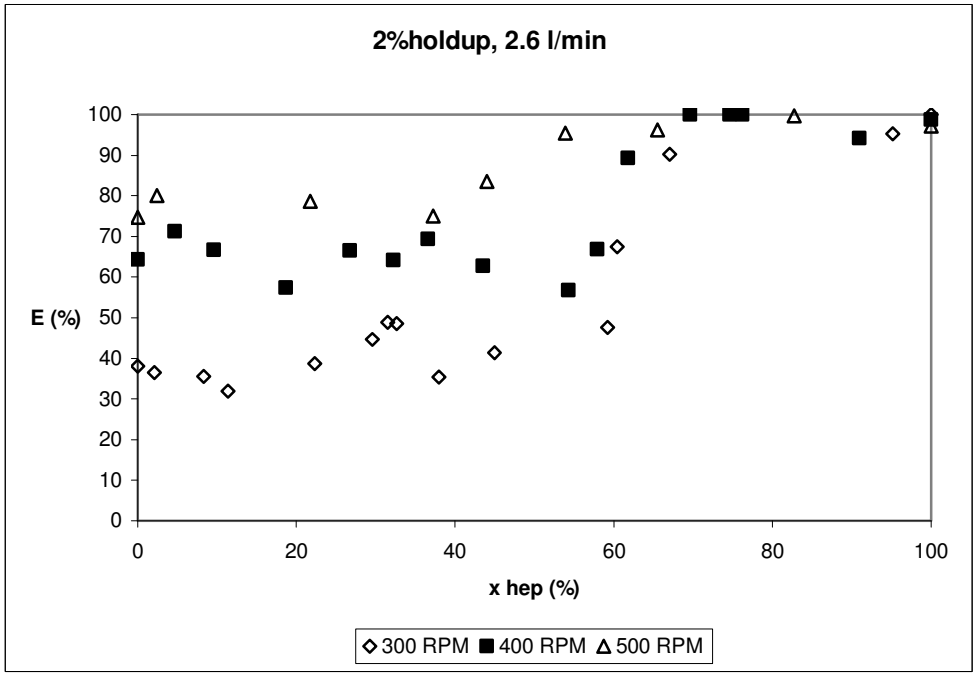

Figure 1 - % saturation (= *E*.100) vs. mol % heptane in the organic phase for Q_v=2.6 l/min and 2% organic holdup, at varying stirrer speeds.

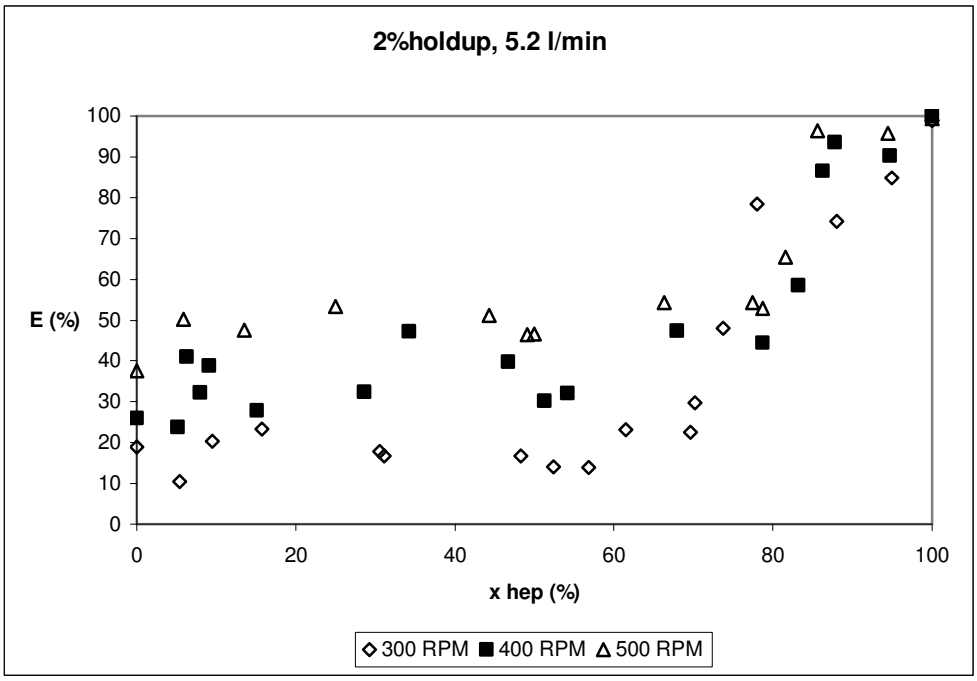

Figure 2 - % saturation (= *E*.100) vs. mol % heptane in the organic phase for Q_v=5.2 l/min and 2% organic holdup, at varying stirrer speeds.

The most striking features that we can see in these figures are the following:

(i) For any given set of conditions (constant N, constant Q_v) % saturation of heptane in the outlet gas is low at low concentrations of heptane in the organic liquid, high for high concentrations. In fact there appear to be two plateaus of approximately constant % saturation in the gas separated by a steep change at between 50% and 80% heptane in the liquid.

(ii) Above this transition-concentration the gas leaves almost saturated in heptane. The exception is when N = 300 rpm and Q_v = 5.2 l/min, which corresponds to the lowest agitation power.

(iii) Stirrer speed, as expected increases outlet percentage saturation, due to increased mass transfer coefficient.

The transition concentration happens to coincide roughly with the concentration of heptane at which the spreading coefficient of the organic solution changes from negative to positive. The spreading coefficient at 25ºC is 2.4 for heptane, and -5.5 for dodecane [Drelich 1999]. Assuming that surface tension varies approximately linearly with mole fraction [Tahery 2005] so will the spreading coefficient, in which case the transition composition is $x_{heptane}$ = 0.70. It may therefore be concluded that there are two mechanisms of mass transfer, depending on the spreading properties of the organic phase.

4 Conclusions

Change in outlet gas saturation (saturation in the transferred organic solute) as a function of organic phase composition in a gas-liquid-liquid system unequivocally shows that organic phase spreading coefficient is an extremely important factor in mass transfer rate in gas-liquid-liquid systems.

Keywords: vectors, transfer pathway, transfer enhancement, OTR
Topic: Advancing the chemical engineering fundamentals

Abstract

This paper presents the quantification of the air/vector and the air/vector/water oxygen transfer in three-phase reactors. A mathematical model was developed and used to characterize mass transfer in an airlift (AL) and a stirred-tank (ST) reactors containing from 0 to 50% of silicone oil as vector. A positive effect of the vector on oxygen transfer was observed. In both reactors, the optimum oxygen transfer was observed with 10% vector. Under these conditions, a transfer increase of 65 and 84% for the AL and ST respectively was observed, compared to reactors operated without silicone oil. It was also observed that the overall transfer enhancement was mainly due to a better air/water transfer. With 10% vector, the air/water transfer contribution to the overall oxygen transfer was 94.7 and 93.0% for the AL and ST, respectively.

1. Introduction

Transfer of poorly water-soluble compounds is a key issue in numerous biotechnological processes. Several methods have been proposed to overcome mass transfer limitations. Among these, the use of vectors has been explored for more than 30 years (Deziel et al., 1999). The use of vectors is based on the addition of an immiscible liquid with high affinity towards the target compound (Muñoz et al., 2007). An additional gas/vector/water transfer pathway is established. Numerous liquids have been used as vectors, including perfluorocarbons, silicone oil and long-chain alkanes. Despite numerous published works, no agreement on the positive or negative effect of vectors on mass transfer has been reached (Dumont and Delmas, 2003).

The effect of vectors on mass transfer has been traditionally assessed by the determination of the overall transfer rate. Due to the difficulty to characterize the vector phase under real operational conditions, a common simplification made in the literature is to assume that water and vector constitute a single homogeneous phase (Cesario et al., 1997). This simplification, adopted by many authors (Clarke and Correia, 2008), does not allow a separate estimation of the partial transfer rates (i.e. gas/vector, vector/water and gas/water transfers). To our knowledge, no report on partial mass transfer in three phase reactors has been made. The aim of this work was the quantification of the partial transfer rates of oxygen in an air/silicone-oil/water system. These oxygen transfer rates were estimated in an airlift (AL) and a stirred tank (ST) lab-scale reactor.

2. Mathematical model development

This work considers air and silicone oil (vector) dispersed in an aqueous sulfite solution (called water for simplification). Sulfite oxidation simulates oxygen uptake as occurring in biological processes. In this system two assumptions were made; (*i*) oxygen is transferred from air to water directly or through the vector and (*ii*) oxygen uptake occurs only in water.

* Corresponding author. Tel +5255-5061-3320; fax: +5255-5061-3313. E-mail: thalasso@cinvestav.mx

According to these assumptions, oxygen is transferred directly from air to water, and indirectly, from air to vector and then from vector to water. Mass transfer was characterized by two transfer rates; the actual transfer rate (OTR_{ij}) and the maximum transfer rate also called oxygen transfer capacity (OTC_{ij}). Subscripts *i* and *j* refer to the origin and the target phases; *g*, *v* and *w* for gas, vector and water respectively. Both OTR_{ij} and OTC_{ij} were expressed per unit of reactor volume to allow comparison. OTC_{ij} are the OTR_{ij} observed when the maximal gradient concentration is reached between the i^{th} and j^{th} phases. Thus OTR_{ij} can be expressed as a fraction of OTC_{ij} as follows;

$$OTR_{gv} = OTC_{gv}\left(1 - \frac{C_v}{C_v^*}\right) \quad (1)$$

$$OTR_{vw} = OTC_{vw}\left(1 - \frac{C_w}{C_w^*}\right)\left(\frac{C_v}{C_v^*}\right) \quad (2)$$

$$OTR_{gw} = OTC_{gw}\left(1 - \frac{C_w}{C_w^*}\right) \quad (3)$$

In these equations, C_i and C^*_i represent the actual and the saturation concentration of oxygen in the i^{th} phase. In presence of sodium sulfite, oxygen mass balance in vector and water can be written as follows;

$$\frac{dC_v}{dt} = \left[OTR_{gv} - OTR_{vw}\right]\frac{V_r}{V_v} \quad (4)$$

$$\frac{dC_w}{dt} = \left[OTR_{gw} + OTR_{vw} - q\right]\frac{V_r}{V_w} \quad (5)$$

In Equations 4-5, V_r, V_v and V_w represent the reactor, vector and water volume respectively; *q* is the oxygen consumption rate due to sulfite oxidation. In Equations 4 and 5, OTR_{ij} can be substituted by Equations 1-3. Additionally, the presence of sulfite ensures that C_w equal zero, giving Equations 6 and 7. Equation 8 gives the sulfite oxidation rate in which $Y_{SO_3^{2-}/O_2}$ is the sulfite /oxygen yield.

$$\frac{dC_v}{dt} = \left[OTC_{gv}\left(1 - \frac{C_v}{C_v^*}\right) - OTC_{vw}\left(\frac{C_v}{C_v^*}\right)\right]\frac{V_r}{V_v} \quad (6)$$

$$\frac{dC_w}{dt} = \left[OTC_{gw} + OTC_{vw}\left(\frac{C_v}{C_v^*}\right) - q\right]\frac{V_r}{V_w} \quad (7)$$

$$\frac{dSO_3^{2-}}{dt} = -\left(Y_{SO_3^{2-}/O_2} \cdot q\right)\frac{V_r}{V_w} \quad (8)$$

2.1 Model Solution

In order to estimate OTC_{gw}, OTC_{gv} and OTC_{vw}, Equations 6 to 8 were solved simultaneously and adjusted to experimental data obtained during mass transfer experiments as described below. A fitting procedure based on Runge-Kutta method with Marquardt optimization was

used. Once OTC_{ij} were determined, OTR_{ij} values were obtained from Equations 1-3. Model solution and statistic analyses were performed with Model Maker (Cherwell Scientific Publishing, 1993) and NCSS (Jerry Hintze, 2001), respectively.

3. Experimental

3.1 Setup and operating conditions

The AL reactor was a glass column (0.12 m inner diameter, 0.57 m height, 6.4 L total volume, 5 L working volume) with a concentric tube (0.075 m inner diameter, 0.35 m height) located at 0.05 m of the bottom of reactor. A porous plate (0.05 m diameter) was used for air supply. The ST reactor was a glass reactor (0.133 m inner diameter, 0.55 m height, 7.6 L total volume, 5 L working volume), mixed with a double Rushton turbine operated at 300 rpm. A perforated ring (orifice diameter of $1x10^{-3}$ m) was used for air supply. In both reactors, the air flow-rate was maintained at 1 vvm and controlled with a variable area flow-meter (Cole Parmer, Mexico) previously calibrated with a mass flow controller (GFC171S, Aalborg). Experiments were performed at 23 ± 2 °C. Reactors were operated with 0 to 50% v/v silicone oil (polydimethylsiloxane 200R, Dow Corning. México), characterized at 25ºC, by kinematic viscosity of 20 cSt, specific gravity of 0.95 and surface tension of 20.6 din cm^{-1} (Ascon-Cabrera and Lebeault, 1993).

3.2 Mass transfer experiments

Mass transfer was characterized in both reactors operated with air, sulfite solution (2.6×10^{-2} M) and silicone oil. Before mass transfer measurements, the reactor was operated until vector and water saturation was reached; this typically lasted about 10 minutes. Then cobalt sulfate, as sulfite oxidation catalyser, was added to the reactor (final cobalt concentration of 2.5×10^{-4} M) and measurements of C_w, C_v and sulfite concentration were immediately started. Experiments were made in triplicate for each tested condition.

3.3 Measurements techniques

Sulfite concentration and C_v were measured from time to time as follows: aeration and mixing were interrupted, then vector and water started to separate immediately. Samples of water were taken at the bottom of reactor and samples of the vector were taken from the top of the reactor. After sampling, the aeration and/or mixing were resumed. For data interpretation time scale was corrected to discard times during which aeration and mixing were interrupted. Sulfite concentration in water was measured by iodometric back-titration according to Zhao et al. (1999). The samples of vector were transferred to serological bottles with inert atmosphere (N_2, 99.97% purity) containing an aqueous sulfite solution of known concentration. Bottles were maintained at 23° C and 160 rpm during 24 h. Final sulfite concentration was then measured and C_v was assumed to be the amount of oxygen consumed by sulfite per volume of vector sampled. C^*_v was measured by the same procedure using a sample of vector aerated for 2 hours. C_w and C^*_w were measured with a dissolved oxygen probe (Hannah Instrument HI 2400, Mexico). The total gas holdup was measured by height differences according to Vandu et al. (2004).

4. Results and discussion

4.1 Validation of the sampling methods

The method used in this work was based on mixing and aeration interruption. It was therefore important to confirm that (*i*) the successive interruption did not affect the overall oxygen transfer and (*ii*) that C_v measurements were not affected significantly due to aeration and mixing interruption. To guarantee that the successive interruption did not affect the overall oxygen transfer, overall transfer rates with and without successive aeration and mixing interruptions were compared. No significant difference (p<0.05) were observed between both experimental conditions (data not shown). The second experiment to confirm

the validity of the vector sampling method was to measure C_v after aeration and mixing interruption. Vector samples were taken immediately after aeration and mixing interruption and up to 9 minutes later. Figure 1 shows an example of the results observed in the ST reactor, operated with 20% vector. No significant difference ($p<0.05$) was observed between C_v measured at several time after aeration and mixing interruption. Similar results were observed in all experimental conditions. It was concluded that mixing and aeration interruption did not affect significantly C_v determinations.

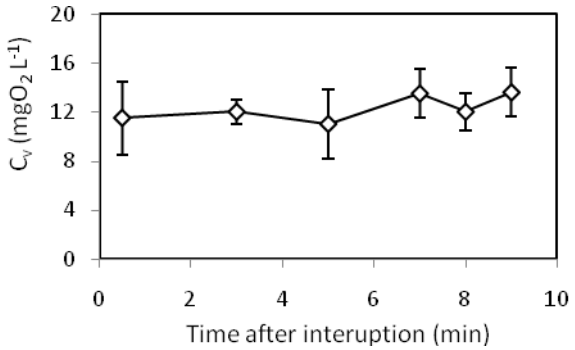

Figure 1. C_v trends after aeration and mixing interruption.

4.2 Mass transfer estimation

Figure 2 presents an example of experimental data fitting using Equations 6-8. These experimental data were obtained in the AL reactor operated with 10% vector. The model fitted correctly the experimental sulfite concentration, C_v and C_w. The goodness of fit was estimated by weighted sum of squares calculation after running the model against experimental data (intrinsic Model Maker tool). The coefficient of determination, r^2, was systematically over 0.97 (maximum, 0.999; minimum, 0.947; average, 0.978; Std. Deviation, 0.018).

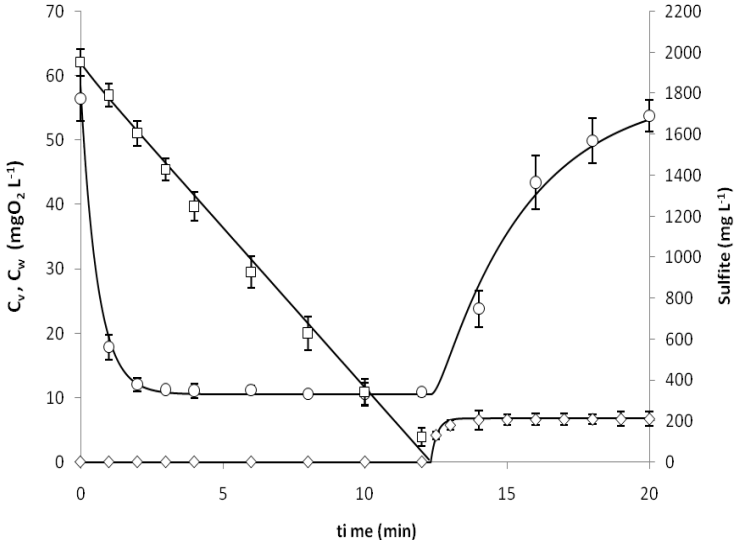

Figure 2. C_v (○), C_w (◊) and sulfite concentration (□) trends observed in the ALR operated with 10% vector versus model solution (solid lines).

Figure 2 shows that C_v rapidly reached a pseudo-steady state. During this pseudo-steady state, both OTR_{gv} and OTR_{vw} are equal (Equation 6). Thus, the indirect air/vector/water transfer rate can be represented by the global parameter OTR_{gvw}. Figure 3 presents the values of the direct transfer rate (OTR_{gw}) and the indirect transfer rate (OTR_{gvw}) observed in the AL (A) and the ST (B) reactors. It was observed that the vector had a positive effect on

the overall oxygen transfer rates in all tested vector percentages. In both reactor designs the optimum overall transfer rates was observed with 10% vector. Under these conditions, the overall transfer rates was 65% and 84% superior to the transfer rate observed with no vector, for the AL and the ST reactor, respectively. This result is in accordance to the Literature. According to the Clarke and Correia (2008) literature review, 10% is the tested percentage for which most of the authors have observed the optimum effect of vector on mass transfer. Figure 2 also shows the contribution of the direct air/water transfer to the overall transfer. With 10% vector, it was observed that the direct air/water transfer accounted for 94.7 and 93.0% of the overall transfer rate, in the AL and the ST reactors, respectively.

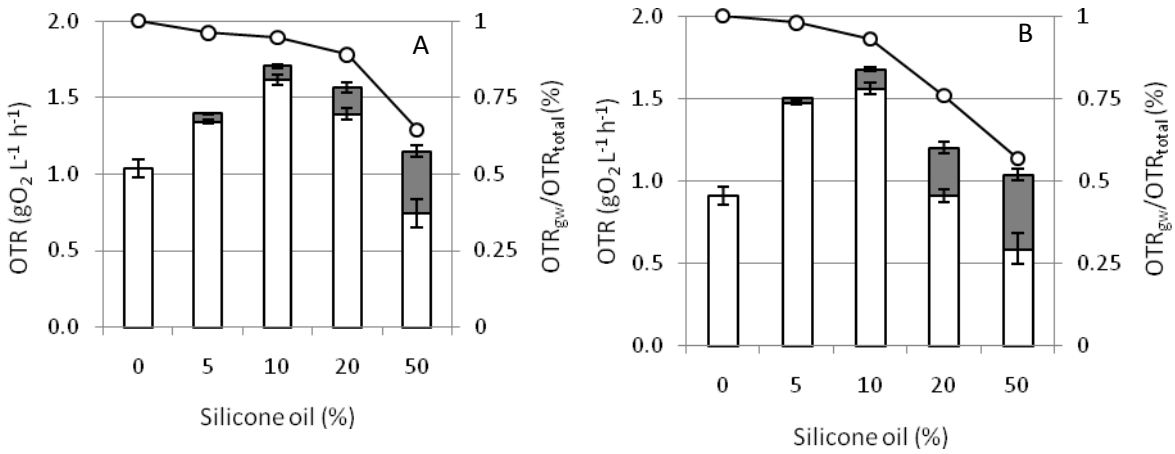

Figure 3. OTR_{gw} (□), OTR_{gvw} (■) and the OTR_{gw} contribution to the overall oxygen transfer (○), observed in the AL (A) and the ST (B) reactors.

According to these results, the presence of vector had a positive effect on the direct air/water transfer rates which could be explained by a better gas/water dispersion. Indeed, Galindo et al. (2000) reported that the presence of vector (castor oil) in a three-phase reactor decreased the bubble mean diameter and consequently increased the gas/water interfacial area. To evaluate the effect of vector on gas/liquid dispersion, the gas holdup (ε_G) was measured. Figure 4 shows the ε_G values observed at different vector percentages. It was observed that ε_G increased significantly in the AL reactor. Furthermore, in the ST reactor, practically no change in ε_G was observed. These results suggest that the vector had an indirect effect on air/water interface. Interfacial modification or complex hydrodynamic phenomena are probably involved.

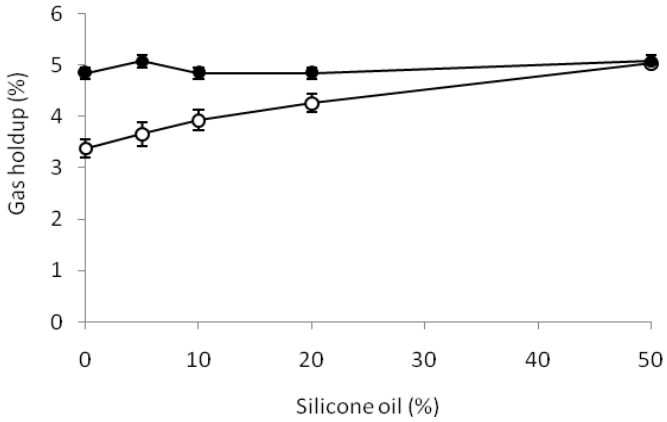

Figure 4. Gas holdup observed in the AL (○) and ST (●) reactors.

5. Conclusion

The mathematical model and the experimental method developed in this work allowed the characterization of direct and indirect oxygen transfer pathways in three-phase reactors. The results obtained confirm that the presence of vector has a positive effect on the overall oxygen mass transfer. In both AL and ST reactor designs, the optimum transfer rate was obtained with 10% vector. Under these conditions, the improvement of the overall oxygen transfer was 65 and 84% for the AL and the ST respectively, compared to reactors operated without vector. It was clearly observed that the presence of vector had mainly a positive impact on the direct air/water transfer. These results differ to what commonly considered by the literature. The positive effect of vector is not due to the creation of an additional air/vector/water pathway or to improved overall oxygen solubility. The effect of the vector on the direct air/water transfer has not been elucidated yet. Additional research is required to understand the effect of vector on the reactors hydrodynamics and gas/liquid interface. The model and the method developed allowed a better understanding of three-phase reactors. This method has been applied so far to two lab-scale reactor designs operated under single mixing and aeration conditions. Further researches are needed and particularly with other reactor design, more extended operational conditions and larger scale.

w3.senadeera@qut.edu.au

Key words: fluidisation, large particulates, physical properties
Topic: Advancing the chemical and biological engineering fundamentals

Abstract
Changes in fluidization behaviour of three geometrical shaped food particulates, cylindrical (beans), parallelepiped (potato) and spherical (green peas) with change in moisture content during drying were investigated using a fluidized bed dryer. Fluidization behaviour was characterised for cylindrical shape particles with three length diameter-ratios; 1:1, 2:1 and 3:1, parallelepiped particles with three aspect ratios, 1:1, 2:1 and 3:1 and spherical particles. All drying experiments were conducted at 50^0C and 15 % RH using a heat pump dehumidifier system. Fluidization experiments were undertaken for the bed heights of 100, 80, 60 and 40 mm and at 10 moisture content levels.

An empirical relationship of the form $\mathbf{U_{mf} = A + B\, e^{-Cm}}$ was developed for change of minimum fluidization velocity with moisture content for cylindrical shapes and for spherical shapes a linear model of $\mathbf{U_{mf} = A + B\, m}$. Due to irregularities in shape minimum fluidisation velocity of parallelepiped particulates (potato) could not fitted to any empirical model. Also a generalized equation was used to predict minimum fluidization velocity.

Introduction

Fluidized bed drying is recognized as a gentle, uniform drying, down to very low *residual moisture* content, with a high degree of efficiency (Borgotte et al., 1981). The application of this technique is best suited to smaller and spherical particles. The disadvantages of this method include entrainment of friable solids by the gas and limited application to larger and poorly fluidized materials. Simultaneous moisture removal, shrinkage and structural changes during drying operations, affect physical properties of the agro-food materials and hence influence fluidization behaviour (Senadeera et al., 1998)

The Ergun equation (Ergun, 1952) is the widely accepted model to determine *minimum fluidization velocity* of a fluid to fluidize the particle (Kunii and Levenspiel, 1977).The Ergun equation (Equation 1) is used to calculate minimum fluidization velocity of peas (Rios et al., 1984) and diced potato and potato strips (Vazquez and Calvelo, 1980; 1982). The values obtained by the Ergun equation are mostly reliable for spherical and relatively small particles. Most agro-food particulates however comprise of various shapes and sizes, and consist of larger particles. Therefore, the minimum fluidization values obtained from Ergun equation do not conform to the experimental values (Mclain and McKay, 1980, 1981; McKay et al., 1987)

$$(1-\varepsilon_{mf})(\rho_s-\rho_f)\,g = 150\frac{(1-\varepsilon_{mf})^2}{\varepsilon_{mf}^{\,3}}\frac{\mu u_{mf}}{(\phi d_p)^2} + 1.75\frac{(1-\varepsilon_{mf})}{\varepsilon_{mf}^{\,3}}\frac{\rho_f u_{mf}^{\,2}}{\phi d_p} \qquad (1)$$

where ε_{mf} – bed porosity at minimum fluidization velocity, ρ_s – particle density (kg/m^3), ρ_f – fluid density (kg/m^3), μ - viscosity (N s/m^2), u_{mf} – minimum fluidization velocity (m/s), d_p – particle equivalent diameter (m), ϕ - sphericity

The Ergun equation consists of *viscous* and *kinetic energy* terms. In the case of larger particles at higher Reynolds numbers (Re > 1000) the fluidization behaviour is mainly governed by the kinetic energy term in the Ergun equation. Hence the Ergun equation can be simplified for (Kunii and Levenspiel, 1977) a wide variety of systems and a generalized equation can be applied to predict minimum fludisation velocity for larger particles when Reynolds number > 1000 using some modification.

$$u^2_{mf} = \frac{\phi\, d_p{}^2}{1.75} \frac{(\rho_s - \rho_f)}{\rho_f}\, g\, \varepsilon^3_{mf} \qquad (2)$$

where, ε_{mf} – bed porosity at minimum fluidization velocity, ρ_s – particle density (kg/m^3), ρ_f – fluid density (kg/m^3), u_{mf} – minimum fluidization velocity (m/s), d_p – particle equivalent diameter (m), ϕ - sphericity, g - acceleration due to gravity (m/s^2)

For wide variety of systems it was found that value $\frac{1}{\phi\, \varepsilon_{mf}{}^3} \cong 14$ (Wen and Yu, 1966) and a generalized equation can be applied to predict u_{mf} for larger particles when Re > 1000.

$$u^2_{mf} = \frac{d_p(\rho_s - \rho_f)}{24.5\, \rho_f}\, g \qquad (3)$$

where, ρ_s – particle density (kg/m^3), ρ_f – fluid density (kg/m^3), u_{mf} – minimum fluidization velocity (m/s), d_p – particle equivalent diameter (m), Re – Reynolds number

It is important to understand changes in fluidisation behaviour, so that the air-flow during drying can be controlled to achieve an optimum fluidization. The objective of this study is to study the continuous change in minimum fluidization velocity for a given shape of food material during drying and relate this to moisture content by a suitable model, and compare with the generalized model.

Material and Methods

Fresh green beans *Phaseolus vulgaris* of Labrador variety with consistence diameter 10 $\pm$ 1 mm was used for producing cylindrical particles. Samples were prepared at three length to diameter ratios of 1:1, 2:1 and 3:1, respectively. Potato *Solanum tuberosum* of the variety Sebago was used to make parallelepipeds in a Dicing Machine (Hobart, Australia), by incorporating a cutter which makes 6.5mm X 6.5mm square cross-section and lengths of 19.5, 13 and 6.5 mm to obtain aspect ratios of 3:1, 2:1 and 1:1, respectively. Fresh green peas *Pisum sativum* of the variety Bounty were shelled by hand and graded using a wire mesh. Those with average diameter 10$\pm$1 mm were selected.

Particle density was obtained measuring the volume of the weighed particles by the liquid displacement method using liquid paraffin (SG = 0.8787 at 30^o C) as the medium (Zogsas, 1994). The vacuum oven was used to measure the moisture content of the particles according to the AOAC method 934.06 (1995).

First, fluidisation characteristics of the un dried samples were measured in the fluidizing column (Figure 1) with the prepared samples. After that samples were dried on a fixed bed in a heat pump dehumidifier system (Intertherm P/L, Brisbane, Australia) and withdrawn at nine pre-determined time intervals during drying and used for measurement of minimum fluidisation velocity at four bed heights of 100, 80, 60, and 40 mm in same fluidized bed column.

Graphs of bed pressure drop versus velocity of fluidising air were constructed to determine the minimum fluidisation velocity at different moisture contents. This was also confirmed with the visual observation of the bed, such as expansion and movement.

Figure 1 Fluidisation column connected to the heat pump dryer

Analysis of experimental data and modelling procedure

The data were analysed for the analysis of variance (ANOVA) to evaluate differences, and, linear and non-linear regression to obtain suitable models. The coefficients were estimated using SAS (1985) least squares routine on a personal computer. Model validity was tested using measures of coefficient of determination (R^2) and mean absolute error percentage (MAE%).

Results and Discussion

Fluidisation behaviour of cylindrical food particulates - beans

Slugging and channelling were a common phenomena at higher moisture contents for every L:D ratio. It was difficult to achieve good fluidisation at initial moisture levels. This was more evident as the L:D ratio increased. As moisture was reduced, the quality of fluidisation improved, with reduced slugging and channelling.

Modelling the minimum fluidisation velocity with change in moisture content

The data were best fitted to the model $u_{mf} = A + B\, e^{-C\, m}$ and its parameters are shown in the Table1 for L:D = 1:1 and Table 2 for 2:1 for different bed heights.

Table 1 Parameters for Equation $u_{mf} = A + B\, e^{-Cm}$ for L:D = 1:1

Bed height (mm)	A	B	C	R^2	MAE%
100	2.3541	-0.8825	0.0017	0.91	3.89
80	2.2990	-0.8514	0.0015	0.91	4.07
60	2.0793	-0.7097	0.0019	0.86	4.62
40	2.1202	-0.7691	0.0016	0.86	4.52

Table 2 Parameters for Equation $u_{mf} = A + B\, e^{-Cm}$ for L:D = 2:1

Bed height(mm)	A	B	C	R^2	MAE%
100 mm	2.3632	-0.7446	0.0021	0.73	11.23
80 mm	2.3409	-0.7480	0.0025	0.72	11.54
60 mm	2.1965	-0.6884	0.0020	0.76	11.23
40 mm	2.1204	-0.6532	0.0032	0.79	9.58

This model adequately described the fluidisation behaviour of beans at L:D = 1:1. The model for L:D = 2:1 and 3:1 gave poor correlation coefficients and higher mean absolute error percentage values, could be due to irregular variation of the minimum fluidisation velocity.

Calculation of minimum fluidisation velocity based on dimensional changes during drying

The Generalized model (Equation 3) was used to calculate the predicted values of minimum fluidisation velocity. For all three L:D ratios (Table 3).

Table 3 Mean Absolute Error % for predicted versus observed minimum fluidisation values in the generalized model

L:D ratio/ Bed height	MAE%			
	100mm	80mm	60mm	40mm
1:1	9.54	3.81	1.61	3.18
2:1	7.66	1.83	6.13	2.74
3:1	5.32	1.62	0.36	4.03

Fluidisation behaviour of parallelepiped particles - potato

Good fluidisation was impossible at higher values of moisture at all aspect ratios. Decreasing the moisture resulted in a bed which was fluidised, but was accompanied by channelling and slugging. At lower moisture levels quality of fluidisation improved. An increase in minimum fluidisation velocity was attributed to the increase in particle density and interlocking of particles in the bed (Figure 2).

Modelling of minimum fluidisation velocity with change in moisture content

Fluidisation behaviour of potato particles could not be modelled due to the irregular trend of change of minimum fluidisation velocity with moisture content for all aspect ratios.

Minimum fluidisation velocity calculation based on the generalized equation

The Generalized model was used to calculate the predicted values of minimum fluidisation velocity. For all three aspect ratios, this generalized model value was compared with the experimental value. The mean absolute error percentage value is more than 10% for the aspect ratio 3:1, for the bed heights of 100, 80 and 60 mm (Table 4).

Table 4. Mean absolute error percentage (MAE%) of observed and predicted values of potato based on the generalized model

Aspect ratio	MAE%			
	100mm	80mm	60mm	40mm
1:1	8.83	4.09	2.75	2.03
2:1	7.55	6.26	1.03	1.02
3:1	13.46	12.98	10.80	3.68

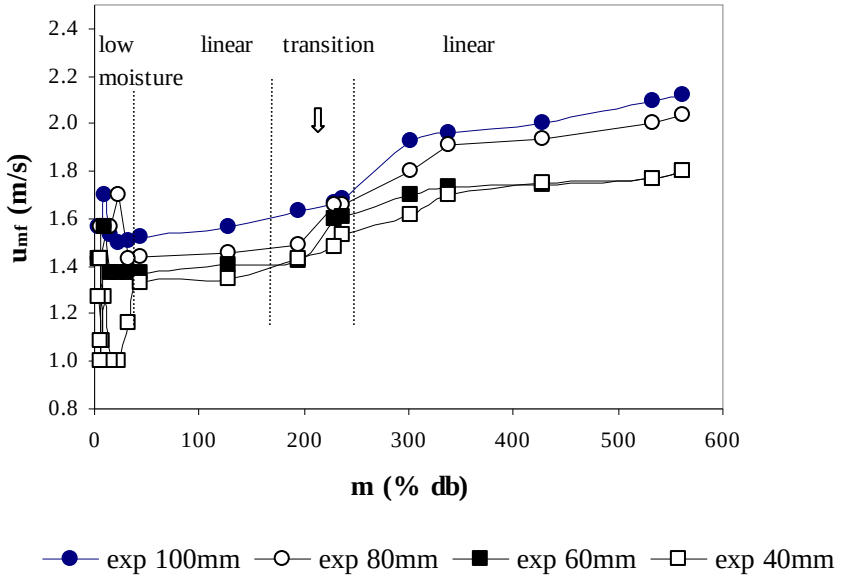

FIGURE 2 Fluidisation behaviour of potato L:D = 1:1

Fluidisation behaviour of spherical particles -green peas

In the case of peas, fluidisation was possible even at the higher moisture contents. Minimum fluidisation velocity decreased as drying proceeded. Slugging, and channeling phenomena was less than in the case of beans and potato due to good packing and spherical shape of the material in the bed.

Modelling of minimum fluidisation velocity with change in moisture content

The change in minimum fluidisation velocity was modelled linearly with the moisture content of the form $u_{mf} = A + B\ m$ for all bed heights. Model parameters are given in Table 5. MAE% lower than 10% indicating that the model equations can be used to predict the fluidisation behaviour reasonably.

Table 5. Coefficients for green pea models at different bed heights

Bed height (mm)	A	B	R^2	MAE%
100	1.5589	0.025	0.88	3.93
80	1.4786	0.0023	0.88	4.20
60	1.3853	0.0022	0.87	4.69
40	1.2685	0.0023	0.81	7.07

Minimum fluidisation velocity calculation based on the Generalized equation

The Generalized model (Equation 2) was used to calculate the predicted values of minimum fluidisation velocity of peas, and found that it can be used to predict minimum fluidisation velocity accurately for all bed heights and all moistures.

Table 6. Mean absolute error percentage (MAE%) for different bed heights of

peas for Generalised model

Bed height (mm)	MAE %
100	7.24
80	1.75
60	4.76
40	9.51

Conclusion

This work showed effect of moisture and shape on fluidisation behaviour of three real food materials. Fluidisation behaviour was modelled into empirical equations for cylindrical (beans) and spherical (peas) with moisture and could not be for parallelepiped (potato) particles due to its irregular nature. Generalised equation predicts the minimum fluidisation with a reasonable accuracy for all particle shapes. If sphericity changes during drying is measured an accurate predictions of minimum fluidisation velocity could be obtained using Ergun Equation.

Topic: Advancing the chemical and biological engineering fundamentals

Introduction

Photocatalytic synthetic processes using selective oxidation are currently not industrially applied, partially due to the lack of a proper design of multiphase photo-reactors. Currently photo-reactors for liquid phase oxidation are typically based on slurry systems i.e., the solid phase is dispersed within the liquid in the reactor. Although this design offers ease of construction and high catalyst loading, it has clearly drawbacks, such as the difficulty of separation of catalyst particles from the reaction mixture, and low light utilization efficiencies due to the scattering and shielding of light by the reaction medium and catalyst particles.
Various attempts have been made to amend the aforementioned light distribution problem with immobilized photocatalytic systems (de Lasa et al. 2005; Schiavello 1997). One approach was to employ optical fibers as light distributing guides and support for photocatalysts, the so-called Optical Fiber Reactors (OFR's). Light propagates through the fiber core, whilst certain amount of photons is refracted into the coated titania layer. By this means, the optical fibers enable the remote delivery of photon energy to the reactive sites of the photocatalyst. Ollis and Marinangeli were the first to conduct studies on an optical fiber reactor (OFR) (Ollis and Al-Ekabi 1993).The most recent example is the development of an optical fiber monolith reactor, as reported by Lin and Valsaraj (Ollis and Al-Ekabi 1993; Lin and Valsaraj 2005). They used the monolith for photocatalytic wastewater treatment with the channels of the monolith completely filled with flowing liquid. The monolith structure was used merely as the distributor of the optical fibers, while the benefits of monoliths, such as low pressure drop and excellent mass transfer characteristics for gas/liquid systems in certain hydrodynamic regimes, were not fully exploited to optimize the photocatalytic oxidation reaction (Kreutzer et al. 2005). Later in our group we developed the Internally Illuminated Monolith Reactor (IIMR), (Du et al. 2008). This reactor system is based on a modified design of the abovementioned combination of side light emitting fibers and ceramic monoliths. The 'side-light fibers' are evenly distributed inside a ceramic monolith structure, on the inner walls of which titania photocatalyst is coated. The reaction system is so constructed that the hydrodynamic regimes of Taylor flow and film flow can be realized. Because no catalyst is coated on the fibers, the emitted light can reach the catalyst-reactant interface without being strongly attenuated by the catalyst coating. Compared with conventional OFR's, this unique configuration provides extra design flexibilities, because the light propagation process from the source to the catalyst-reactant interface is decoupled from the physical properties of the catalyst. Furthermore, the fibers used in this reactor were tip-coated with a reflective material which introduced a new design flexibility since the length of the fiber where light intensity emitted from the sides of the fiber is sufficient to drive the reaction is no longer limited to 10 cm. To investigate the potential of the IIMR in organic synthesis, the selective photo-oxidation of cyclohexane was chosen as the model reaction, a reaction we previously investigated using conventional slurry reactors (Du et al. 2006). The photonic efficiency achieved with the IIMR reactor in the selective photo-oxidation of

* Corresponding author. Tel + 31-15-2784396. E-mail:j.t.carneiro@tudelft.nl

cyclohexane (0.062) was less than obtained with a top illumination reactor, slurry type (0,151). It was concluded that the value for the IIMR could be improved by reducing the TiO_2 layer thickness, which was acting like a “sponge” for the strongly adsorbed product, limiting the amount detected in the recirculated liquid.

With the objective to validate our photoreactor design, a model was developed to compare the Top Illumination Reactor and the IIMR. The difference between these two reactors is mostly in the way the light is guided to the catalyst surface. For the IIMR, the following model has been developed to determine the light intensity that reaches the catalyst particles deposited on the walls of each channel.

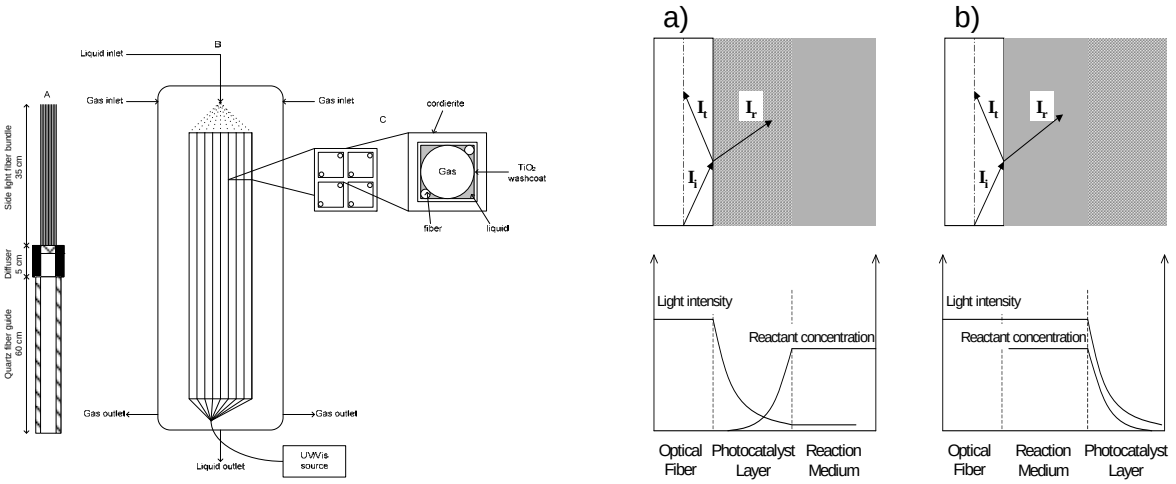

Fig. 1. Left side figure: scheme of the IIMR and optical fiber bundle used. Right side figure: comparison of the catalytic activation mechanism a) OFR’s, b) IIMR.

Light intensity in a square monolith channel illuminated by two light fibers

Light intensity, light position and light profiles play an important role in modeling the performance of photocatalytic reactors. An optimized photocatalytic process requires light of sufficient intensity to be present at all locations where there is catalyst. The design equations for the reaction rate of the slurry type top illumination reactor (TIR) and the IIMR reactor are shown in Eq 1 and 2, respectively.

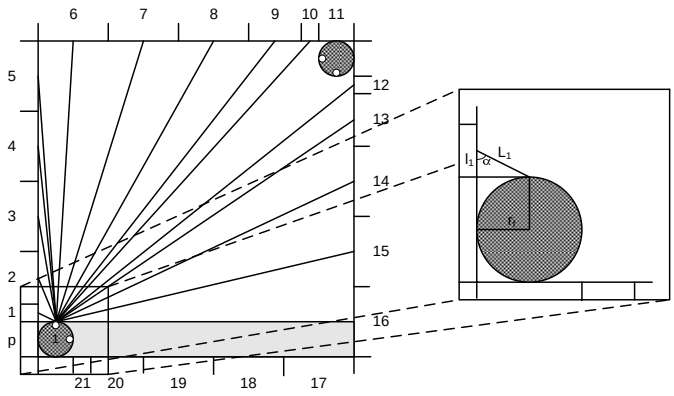
• TIR $$r_1 = k_1 \left(I_0^{''} \right)^m \left(C_A \right)^n C_{sites} \quad (1)$$

• IIMR $$r_1 = gt\, k_1 \left(I_0^{''} \right)^m \left(C_A \right)^n C_{sites} \quad (2)$$

The rate depends on the initial intensity of the light entering the reactor ($I_0^{''}$), the proportionality power of the light intensity (*m*), the reaction order (*n*), and the concentrations of the reactant (C_A) and the concentration of the catalytically active sites in the coating (C_{sites}). For the IIMR an additional factor is added, the geometric term (*gt*), which will be explained later.

The initial light intensity ($I_0^{''}$) is, in the TIR, the light entering the reactor through a pyrex window and in the IIMR corresponds to the light irradiated from the side light fibers. The value of $I_0^{''}$ can be determined, using a calibrated spectrophotometer S-2000 (Avantes) equipped with a cosine collector. The output generated by this equipment consists of the spectral irradiance, I_λ, in $J.s^{-1}.m^{-1}.nm^{-1}$, which can be converted into an $I_0^{''}$ in $Einstein.m^{-2}$ (Du et al. 2008). For the IIMR this intensity depends on the distance of the catalytic site to the light fiber (L_i), the incident angle (α) and the depth in the coating. Fig. 2 shows our

approach to estimate the light intensity at 21 wall sections of the monolithic channels. In each channel two fibers are located in diagonally opposite corners. It is assumed that the light is emitted from two point sources on each fiber. It is also assumed that the liquid in the corners where the fibers are located is stagnant, indicated by section p in Fig. 2, causing the light emitted from the two point sources located against the wall to be lost. These two point sources are therefore omitted in Fig. 2. and it also shows the lengths of the wall segments considered.



Segment	l_s (m)
1/10/12	$2.5.10^{-4}$
2/9/13	6.10^{-4}
3/8/14	1.10^{-3}
4/7/15	1.10^{-3}
5/6/16	1.10^{-3}
P	$4.5.10^{-4}$

Fig. 2. Light directions in a monolith channel illuminated by two side-light fibers and length of the segments considered in the monolith walls.

The light intensity for each point source, with radius r_p is obtained by Eq. (3) where I is the incident light flux at z = 0 and r_f the fiber radius. For each point source it is considered that 50% total of light is lost in the wall of the corner behind the fibers. As shown in the Fig. 1, segment p is not illuminated by light source 1. The same procedure is followed for the other point sources.

$$I_p^{"} = \frac{1}{4} I_0^{"} \frac{r_f}{r_p} \tag{3}$$

Fig. 2 shows that each light beam forms a right triangle. Considering point source 1, the incident light flux at the surface of each segment (in this case 1 to 15), $I_s^{"}$, can be estimated with Eq. 4. Here L_i is the distance between the light point source and the surface in segment 1, as calculated by using Eq. 5. In this equation l_i is the distance as indicated in Fig. 2.

$$I_s^{"} = \frac{I_0^{"} r_f}{4} \frac{\sin(\alpha)}{L_i} \tag{4}$$

$$L_i = \sqrt{\left(r_f\right)^2 + \left(\frac{l_i}{2}\right)^2} \tag{5}$$

Since the total amount of light irradiated must be equal to the total amount of light received at all the segments, Eq. 6, a correction factor is introduced given by Eq. 7. The recalculation of the local light at the catalyst external surface becomes Eq. 8.

$$\frac{I_0^{"} 2\pi r_f}{4} = c_f \frac{I_0^{"} r_f}{4} \sum_{i=1}^{15} \left(l_i \frac{\sin(\alpha)}{L_i} \right) \tag{6}$$

$$c_f = \frac{2\pi}{\sum_{i=1}^{15} \left(l_i \frac{\sin(\alpha)}{L_i} \right)} \tag{7}$$

$$I_s^{"} = c_f \frac{I_0^{"} r_f}{4} \frac{\sin(\alpha)}{L_i} \tag{8}$$

From the surface to a certain depth (x) into the catalyst layer in a perpendicular direction, the intensity will be attenuated according to a Lambert-Beer law type of equation, Eq. 9.

$$I_x^{"} = I_s^{"} e^{\frac{-bx}{\sin(\alpha)}} \tag{9}$$

The effective surface reaction rate for point source 1, i.e. the rate per unit area of external coating surface, is obtained by integration of the reaction rate over the depth of the coating using the linear absorption coefficient *b* and assuming the chemical reaction rate to be proportional with the light intensity to the power *m* yielding Eq. 10. The rate depends on the intensity of the light reaching the wall section ($I_s^{"}$), the incident angle (α), the linear absorption coefficient (b), the proportionality power of the light intensity (m), the reaction order (n), and the concentrations of the reactant (C_A) and the concentration of the active sites in the coating (C_{sites}). Since there is no significant diffusion limitation inside the porous walls, the total activity follows from integration over the depth (i.e. C_A and C_{sites} are independent of x), that yields Eq. 11 for the case where the layer thickness is much higher than the penetration depth.

$$r_i = \left(I_s^{"} \right)^m e^{\frac{-mbx}{\sin(\alpha)}} k_i C_A^n C_{sites} \tag{10}$$

$$\int_0^x \left(\left(I_s^{"} \right)^m e^{\frac{-mbx}{\sin(\alpha)}} \right) dx = \left(I_s^{"} \right)^m \left(\frac{\sin(\alpha)}{mb} \left(1 - e^{\frac{-mbx}{\sin(\alpha)}} \right) \right) \approx \left(I_s^{"} \right)^m \left(\frac{\sin(\alpha)}{mb} \right) \tag{11}$$

Thus, the reaction rate multiplied with the depth for the 4 light sources considered is given by Eq. 12 in the case of 1 segment.

$$xr_i = \sum_{i=1}^{4} \left\{ \left(c_f \frac{r_f}{4} \frac{\sin(\alpha)}{L_i} \right)^m \frac{\sin(\alpha)}{mb} \right\} \left(I_0^{"} \right) k_i C_A^n C_{sites} \tag{12}$$

To finalize, this geometric term takes into account the 5 segments at the 3 walls that each light source can illuminate.

Results and discussion

The model developed has been validated. Results showed that, intrinsically, and only comparing the TIR and the IIMR for a range of light intensities, the IIMR results in a higher conversion for a first order reaction, Fig.3. For each photoreaction considered this model has to be adapted since a reaction may be limited by the *photo-physical properties of the catalyst* (interaction of the semiconducting material with light) or by the *surface chemistry* (formation of radicals/active sites on the surface). Modeling results will be presented for a specific photoreaction.

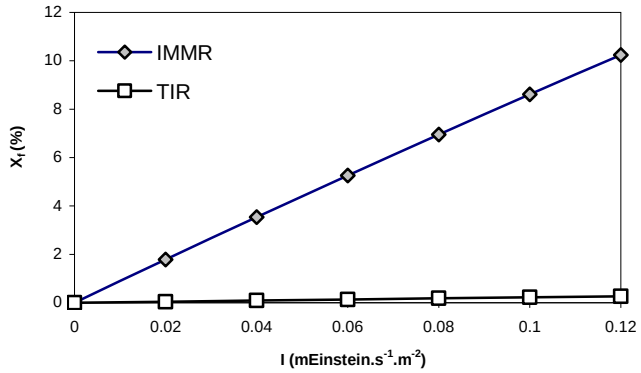


Fig. 3. Model results for the conversion vs light intensity for the two photoreactors in study.

With the reaction studied by our group, the cyclohexane selective photo-oxidation, several drawbacks make a comparison between the experimental values and the model values difficult. The reaction mechanism is not fully developed yet, and slow product desorption doesn't allow full quantification of the product formed (Du et al. 2008). Furthermore, catalyst deactivation is extensive. We observed that the values delivered by the model were higher for both reactors, when compared with the experimental ones, which was expected. Furthermore this model offers a very flexible design since it is possible to change the dimensions of the reactors and lamps in order to adapt to each situation. The dimensions of the reactors can be modified for the slurry system and the IIMR maintaining the principle of each photoreactor.

Future work will consist of evaluation of the model with a simple photocatalytic reaction (in water, limiting catalyst deactivation), and study of the effect of hydrodynamics on reactor preformance.

Conclusions

A model for a novel multiphase photoreactor was developed. The light distribution inside each monolith channel was described. The model predicts that for the same initial light intensity and a first order reaction, the IMMR results in a higher conversion as compared to the TIR. Furthermore the reaction performed for validating the model (cyclohexane oxidation) has several intrinsic drawbacks, leading to significant differences between experimental and theoretical values for the conversion. We propose to perform a simple photocatalytic reaction to further validate the model, such as the photocatalytic decomposition of formic acid.

Topic: Advancing the chemical engineering fundamentals.

Abstract

In the present work a new methodology to estimate a mean bubble size (d_B) in internal-loop airlift reactor (ALR) is proposed. The semi-theoretical method is based on Higbie´s penetration theory and uses for the estimative of d_B the experimental data of gas hold-up (ε) and volumetric mass transfer coefficient (k_La) obtained in three scales of internal-loop ALR of 2, 5 and 10 dm^3. Mean bubble size (d_B) and convective oxygen transfer coefficient (k_L) showed it is not dependent on the superficial gas velocity (U_{GR}) for all scales in the experimental range studied. The results indicate the k_La is a function only of the gas-liquid interfacial area of the bubbles (a) and therefore of the gas hold-up (ε).

1. Introduction

Internal-loop airlift reactors (ALR) are a special class of pneumatic reactors. This type of reactor is attractive for chemical and biological reactions due to their inexpensive and simple construction without moving mechanisms and low energy costs, when compared to stirred tank reactors (Blažej *et al*., 2004a).

One of the most significant parameters in the design of such airlift reactors is the volumetric mass transfer coefficient (k_La) commonly used to evaluate the capacity of oxygen transfer in bioreactors. This quantity depends on the system geometry and fluid properties which are related to several other parameters (Ruen-gnam *et al*., 2008). Most investigations performed on aerobic systems are limited to the determination of the k_La. Unfortunately, this parameter is global and insufficient to provide an understanding of the mass transfer mechanisms. Normally, the influence of each parameter, convective oxygen transfer coefficient (k_L) and interfacial area of the bubbles (a), in the oxygen mass transfer rate are not clear. Therefore, the separation of the parameters k_L and should be considered for a better comprehension of gas-liquid mass transfer mechanisms (Bouaifi, *et al* 2000). The interfacial area (a) can be determined from the fractional gas hold-up and the mean bubble diameter (d_B), which is a very important parameter in gas liquid reactor design and a good criterion for evaluating the efficiency of gas liquid contactor. Small bubbles and a uniform distribution over the cross section of the equipment are desired to maximize the interfacial area, hence improving transport phenomena.

Many authors have studied the influence of the bubble size in the mass transfer phenomena; most of the bubble size measurements were taken using photographic techniques. Tung *et al.* (1998) compared the bubble size and hydrodynamic behavior in airlift and bubble column reactors. They noticed that the circulation velocity did not have a significant effect on bubble size, however it had a large influence on the bubble frequency. Wongsuchoto *et al.* (2003) investigated the effect of various designs and operating parameters on bubble size distribution in annulus sparged airlift contactors. It was found that the interfacial area, rather than the mass transfer coefficient, played a more significant role in controlling the overall oxygen transfer rate in the system. At high superficial air velocity (U_G), the bubble size was smaller and uniform. In the range of U_G from 0 to 0.08 $m.s^{-1}$, the average bubble diameter was found to be between 3 and 8 mm. Ruen-gnam *et al.* (2008) investigated the effect of

salinity on the performance of an ALR. The bubble mean diameter appeared to be smaller in saline water than in fresh water. For fresh water, the average bubble diameter was found to be between 5 and 8 mm in the range of U_{GR} from 0 to 0.06 $m.s^{-1}$.

Mass transfer by convection involves the transport of material between a boundary surface and a moving fluid or between two relatively immiscible moving fluids. The determination of the mass transfer coefficient is not a simple undertaking. It is not related to the physical properties of the fluid, to the dynamic characteristics of the flowing fluid and the geometry of the system. It is the reason for expecting an analytical treatment to estimate k_L. At constant temperature, any improvement in the k_L, and therefore k_La, may be achieved only by changes in the liquid film thickness (two-film theory), the exposure time (penetration theory) or surface renewal rate (surface renewal theory), depending on the mass transfer hypothesis that is chosen (Cerri *et al*., 2008). The oxygen transfer rate depends not only on the gas hold-up and bubble size but also on the value of k_L. The liquid side mass transfer coefficient k_L depends on the diffusivity coefficient and turbulence created in the liquid phase (Bouaifi, *et al* 2000). According to the results of Wangsuchoto *et al.* (2003), the k_L to pure water in an ALR is constant in the range of U_{GR} from 0 to 0.08 $m.s^{-1}$. Ruen-ngam *et al*. (2008) found that this system with water provided a higher level of k_L than saline solutions.

In the literature review there are many works where the bubble size measurement in pneumatic reactors is conducted by experimental methods, but none of them present a correlation to estimate the bubble size. Therefore, the aim of this work proposes a methodology to predict the convective oxygen transfer coefficient (k_L) and the mean bubble diameter (d_B) from experimental values of volumetric oxygen transfer coefficient (k_La) and gas hold-up (ε) in three scales of internal-loop ALR (2, 5 and 10 dm^3) with similar geometric configurations using water as the liquid phase.

2. Materials and Methods

Fluids: Distilled water at 28 ºC was used as Newtonian fluid.

Equipments: concentric-tube airlift reactors (ALR) with 2, 5 and 10 dm^3 total working volumes were used in this study. The external tube was made of glass, but the bottom and top plates, the draft tube, the gas sparger, and the condenser were made of stainless steel. The temperature of the reactor was controlled by the circulation of water through the hollow draft tube. Geometrical characteristics, relationships between distances are shown in Table 1 for the three different scales of airlift bioreactor. The holes of the cross-piece type sparger are 0.5 mm diameter and are spaced at 5 mm (Badino *et al.*, 2006).

Volumetric oxygen transfer coefficient (k_La): the volumetric oxygen transfer coefficient ((k_La) was determined by the dynamic pressure-step method (Blažej et al. 2004b). In this experimental method, the pressure in the vessel is changed abruptly by approximately 15 kPa, and an increase in the dissolved oxygen concentration (C_e) in the bubble dispersion occurs regardless of the gas flow pattern. Equation 1 was fitted to the experimental data (C_e as a function of time) and k_La values were estimated through the procedure that uses the least squares non-linear regression.

$$C_e = C_{e0} \cdot e^{-k_e \cdot (t-t_0)} + C_{es} \cdot (1 - e^{-k_e \cdot (t-t_0)}) + \frac{k_e \cdot (C_{es} - C_{e0})}{k_e - k_L a} \cdot (e^{-k_e \cdot (t-t_0)} - e^{-k_L a \cdot (t-t_0)}) \qquad (1)$$

In Equation 1, C_{e0} is the signal of the electrode in the initial condition when $t = t_0$; C_{es} is the signal of the electrode or the dissolved oxygen concentration in the liquid phase in the saturation with air, and k_e is the time constant of the oxygen probe calculated from the inverse of the response time (τ_e). The response to a unit step function, in triplicate, allowed the calculation of k_e = 0.125 s^{-1} assuming the "first order response". The dissolved oxygen concentration was measured by means of a sterilizable amperometric electrode (Mettler-Toledo, model InPro 6800) bearing a Teflon membrane (Mettler-Toledo, model InPro T96). Values of k_La were obtained in duplicate for Newtonian and non-Newtonian systems with the superficial gas velocity (U_{GR}) for the three scales of airlift bioreactor.

Gas hold-up (ε): The gas holdup was determined by measuring the increase in height of the dispersion upon aeration as follows (Chisti, 1989):

$$\varepsilon = \frac{h_D - h_L}{h_D} \tag{2}$$

where h_D is the height of the gas-liquid dispersion and h_L is the height of gas free liquid.

Table 1. Geometric characteristics of the three scales of concentric-tube internal-loop ALR

Liquid volume (dm^3)	2.0	5.0	10.0
H1 (m)	0.032	0.045	0.055
H2 (m)	0.033	0.055	0.045
H3 (m)	0.262	0.350	0.450
H4 (m)	0.327	0.450	0.550
H5 (m)	0.450	0.600	0.700
De2 (m)	0.100	0.135	0.170
H4/De1	3.63	3.60	3.44
A_D/A_R	1.68	1.78	1.84
D_{i2}/De1	0.61	0.60	0.59

Theory: the prediction of the convective oxygen transfer coefficient (k_L) in the ALR was made according to a theoretical mass transfer model based on Higbie´s penetration theory.

$$k_L = \frac{2}{\sqrt{\pi}} \cdot \sqrt{\frac{D_L}{\theta}} \tag{3}$$

where D_L is the oxygen diffusivity and θ is the surface renewal time, which is defined in terms of the mean diameter of the bubbles (d_B) and the bubble liquid slip velocity (u_S) by Shamlou *et al.* (1995) as follows:

$$\theta = \frac{d_B}{u_S} \tag{4}$$

The bubble liquid slip velocity (u_S) is proposed by Ruen-ngam *et al.* (2008) as follows:

$$u_S = \frac{u_\infty}{(1-\varepsilon)} \tag{5}$$

Talaia (2008) proposed a new model to determine the terminal velocity of bubble (u_∞):

$$u_\infty = 0.694 \cdot \left(\frac{g \cdot d_B \cdot \Delta\rho}{\rho_L} \right)^{1/2} \tag{6}$$

The relationship between k_L and d_B (ψ) was proposed by Chisti (1989), where ψ can be obtained experimentally using k_La and gas hold-up (ε).

$$\frac{k_L}{d_B} = \psi = \frac{k_L a \cdot (1-\varepsilon)}{6 \cdot \varepsilon} \tag{7}$$

Substituting equation 6, 5 and 4 into equation 3 and rearranging it, results in semi-empiric (or semi-theoretical) correlation to calculate the d_B from experimental values of k_La and ε. Values of k_L can be calculated from equation 7.

$$d_B = \left(\frac{4 \cdot D_L \cdot 0.694}{\pi \cdot (1-\varepsilon) \cdot \psi^2} \right)^{\frac{2}{5}} \cdot \left(\frac{g \cdot \Delta\rho}{\rho_L} \right)^{1/5} \tag{8}$$

3. Results and Discussion

From experimental data of k_La and gas hold-up (ε), the values of d_B for the three scales of ALR were estimated by equation 8 and are presented in Figure 1 as function of the superficial gas velocity in the riser region (U_{GR}). The results of d_B obtained by the proposed

method are in excellent agreement with the experimental values found in recent literatures (Wongsuchoto *et al.*, 2003 and Ruen-ngam *et al.*, 2008). It can be observed in Figure 1 that d_B changed with U_{GR} in a close range between 3 and 5.5 mm for three scales of the bioreactor studied. These results are in agreement with those of Wangsushoto *et al*. (2003) that observed a d_B range from 3 to 8 mm. Tung *et al.* (1998) also observed that U_{GR} has a weak influence on the mean bubble diameter (d_B), but a strong influence on bubble frequency (number).

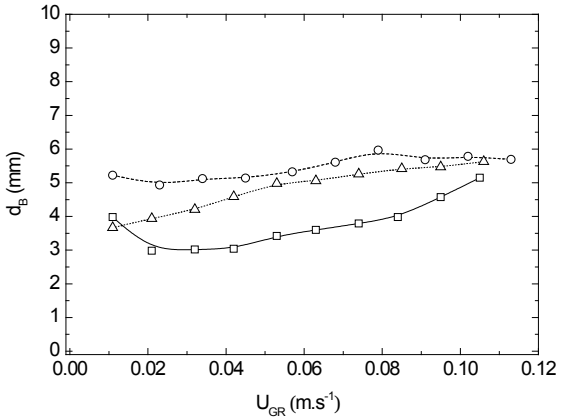

Figure 1: Mean bubble diameter (d_B) as a function of U_{GR}. (□) 2 dm^3, (○) 5 dm^3, (Δ) 10 dm^3.

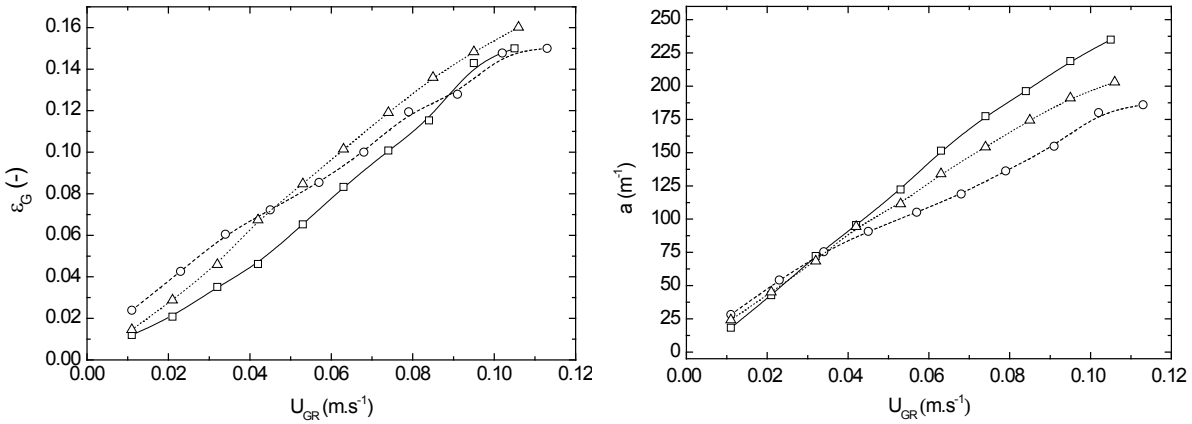
The results of gas hold-up (ε) and interfacial area (a) as a function of the superficial gas velocity (U_{GR}) are illustrated in Figure 2. It can be observed in Figure 2a that ε increases with the increase of U_{GR} in the experimental range investigated and the ε values are very close to the three scales of ALR. A similar behavior is observed in Figure 2b for interfacial area (a). As the d_B is practically constant with U_{GR}, "a" is a direct function of the gas hold-up (ε) according to equation 9. Therefore, the gas hold-up is the main factor which influences the interfacial area of the bubbles.

$$a = \frac{6 \cdot \varepsilon}{d_B \cdot (1 - \varepsilon)} \tag{9}$$



(a) (b)

Figure 2. Effects of superficial gas velocity (U_{GR}) in (a) gas hold-up (ε) and (b) interfacial area (a) for three scales of ALR: (□) 2 dm^3, (○) 5 dm^3, (Δ) 10 dm^3.

The volumetric oxygen mass transfer (k_La) is a product of the liquid-film convective oxygen transfer coefficient (k_L) and the interfacial area (a). Figure 3 shows the dependence of k_L, calculated by equation 3, with the superficial gas velocity (U_{GR}).

It can be observed in Figure 3 that for all ranges of U_{GR} (0.01 - 0.11 $m.s^{-1}$) the value of k_L remained nearly constant for the three scales of ALR studied.

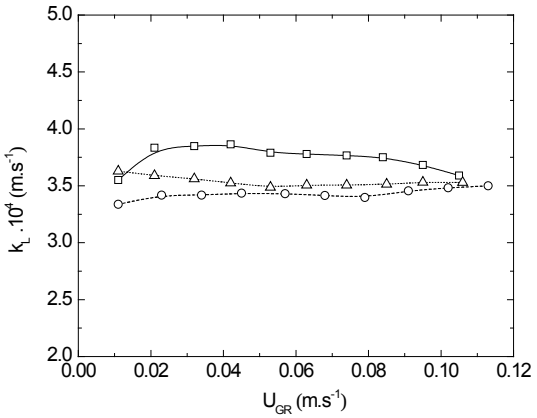


Figure 3. Convective oxygen transfer coefficient (k_L) as a function of U_{GR} for three scales of ALR: (□) 2 dm^3, (○) 5 dm^3, (Δ) 10 dm^3.

This demonstrates that the increase in the values of k_La with an increase of U_{GR} is due to the gas-liquid interfacial area (a) and not to the convective oxygen transfer coefficient (k_L). As demonstrated before, "a" is a direct function of the gas hold-up (ε). It shows that k_La depends solely on the gas hold-up (ε). Therefore, this observation should be considered in the design of ALRs. In a recent work, Ruen-ngam *et al*. (2008) investigated the effect of salinity on k_L in a 17 dm^3 internal-loop ALR using water and salt solutions as liquid phase. The results revealed that k_L only became significantly different at high values of U_{GR}. For low values of U_{GR}, the convective oxygen transfer coefficient remains practically constant. In Figure 4, k_La is plotted as a function of $6\cdot\varepsilon/(1-\varepsilon)$. Equation 7 was fitted to the experimental data for three scales of ALR. The slopes of the curves ($k_L/d_B=\Psi$) were obtained as follows:

2 dm^3: $\Psi=0.065\ s^{-1}$ ($R^2=0.98$)

5 dm^3: $\Psi=0.060\ s^{-1}$ ($R^2=0.993$)

10 dm^3: $\Psi=0.059\ s^{-1}$ ($R^2=0.998$)

The excellent fitting can be noted between the calculated and experimental data. The values of $k_L/d_B=\Psi$ were very close among each other and when compared to those of the literature (Mirón *et al.*, 2000). The fact that the relation $k_L/d_B=\Psi$ is constant demonstrates the non-dependence of k_L and d_B with operational conditions as previously discussed.

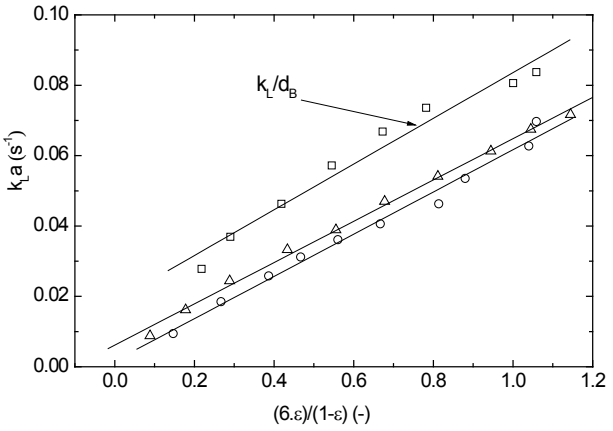

Figure 4. Volumetric oxygen transfer coefficient (k_La) as a function of $6\cdot\varepsilon/(1-\varepsilon)$ for three scales of ALR: (□) 2 dm^3, (○) 5 dm^3, (Δ) 10 dm^3.

4. Conclusions

This work proposed a simple methodology for evaluating the mean bubble size in internal-loop ALR using an air-water system. The results showed that the variable responsible for the increase of the bubbles' interfacial area is the gas hold-up, because the mean bubble-size value was independent of the superficial gas velocity (U_{GR}). The convective oxygen transfer coefficient (k_L) was dependent on the physical properties of fluid and on the mean bubble size, remaining practically constant for any values of U_{GR}. The fact that the relation $k_L/d_B=\Psi$ is constant demonstrated the non-dependence of k_L and d_B with operational conditions. It is an important conclusion for the design of bioreactors, indicating that the gas hold-up is the principal variable to increase the volumetric oxygen transfer coefficient (k_La), excluding the operational conditions and should be taken into account for the scale-up of this type of bioreactor.

Abstract

In this work, the aqueous solubilities of four hydroxybenzoic acids and four phenilpropenoic acids were measured as function of temperature (between 288.15 and 323.15 K), using the shake-flask method, followed by compositional analysis by spectrophotometry. In the modeling, two approaches were used: the modified UNIQUAC model and the Cubic-plus-Association equation of state. CPA is used with a new methodology that explicitly takes into account the number and nature of the associating sites and predicting the pure component parameters only from molecular structure. Both approaches show to be appropriate to represent the water solubility of these molecules.

1. Introduction

Numerous molecules in the pharmaceutical, food and chemical industries present complex chemical structures with different functional group substitutions. Many of these groups such as amine, carboxyl and hydroxyl can form hydrogen bonds. To adequately describe the phase equilibria of these complex chemicals, models able to take into account association effects are required. Still, for model development and evaluation, experimental data on some representative systems are needed. In this work, new experimental measurements and literature data were combined to develop a methodology to model the phase equilibria of phenolic acids using the Cubic-plus-Association (CPA) equation of state (Mota et al., 2008). A comparison with the modified UNIQUAC activity coefficient model (Peres and Macedo, 1996) is also presented.

Within the different classes of multifunctional associating molecules, phenolic compounds, due to their chemical and biological importance, are among the most important, having properties like antioxidant, chelating, free-radical scavenging, anti-inflammatory, antialergic, antimicrobial, antiviral, anticarcinogenic, chemopreventive and Uv filtering properties. Fruits, vegetables, spices and aromatic herbs are a natural source of these compounds. Apart from being starting materials for many chemical synthesis, such as some drugs, cosmetics, antioxidants, antiseptics and flavors, they can be used in the preparation of resins, plasticizers, dyes, inks and pharmaceutical products. There is also huge evidence that some phenolic compounds have beneficial effects on human health. Perhaps the oldest medical application of phenolic compounds is the use of phenol as antiseptic (Vermerris and Nicholson, 2006). Another very common use of these compounds is in sunscreens. Because their hydrogen-bonding ability and aromaticity, they can frequently act as free-radical scavengers, forming aryloxyl radicals. The stabilization of these radicals by other functional groups enhances the antioxidant activity (Chen and Ho, 1997). They also have ability to scavenge the oxidative radicals that are caused by cumulative and prolonged exposure to Uv

* Corresponding author. Tel +351 225 081 686. E-mail:ajq@fe.up.pt

radiation, which has been recognized to induce harmful reactions in human skin (Saija et al., 2000). Also, the low incidence of coronary heart disease, artherosclerosis and some types of cancer has been correlated by several authors with the phenolic content of olive oil (de Lorgeril et al., 1999).

Although the importance of these molecules is well known, very few solubility data are available and comprehensive experimental studies combining solubility with melting properties and acidity constants are clearly lacking in literature. In this work, aqueous solubilities of the hydroxybenzoic acids, salicylic, gallic, protocatechuic and syringic, and the phenilpropenoic acids, cinnamic, ferulic, coumaric and caffeic, were addressed. The work is part of a project concerning the solubility of natural phenolic compounds in water and organic solvents. Its final aim is to understand and predict their solubility in different solvents and to adequately understand the fate and separation processes of these molecules.

2. Experimental

Solid-liquid equilibria of hydroxybenzoic acids such as gallic, salicylic, syringic and protocatechuic acids and phenilpropenoic acids such as trans-cinnamic, ferulic, o-coumaric and caffeic acids were measured from 288 K up to 323 K using the analytical shake-flask method. Particular attention was given to aqueous solubilities. Constant-temperature jacketed glass cells were used to prepare the saturated solutions, where excess solute and solvent were mixed and stirred in a plate stirrer. Temperature was maintained constant with a constant-temperature circulating water bath and monitored with platinum resistance probes placed in the thermostatic jackets connected to a data acquisition unit. Some phenilpropenoic acids were reported to suffer photodegradation with daylight, and to prevent that, the cells were isolated with aluminum foil. When the equilibrium was attained, the agitation was stopped and then the solution was kept still, to allow undissolved solid to settle. Samples were taken from the liquid phase using plastic syringes coupled with syringe filters previously thermostatized at the equilibrium temperature and analyzed by spectrophotometry. The corresponding pHs of the saturated aqueous solutions were determined by potentiometry with a glass electrode. To verify the accuracy of the spectrophotometric method, some measurements were performed using the gravimetric method.

Besides solubility data, the melting properties (fusion enthalpies and temperatures) were also determined by DSC. Because phenolic compounds are organic acids, their acid dissociation constants (pKa) were obtained by potentiometric titration of aqueous solutions with aqueous NaOH solutions.

3. Modeling

The scarcity of literature data increases the importance of the development of correlation and prediction models. Different approaches can be used for modeling the solid solubility. In this work, an activity coefficient model, the modified UNIQUAC (Peres and Macedo, 1996) and an equation of state, the CPA EoS (Mota et al., 2008) were evaluated for modeling the measured data, neglecting the heat capacity term in the general solid-liquid equilibria equation (Prausnitz et al., 1999).

As both the solute and the solvent can associate (self and cross-association is present in these mixtures), the CPA EoS was adopted in this work. In terms of compressibility factor (Z), this equation can be expressed as the sum of two contributions: one accounting for physical interactions (in this work the Soave-Redlich-Kwong-EoS is used), and another accounting for the association contributions (the Wertheim association term).

$$Z = Z^{phys.} + Z^{assoc.} = \frac{1}{1-b\rho} - \frac{a\rho}{RT(1+b\rho)} - \frac{1}{2}\left(1+\rho\frac{\partial \ln g}{\partial \rho}\right)\sum_i x_i \sum_{A_i}(1-X_{Ai}) \quad (1)$$

where *a* is the energy parameter, *b* is the co-volume parameter, ρ the density, *g* a simplified hard-sphere radial distribution function, X_{Ai} the mole fraction of pure component *i* not bonded at site A, x_i the mole fraction of component *i*, *R* the ideal gas constant and *T* the absolute temperature. The pure component energy parameter is obtained from:

$$a(T) = a_0\left[1+c_1\left(1-\sqrt{T_r}\right)\right]^2 \quad (2)$$

where a_0 and c_1 are constants and T_r is the reduced temperature. The mixture *a* and *b* parameters are obtained through the classical mixing and combining rules, with a single, temperature-independent binary interaction parameter being used in the cross-energy parameter (a_{ij}):

$$a_{ij} = \sqrt{a_i a_j}\left(1-k_{ij}\right) \quad (3)$$

X_{Ai} is related to the association strength $\Delta^{A_iB_j}$ between two sites belonging to two different molecules and is calculated by solving the equation:

$$X_{Ai} = \frac{1}{1+\rho\sum_j x_j \sum_{B_j} X_{Bj}\Delta^{A_iB_j}} \quad (4)$$

For self-associating molecules,

$$\Delta^{A_iB_i} = g(\rho)\left[\exp\left(\frac{\varepsilon^{A_iB_i}}{RT}\right)-1\right]b_{ii}\beta^{A_iB_i} \quad (5)$$

where $\varepsilon^{A_iB_i}$ and $\beta^{A_iB_i}$ are the association energy and the association volume, respectively, and g(ρ) is a radial distribution function. For sites that belong to two different associating molecules, the Elliot combining rule is used:

$$\Delta^{A_iB_j} = \sqrt{\Delta^{A_iB_i}\times\Delta^{A_jB_j}} \quad (6)$$

As the studied phenolic acids are multifunctional associating molecules, a new methodology is proposed to take into account the different associating groups as well as their repetitions and ring positions in the chemical structure. Values for the associating energies and volumes of these groups are proposed. Additionally, to effectively model their water solubility, the acid dissociation must also be considered (Mota et al., 2008). Different results will be used to demonstrate the reliability of the proposed model.

Following a more classic approach, the UNIQUAC equation is also applied. It consists of two terms: a combinatorial one that attempts to describe the dominant entropic contribution (that depends on the composition, sizes and shapes of the molecules), and a residual one that is due mainly to the intermolecular forces responsible for the enthalpy of mixing. Peres and Macedo (1996) proposed a modified version of this model, that turned to be very successful in the representation of highly associating mixtures.

4. Discussion

Among the hydroxybenzoic acids, protocatechuic and gallic acids present higher solubilities due to the higher number of hydroxyl groups, leading to increased association interactions with water. When possible, our results were compared with the literature data. For gallic acid, our results, were compared with published data (Lu and Lu, 2007), showing a slight disagreement at lower temperatures. Our results for gallic, protocatechuic and syringic acids were compared to the results obtained by Noubigh et al. (2007), but their data do not

increase significantly with temperature, which is contrary to what would be expected. For salicylic acid, our results are in good agreement with previous works (Apelblat and Manzurola, 1989; Nördstrom and Rasmuson, 2006; Peña et al., 2004), as can be seen from Figure 1. In the phenilpropenoic series, higher solubilities were found for caffeic, followed by ferulic, coumaric and cinnamic acid. This order follows the extent of hydrogen bonding of each molecule with water. For ferulic acid, our results are very different from those obtained by Noubigh et al. (2007), but the equilibrium time reported by these authors are very different from ours: while we had equilibrium times between 64h and 84h, depending on the working temperature, these authors had always equilibrium times of 3 hours. Ferulic acid is reported to have two polymorphic forms that are obtained by recrystallization from various solvents (Sohn and Oh, 2003). Thus, we may be comparing different crystalline structures of the same compound, which may explain the different results. For cinnamic acid, our value compare well with the value given in the *Merck Index* (O'Neil and Budavari, 2001).

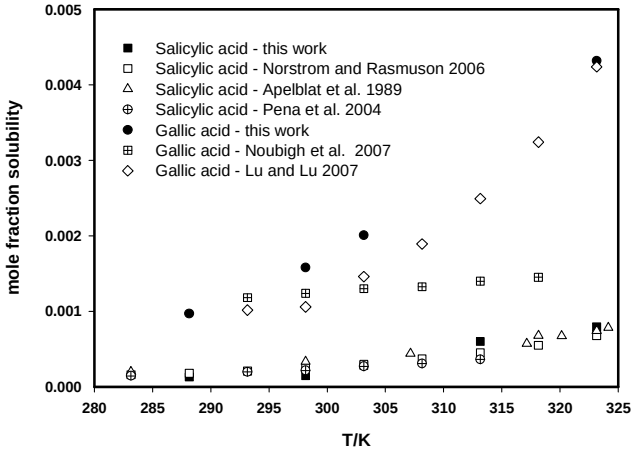

Figure 1. Solubility of hydroxybenzoic, gallic and salicylic acids in water, as function of temperature.

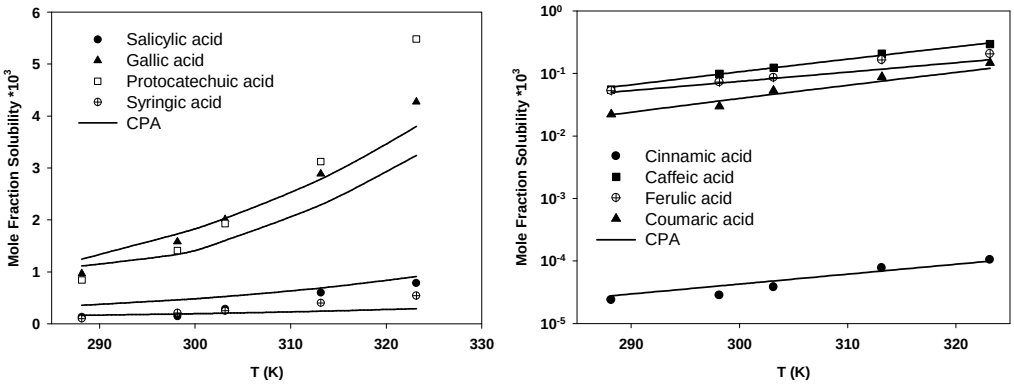
Another important fact about solubilization of solids in liquids is related to the fusion enthalpies and melting temperatures. From the results found so far, it can be concluded that the extent of hydrogen bonding with water is certainly more important than the fusion process for determining the degree of solubilization. Also, the results for the acid dissociation constants lead to the conclusion that acid dissociation is not so important in the solubilization process of these molecules (Mota et al., 2008).

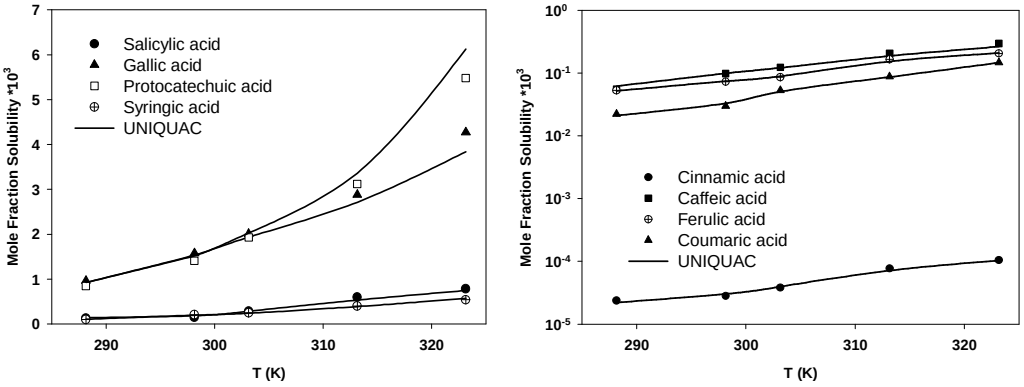
CPA parameters are frequently obtained from pure-component vapor-pressure and liquid-density data. In the particular case of the phenolics studied in this work, these data are only available for salicylic and cinnamic acids. Another drawback is the presence of different associating groups on the same molecule, some of them repeated in different positions. Thus, it is appropriate to individually assign association energies and volumes for each group and to consider multiple group substitution, either or not with the same association parameters. These parameters were obtained using the critical temperatures, pressures and van der Waals volumes (Mota et al., 2008), obtained from Marrero and Gani (2001) and Bondi (1964) group-contribution approaches. As can be seen from Figures 2 (a) and (b), a good description can be achieved with the CPA-EoS, but a small k_{ij} value was always required to obtain smaller deviations. Still, in all cases, only a single, temperature-independent k_{ij} value was sufficient. Maximum absolute average deviations of 59% were obtained for salicylic acid and 53% for ferulic acid, while for the other phenolics the average deviations did not exceed 30%.



(a) **(b)**

Figure 2. Experimental solubility data and modeling results by CPA for (a) hydroxybenzoic acids (b) phenilpropenoic acids. Modeling results: gallic acid, k_{ij} = -0.13; salicylic acid, k_{ij} = -0.06; protocatechuic acid, k_{ij} = -0.10; syringic acid, k_{ij} = -0.17; *trans*-cinnamic acid, k_{ij} = -0.05; caffeic acid, k_{ij} = -0.10; ferulic acid, k_{ij} = -0.13; and coumaric acid, k_{ij} = -0.05.

For the modified UNIQUAC model, the residual term binary interaction parameters were fitted to the measured data. Two temperature independent interaction parameters were regressed per binary water + phenolic system. In the next figures, the experimental and calculated solubilities are compared, with an excellent description being obtained. The root mean square deviations (RMSD) are smaller than 5% and the absolute average deviations (AAD) smaller than 9% for the correlation of all studied systems.



(a) **(b)**

Figure 3. Experimental solubility data and modeling results by modified UNIQUAC model for (a) hydroxybenzoic acids (b) phenilpropenoic acids.

5. Conclusions

In this work, aqueous solubility data were measured for some phenolic compounds, in the temperature range from 288 K to 323 K, using the shake-flask method, coupled with spectrophotometric analysis. For all compounds under study, the solubility follows the general increasing trend with temperature. Besides solubility, melting data and apparent acid dissociation constants were also determined, providing a broader knowledge about the solubilization processes of these molecules. From the measured data, it can be concluded that the extent of hydrogen bonding with water is the dominant effect in determining the degree of solubilization.

The CPA EoS was used with different association energies and volumes for the different associating groups. A methodology to obtain the pure-component parameters without requiring experimental data was developed, and the results indicate that CPA is an adequate tool to correlate the water solubility of these molecules. The modified UNIQUAC model, with two adjustable parameters from solubility data, showed and excellent description of solubilities of these phenolics compounds.

Topic: Suitable conference topic — Advancing the chemical engineering fundamentals, ionic liquids

Abstract

In this study, the mutual diffusion coefficients of some ionic liquids (ILs) in water at infinite dilution for temperatures (303.2 to 323.2) K were measured using the Taylor dispersion technique. The investigated ILs were as follows: 1-ethyl-3-methylimidazolium dicyanamide [Emim][C_2N_3], 1-ethyl-3-methylimidazolium tetrafluoroborate [Emim][BF_4], 1-ethyl-3-methylimidazolium ethylsulfate [Emim][$EtSO_4$], 1-ethyl-3-methylimidazolium trifluoromethanesulfonate [Emim][CF_3SO_3], and 1-ethyl-3-methylimidazolium 2-(2-methoxyethoxy) ethylsulfate [Emim][$MDEGSO_4$]. The present diffusion coefficients data were correlated using two different approaches: (a) the diffusing component was treated as an organic solute using the Wilke–Chang equation and (b) as an electrolyte solute using the Nernst–Haskell equation. The Wilke–Chang equation underestimated the present data of diffusion coefficients, thus, it was modified by introducing temperature-dependent empirical parameters and the results were satisfactory. The Nernst–Haskell equation requires infinite dilution conductances of ions and to this end, the molar conductivities of several infinitely dilute concentrations of aqueous ionic solutions for the temperatures (303.2 to 323.2) K were also measured using a commercial conductivity meter. Considering the experimental error involved and that no adjustable parameter was used, the predictions using the Nernst–Haskell equation are reasonably accurate.

Introduction

Since the vapor pressure of ILs is very small, the most likely way for them to pollute the environment is in the waste water stream. To predict the behavior of a chemical substance in the waste water stream, it is important to know such physical properties as partition and sorption coefficients and solubility in water. For several imidazolium-based ILs, Ropel *et al.* (2005), reported the partition coefficients (index of bioaccumulation in an aquatic environment)

to the mixture of 1-octanol and water. The study of Wong *et al.* (2002) reported the solubility of [emim][PF_6] and [bmim][PF_6] in water.

Aside from the previously mentioned properties, another important property that can be used to determine the ability of IL to spread in the environmental stream (water) is the diffusion coefficients. In the past years, a number of measurements of diffusion coefficient for different species such as carbon dioxide and several hydrofluorocarbons, in ILs were reported by different research groups (Every *et al.*, 2000; Every *et al.*, 2004; Morgan *et al.*, 2005; Shiflett and Yokozeki, 2005; Shiflett and Yokozeki, 2006). However, there were few data of diffusion coefficients of ILs in solvents, even in water. Richter et al. (2003) reported the diffusion coefficient measurements of molten salts and ionic liquids in methanol using digital image holography. Su et al. (2007) reported diffusion coefficient measurements of alkylimidazolium tetrafluoroborates and hexafluorophosphates in water at 303.2 K using Taylor dispersion experiment.

Thus, in this present work, we reported the measurements of diffusion coefficients of five [Emim]-based ILs for the temperatures ranging from (303.2 to 323.2) K using Taylor dispersion method. The studied ILs were [Emim][C_2N_3], [Emim][BF_4], [Emim][$EtSO_4$], [Emim][CF_3SO_3], and [Emim][$MDEGSO_4$]. The present diffusion coefficients data were correlated using two different approaches: (a) the diffusing component was treated as an organic solute using the Wilke–Chang equation (Wilke and Chang, 1955) and (b) as an electrolyte solute using the Nernst–Haskell equation (Robinson and Stokes, 1965). In the prediction of diffusion coefficients using Wilke–Chang equation, the density values of the solute (IL) and viscosity of the solvent (water) were needed, so the densities and viscosities at the studied isotherms, (303.2 to 323.2) K, were also determined. The densities of ILs were measured while the viscosities of water were calculated from a reliable correlation (Hsu and Li, 1997). The use of Nernst–Haskell equation requires an infinite dilution conductance of individual cations and anions, thus, the molar conductivities of the investigated ILs in water at various concentrations were also measured.

Materials and methods

All ILs used in this work were supplied by TCI Co. with minimum purity of 97 %. The ILs were used without further purification. A water purification system supplied by Barnstead Thermodyne (model Easy Pure 1052) was used to provide Type I reagent-grade water with a resistivity of 18.3 (M·Ωcm) and with a total organic carbon content of less than 15 ppb. The infinitely dilute concentration aqueous solutions were prepared by mass, with a weighing accuracy of $\pm 1 \times 10^{-4}$ g.

The Taylor dispersion apparatus used in this study was described previously by Kao and Li (2006). In this work, the mutual diffusion coefficients of the investigated ionic liquids in water were measured at infinite dilution. The samples of dilute solutions of ionic liquids in water

were injected into a carrier fluid of pure deionized water. The concentration of the solution greatly affects the diffusion coefficient. To this end, the concentration of the injected samples were kept as dilute as possible so that the measured diffusion coefficients were not influenced by concentrations of the samples, but still a steady detectable signal could be obtained.

The molar conductivity Λ was measured using a commercial electrical conductivity meter (model SC-170) manufactured by Suntex. The uncertainty of the conductivity measurement was $\pm$0.001 (mS·cm^{-1}) for readings below 50 (mS·cm^{-1}). The temperature was monitored using digital thermometer (model 3002) from CROPICO, with an uncertainty of $\pm$0.01 K.

The densities of IL (solute) were measured using a viscometer from Anton Paar Stabinger (model SVM 3000). The density was measured by the integrated density measuring cell, which used the principle of the oscillating U-tube. The repeatability of the density measurement was ±0.0002 (g·cm^{-3}). The estimated uncertainty of temperature was ±0.002 K. The estimated uncertainty of the density was ±0.0004 (g·cm^{-3}).

The viscosities of water at various temperatures were calculated using a correlation used in the study of Hsu and Li (1997) and is given by the expression

$$\ln \eta = a_1 + \frac{a_2}{T + a_3} \tag{1}$$

Results and discussion

The present experimental results of diffusion coefficient measurements for the studied [Emim]-based ILs in water at infinite dilution are presented in Table 1 and also shown in Fig. 1. Among the studied ILs, [Emim][BF_4] has the highest value of diffusion coefficients while [Emim][$MDEGSO_4$] has the lowest value of diffusion coefficients. The most common correlation used for estimating diffusion coefficient of organic molecules in a solvent is the Wilke-Chang equation (Wilke and Chang, 1955) where the diffusing component is treated as an organic solute and the diffusion of solute A in solvent B is represented by Eq. (2)

$$D_{\mathrm{AB}}^{0} = 7.4\times10^{-12}\frac{\left(\psi M_{\mathrm{B}}\right)^{0.5} T}{\eta_{\mathrm{B}} V_{\mathrm{A}}^{0.6}} \tag{2}$$

As shown in Table 1, the Wilke–Chang equation underestimated the present measurements of diffusion coefficient. To this end, the Wilke–Chang equation was modified by introducing a temperature–dependent correction factor which is expressed as

$$F_{\mathrm{C}} = b_1 + b_2 T \tag{3}$$

Where F_c is the temperature–dependent correction factor, T the absolute temperature in K, and b_i, the empirical parameters. The modified Wilke–Chang equation are then rewritten as

$$D_{\mathrm{AB}}^{0} = F_{\mathrm{C}}\left[\frac{7.4\times10^{-12}\left(\psi M_{\mathrm{B}}\right)^{0.5} T}{\eta_{\mathrm{B}} V_{\mathrm{A}}^{0.6}}\right] \tag{4}$$

The modified Wilke–Chang equation correlated well the present experimental results with an overall AAD % of 1.62.

Diffusion coefficients of electrolytes are related to infinite dilution conductance via the Nernst–Haskell equation (Robinson and Stokes, 1965):

$$D_{AB}^0 = \frac{RT}{F^2}\frac{|z_+|+|z_-|}{|z_+ z_-|}\frac{\Lambda_+^0 \Lambda_-^0}{\Lambda_+^0 + \Lambda_-^0} \tag{5}$$

Figure 2 shows the conductivity of $LiBF_4$ (reference substance) and the investigated ionic liquids. The conductivity varies linearly with the square root of concentration:

$$\Lambda = \Lambda^0 + \left(d_1 \Lambda^0 + d_2\right) C^{1/2} \tag{6}$$

The infinite dilution conductance Λ^0 can be obtained by fitting the experimental data using Eq. (6). The relation between the infinite dilution conductivity of an electrolyte and the infinite dilution conductances of the ions is given by:

$$\Lambda^0 = z_+ \Lambda_+^0 + z_- \Lambda_-^0 \tag{7}$$

From Eq. (7) and the infinite dilution conductivity of the ionic liquids, the infinite dilution conductances of the ions were determined. As shown in Table 1, the Nernst–Haskell equation (Robinson and Stokes, 1965) can be used to predict the diffusivities of ionic liquids, the average absolute error of 6% was found. Considering the experimental error involved and that no adjustable parameter was used, the predictions are reasonably accurate.

Conclusions

The diffusion coefficients of five [Emim]-based ionic liquids in water at infinite dilution were measured using Taylor dispersion method from temperatures of (303.2 to 323.2) K. The

diffusion coefficients were well correlated by a modified Wilke–Chang equation in which a temperature-dependent correction factor was introduced to the Wilke–Chang correlation. The molar conductivities of the investigated ionic liquids were also measured to predict the diffusion coefficient using the infinite dilution conductances of the ions via the Nernst–Haskell equation. The results of the calculation of diffusion coefficients using the Nernst–Haskell equation were reasonably accurate.

Topic: Advancing the chemical and biological engineering fundamentals

Leaching of halite from mineral deposits by solution mining is a technology with worldwide application. For the salt industry, only the valuable components in the mineral deposit must be dissolved and removed to the surface for further processing. Inevitably, several minor impurities, such as calcium sulfate minerals, are also leached and the outgoing contaminated brine must be subject to costly purification treatments. Therefore, the inhibition of the dissolution of calcium minerals is a subject with scientific interest and potential economic impact. The dissolution of anhydrite in saturated brines of sodium chloride may be inhibited by the presence of water-soluble macromolecules, being the effectiveness of the inhibitor evaluated from the degree of coverage of the target surface and the desorption resistance. The ideal macromolecule, besides being selective towards anhydrite, should not harm the morphologic characteristics of the main salt in downstream crystallizations.

In this study, the influence of some selected anionic surfactants on the solubility of gypsum, anhydrite and anhydrite-rich sediments in concentrated brines was investigated.

Introduction

Although the prevention of calcium sulfate scale formation has received a lot of attention from industry and research, studies concerning the inhibition of dissolution of calcium minerals in aqueous brines are scarce. Effective inhibitors are usually good sequestering agents for the lattice cations and it is generally accepted that they exert their action through adsorption at cationic sites on the solid surfaces. Additives may also adsorb upon crystal faces, reducing the rate of dissolution. Since the molecular interactions at the inorganic/organic interfaces depend on the size, ionic charge and structure of the admixture, Nancollas and Zawacki (1984), small molecules with high charge density will interact with charged solids. The concentration and size of the inhibitor molecule are important parameters because the inhibition of dissolution requires a considerable coverage of the surfaces. Anionic surfactants with negative charged head groups seem to have a strong blocking effect upon the dissolution of calcium minerals, according to Mahmoud et al. (2004). The effectiveness of adsorption is inversely proportional to the minimum area demand per molecule, thus making of single-chained surfactants potential good inhibitors. It is not clear however, to what extent the salts present in the solution affect the inhibitor performance.

Within the scope of this study, the effect of some selected anionic benzene sulfonate surfactants on the dissolution of different forms of calcium sulfate are here reported. Because the length of the chain determines the physicochemical behavior of surfactants in solution, representatives of C_8, C_{12} and C_{12}/C_{13} anionic surfactants were studied. Both the acid and the sodium salt forms of the polar head group were considered for some of these surfactants.

Materials and methods

Three different forms of calcium sulfate were used in the study. The samples of anhydrite-rich sediments, $CaSO_4 \geq 42\%$ (w/w), from three salt dissolution caverns under leaching,

* Corresponding author. Tel + 351 218417335. E-mail:fatima.farelo@ist.utl.pt

belonging to the Porto de Mós diapir (Hetangian formation), were kindly provided by REN, Portugal. Gypsum and anhydrite were commercial products with particle mean size < 10 μm and BET surface area of 1.9 and 1.7 m^2/g, respectively. Four anionic surfactants with hydrophilic head group of the benzene sulfonate (BS) type were used. OBS (Na, octyl BS), DBS (Na, dodecyl-BS) and ADBS (dodecyl-BS acid) were purchased from Sigma-Aldrich. A commercial acid surfactant, a mixture of branched and straight chained alkyl, mainly C_{12} and C_{13}, here referred to as D550, was kindly supplied by InChemica, Portugal. Analytical grade sodium chloride, Riedel-de Haën (> 99.8 %), and deionized water were used to prepare the brines by mass to ± 0.01 g. The maximum overall uncertainty in the concentration of the surfactants' stock solutions was ± 0.3 mg L^{-1}.

Anhydrite-rich sediments from 3 different salt caverns under leaching, hereafter referred to as S1, S2, and S3, were used in the experiments. Prior to use the sediments were air-dried, homogenized and sieved. The mean superficial diameter of the solids, calculated from the size distributions, was 52 μm for S1 and S3, and 74 μm for S2, being the BET surface areas 0.4 and 0.2 m^2/g, respectively. Zeta potential measurements showed that all the sediments are negatively charged, ca. – 11 mV.

The mineralogical composition of the sediments was confirmed by X-ray diffraction and FTIR spectroscopy (4000-400 cm^{-1}) and stereo and polarizing microscopy showing the presence of halite, anhydrite, low quartz, carbonate minerals (dolomite, ankerite) and minor contents of clay (clinochlore), organic and inorganic carbon, gypsum, muscovite and pyrite.

Samples of about 6 to 17 g/L of three forms of solid calcium sulfate, gypsum, anhydrite and anhydrite-rich sediments, together with sodium chloride were equilibrated in aqueous solutions with a surfactant concentration ranging from 0 to 73 mg/kg of saturated brine. Although an excess of solid halite was used in most of the runs to mimic the salt caverns environment, the influence of the degree of saturation of the leaching agent was also evaluated. The plastic flasks were shaken for 7 to 14 days in an orbital shaker, at room temperature. Periodically, the solutions were sampled for analysis. After a settling period of about 3 h, liquid samples were collected with a syringe, equipped with a 0.45-μm filter, and aliquots of the liquid were analyzed for calcium content (S.M. 3500-Ca B. "EDTA Titrimetric Method"). The reported concentrations are the mean values of duplicate analyses on each sample. The content of sulfate ion in the samples was also regularly determined (S.M. 4500 SO42- E. "Turbidimetric Method"), as a cross check for the calcium analysis. At the end of each run, the slurry was filtered and the solids air-dried and weighed. The residual solutions and solids were subsequently analyzed for the content of surfactants (MBAS standard method). Blank runs were carried out to account for the natural variability of sediments composition and for the dependence of calcium sulfate solubility on temperature and NaCl content in the brines. In each series of experiments the effect of the surfactants on the dissolution of the calcium salt was assessed against the corresponding control run.

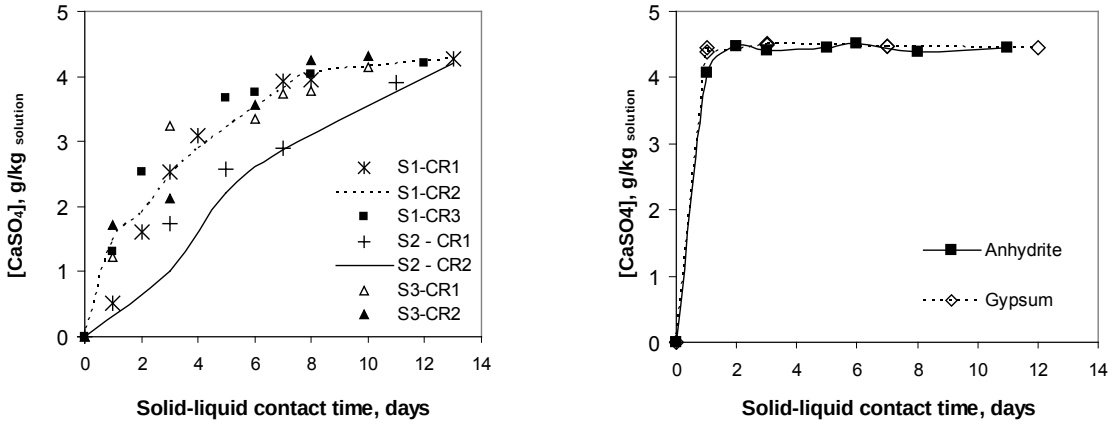
In order to interpret the behavior of the selected surfactants, the surface tension of concentrated NaCl brines (300 g/kg_{water}), with and without admixtures, was determined with a Du-Noüy tensiometer equipped with a Pt ring. All measurements were performed after a 30-min period of equilibration at constant temperature. The tensiometer was previously calibrated against water and NaCl solutions (up to ≈ 6 m), at 298 K.

Results and Discussion

Figure 1 presents the change of calcium sulfate concentration in saturated brines as a function of time, for the three forms of salt studied. The reported rates of dissolution, measured in the presence of solid halite, represent the average values of at least duplicate measurements.

For sediments S1 and S3, Figure 1a, the saturation concentration was reached after one week, whereas for the pure forms of calcium sulfate, Figure 1b, this value was attained in about 24 h. Sediments S2, the coarser of the solids tested, were the slower to dissolve. The

results show that both the availability of the calcium salt in the solid and the size of the particles play an important role on rate of dissolution of the calcium mineral.



(a) (b)

Figure 1- Rate of dissolution of different forms of calcium sulfate in saturated brines

In order to determine how the selected C_8, C_{12} and C_{12}/C_{13} anionic benzene sulfonate surfactants influence the dissolution of calcium sulfate, a total of 76 independent runs were carried out. The decrease of the content of calcium sulfate in solution was evaluated by the relative solubility calculated, for each data point, as the ratio of calcium content in the solution and in the parallel blank run.

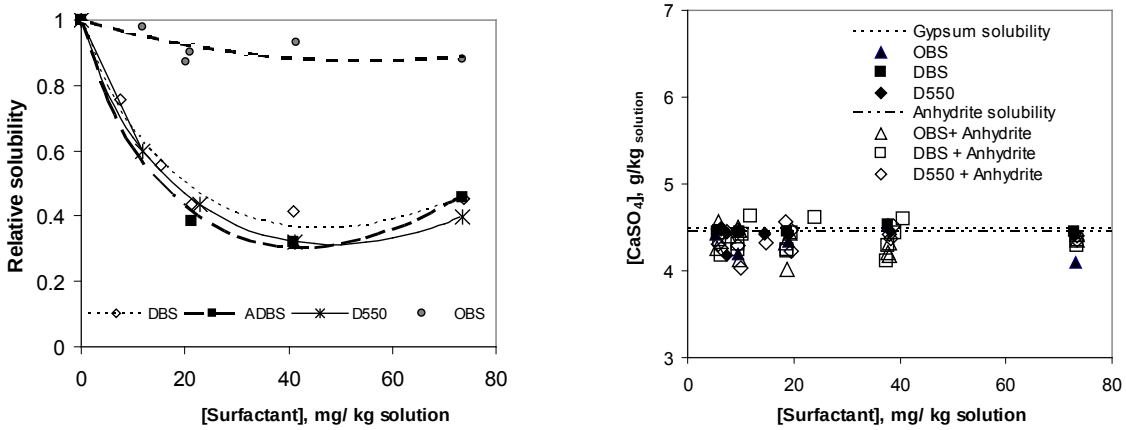
Figure 2a illustrates the effect of the type and concentration of the selected anionic surfactants on the calcium sulfate content, after 14 days of curing in slurries of sediments and halite. The chain's length of the organic molecule clearly determines the admixture effectiveness, as a dissolution inhibitor for the calcium mineral, being the effect of the C_8 surfactant, OBS, almost negligible. The type of the head group of the linear C_{12}-BS surfactants (acid for ADBS and sodium salt for DBS) had no significant influence on the solubility reduction. The curves also indicate that, independent of the C_{12}-surfactant type, the maximum reduction in dissolution ($\cong$ 70%) was obtained in slurries containing an initial concentration of about 40 $mg/kg_{solution}$ of the admixtures. For higher contents, the blocking effect of the surfactants decreases. Oppositely, Figure 2b shows that the tested surfactants had no effect whatsoever on the dissolution of either the hydrate or the non-hydrate calcium sulfate. This behavior stems most probably from a very different order of magnitude between the rates of dissolution and of solid shielding by the surfactants.

The inhibitor effect of the C_{12} and C_{12}/C_{13} surfactants becomes more apparent as the residence time increases, as shown in Figure 3 for DBS and D550. The dissolution of calcium sulfate in the blank run continues up to saturation, whereas in the presence of the surfactants the process is effectively blocked, resulting in a decrease of the relative solubility.

The rate of leaching of the salt caverns determines the concentration of the outgoing brine. The injected water containing the added admixtures is gradually enriched in sodium chloride as the residence time increases, becoming saturated if enough time is allowed. Therefore, to examine the influence of the NaCl content in the admixed solutions upon the rate of the dissolution of the sediments, a series of experiments was carried out using as leaching agents aqueous solutions of DBS and near-saturated NaCl brines (350 g/kg water) containing the same surfactant or its acid form (ADBS).

The results thus obtained are compared in Figure 4 with the relative solubility of calcium sulfate measured in the presence of solid halite. It is clear that the leaching agent, water+surfactant, does no hinder the dissolution of the anhydrite-rich sediments before it becomes enriched in sodium chloride. In near-saturated brines even small concentrations of the admixtures are effective in blocking the dissolution of anhydrite, the equilibrium calcium

content in the solution representing 20 to 30% of the blank run concentration. However, it is worth noting that in the presence of solid halite - a more realistic approach to a salt cavern environment - the hindering effect is less pronounced, a fact that might be explained by the existence of a much larger solid surface area to which the organic molecules will indistinctly adhere.



(a) Sediments (b) Gypsum and anhydrite

Figure 2 - Effect of the type and concentration of OBS, DBS, ADBS and D550 on the dissolution of calcium sulfate after 14 days of curing

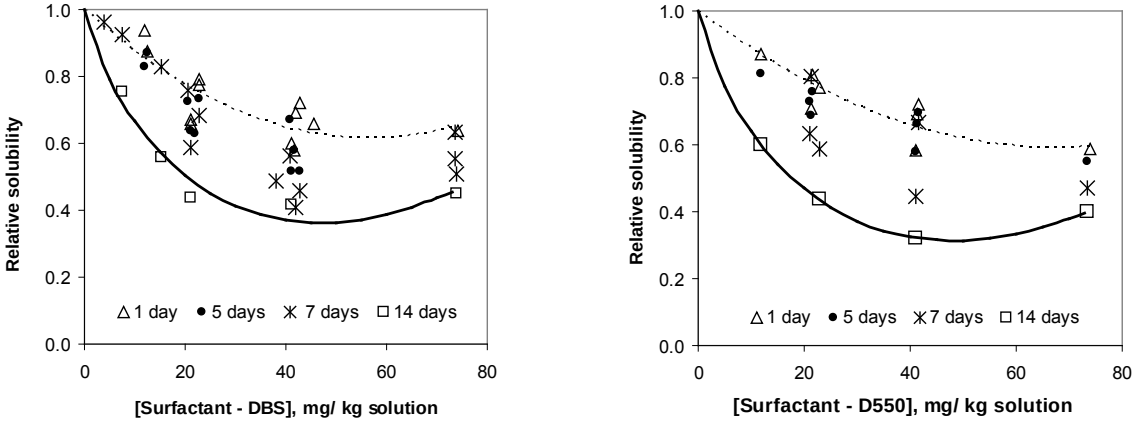


Figure 3 – Influence of the solid-liquid contact time on the dissolution of sediments S3 for several initial contents of two C_{12}BS surfactants

In order to get a better understanding of the observed phenomena, the surface tension of the near-saturated brines containing the studied surfactants was measured at 298 K. Minute amounts of the admixtures originated a sharp reduction in the solution surface tension, but beyond a limiting concentration, which coincided with the appearance of solution opalescence, no further change in this quantity was detected. This surge of turbidity, which represents the onset of a macroscopic phase separation, occurred at concentrations of 0.9, 0.8, 1.4 and 2.3 mg/L for OBS, D550, ADBS and DBS, respectively. It can, therefore, be inferred from these results that during the equilibration of the sediments+halite solid mixtures in the leaching solutions a phase separation will occur, as soon as a high ionic strength is reached. As a consequence of the rejection of the organic phase, the content of the monomers in the leaching solution will remain nearly identical to the clouding concentrations measured. The rejected phase will tend to adhere to the solid surfaces existing in the slurries, thus acting as an organic barrier to the solids' dissolution.

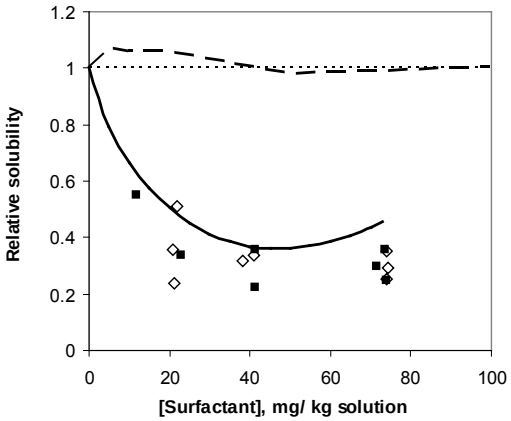

Figure 4- Influence of salt concentration on the solubility reduction of calcium sulfate after 14 days of contact. Lines: broken - DBS in water. Solid - DBS in brines with solid halite. Symbols. Surfactants In near-saturated brines: ■ ADBS; ◇ DBS.

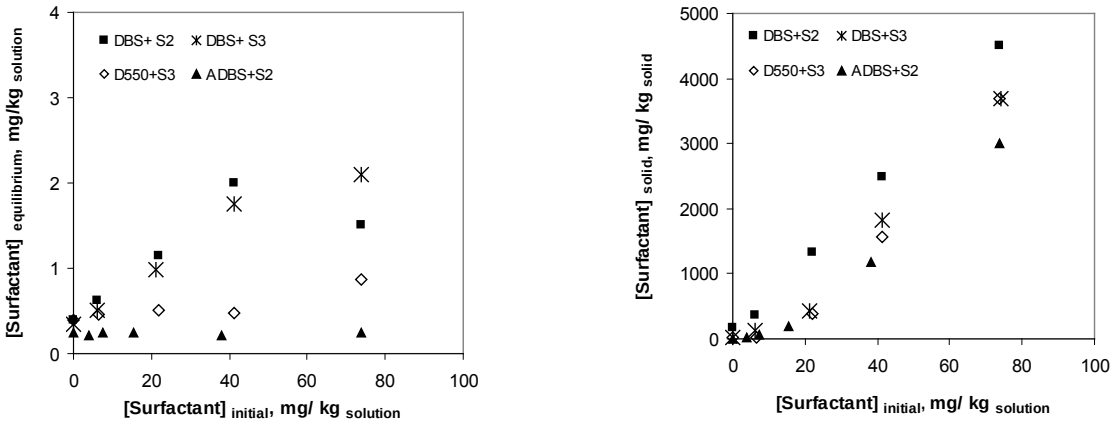
The surfactant contents in the saturated solutions equilibrated during 7 days with anhydrite-rich sediments, shown in Figure 5a, were found to be slightly lower than the corresponding clouding concentrations measured in pure NaCl solutions. These results may indicate that some precipitation of calcium or sodium salts of the benzene sulfonate detergents occurred in the saturated brines. The amount of additives adhering to the anhydrite-rich sediments, Figure 5b, was nearly independent of the type of C_{12}BS surfactants, as well as of the substrata. Due to the negative charge of sediments, electrostatic interactions between the negatively charged head groups and the solid surfaces were ruled out as a possible explanation for the high contents of the admixtures adhering to the sediments.



(a) (b)

Figure 5 – Surfactants concentrations in the (a) liquid and (b) solid phases at equilibrium after 7 days of curing.

As expected, the surfactants are also retained by the halite crystals, Figure 6, although in a much lesser extent than by the sediments. The coverage of the salt, and the consequent decrease in its equilibrium concentration, may help explaining the apparent loss of effectiveness of the surfactants for a content of 73 mg/$kg_{solution}$. Because the equilibrium concentration of calcium sulfate varies inversely with the content of sodium chloride at elevated concentrations of the latter salt, the relative solubility of $CaSO_4$, used as the evaluation tool for the surfactant performance, will increase only because the reference blank run is not affected by the same phenomenon.

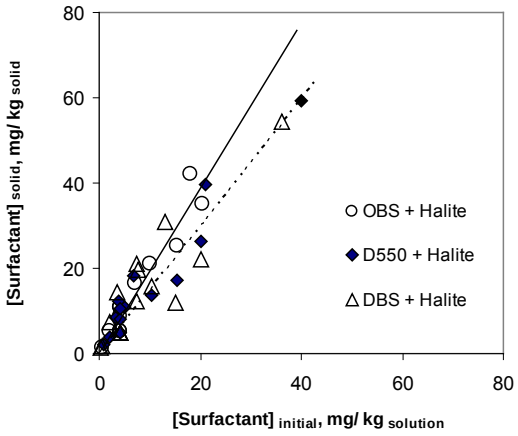


Figure 6 – Surfactants retention in halite crystals after 7 days of solid-liquid contact

Conclusions

Leaching of anhydrite-rich sediments with aqueous solutions of anionic C_{12}-benzene sulfonate surfactants reduces significantly the solubility of calcium sulfate. A maximum reduction of ≅70% was observed in the presence of halite, using brines containing about 40 mg/kg solution of the additives. The type of the surfactant head group (acid or sodium salt) does not influence the detergent performance, but the chain's length of the organic molecule is relevant to the hindering of calcium sulfate dissolution. The availability of the calcium salt in the solid, as well as the size of the "insoluble" debris within the cavern, play an important role on rate of dissolution of the calcium mineral and, therefore, on the contamination of the outgoing brine.

The reduction of the calcium sulfate equilibrium concentration from the negatively charged sediments cannot be attributed to electrostatic interactions between the solid surfaces and the charged head groups of the anionic surfactants. However, the behavior of the C_{12}BS surfactants may be interpreted in terms of the balance between the electrostatic repulsive forces of polar head groups and the attractive forces due to hydrophobic interaction. Aggregation of surface-active molecules stems from the insolubility of the non-polar moiety of the surfactant in the solution. The opposing hydrophilic interactions between polar head groups must be strong enough to ensure the self-assembly of the amphiphile. However, above a certain ionic strength threshold, the hydrophilic interactions are shielded, the driving force to expel the hydrophobic groups from solution augments and macroscopic phase separation occurs, Jönsson et al (1998). It can, therefore, be inferred from the results here obtained that for the examined surfactants a phase separation occurred in the saturated brines. The expelled organic phase, by adhering to the solid surfaces in the slurries, acts as a barrier to the dissolution of the mineral impurities.

Keywords: Optimised Cyclones; Recirculation; Turbulent Dispersion; Particle Agglomeration
Topic: Advancing the chemical engineering fundamentals

Abstract

The purpose of this work is to build a model to predict in a more realistic way the collection efficiency of a gas cyclone recirculating system [Chibante et al., 2007; Salcedo et al., 2007]. These systems consist in an optimised reverse-flow cyclone combined with partial recirculation of uncaptured particles via a straight-through cyclone concentrator, with very high collection efficiencies (η > 90 %) for very fine particles.

The model starts by solving the particle trajectory in a turbulent flow field, and by fixing a set of parameters, it determines if a collision or an agglomeration occurs. In case of agglomeration, the initial particles will have a dynamic behaviour inside the gas-cyclone as a newly formed agglomerate. So the effective collection efficiency of the particles will be different from that proposed by current models, and will in fact increase. This can be observed in various experimental results, and usually referred as "hook-like" grade-efficiency curves.

The hypothesis of particle agglomeration within the cyclone turbulent flow seems a sound justification for the higher than predicted collection efficiencies observed for smaller particles inside a gas-cyclone.

1 Introduction

Collection efficiency models currently developed for gas cyclones, such as the Mothes and Löffer's model [Mothes and Loffler, 1988], can predict with high accuracy the collection efficiencies of particles with diameters above 3-4 μm.

Experimentally, it was observed at laboratory, pilot and industrial-scales that cyclone systems with or without recirculation can have complete collection below about 250 nm, viz the grade-efficiency curves have a very pronounced hook-like shape, showing a minimum in collection at an intermediate particle size (from about 0.8 to 2 μm). However, no model, to the authors' knowledge, can correctly predict this behaviour. Muschelknautz's model [Hoffman and Stein, 2002] predicts, at high solid loadings, a fairly constant value of collection efficiency for the smaller particles, since it is postulated that a portion of the feed is separated unclassified, but it does not predict the abnormal high collection for very fine particles at low loadings.

This abnormal behaviour for very fine particles is attributed to agglomeration within the cyclone turbulent flow field [Salcedo et al., 2007], much as it happens in recirculating fluidised beds [Mao et al., 2002; Sommerfeld, 2001]. Thus, this work concentrates on modelling this phenomena, by considering the particles' trajectories inside the cyclone and the probability of interparticle collisions. If some of

*Corresponding author. E-mail: rsalcedo@fe.up.pt., Phone +351-22-5081644, Fax +351-22-5081449

these collisions result in effective particle agglomeration, then one of the direct implications is that the particle size distribution actually processed by the gas cyclone differs from the feed size distribution to the cyclone.

In fact, upon agglomeration of fine particles by larger ones, the smaller particles will be captured as much larger particles, viz. with a much higher collection efficiency than that predicted by any of the currently available models. If the cyclone is highly efficient above about 4-5 μm, as it indeed happens with high efficiency cyclone systems, then the finest particles will also be collected with these extremely high efficiencies, and this could explain the minima observed in the grade-efficiency curves.

2 Modelling

A model was developed to predict the agglomeration inside a gas-cyclone, which has a fully-developed turbulent flow field. Afterwards, the model can reconstruct the path in terms of agglomeration of each particle, and take that history into account to rebuild the effective efficiencies of the initial (unagglomerated) particles.

Therefore the proposed model was obtained by combining the Mothes and Loffler [1988] model which predicts collection efficiencies in reverse-flow gas-cyclones, the Salcedo et al. [2007] model which is an extension to the Mothes and Loffler [1988] model to recirculating reverse-flow gas-cyclones and the Sommerfeld [2001] model which predicts the agglomeration of particles in turbulent flows.

2.1 Particle behaviour in turbulent flow

In this work, agglomeration was estimated using a stochastic Lagrangian approach of the inter-particle collisions in a turbulent field as proposed by Sommerfeld [2001] and Ho and Sommerfeld [2002]. This is a complex method to predict the evolution of each particle inside a control volume, hence, its simplified structure is presented in Figure 1.

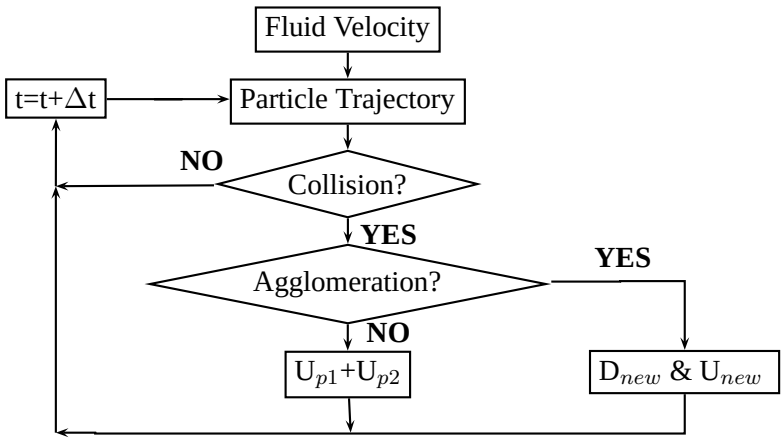

Figure 1: Scheme of the agglomeration model

Inducing a primary flow field in the control volume, we calculate the particles trajectories by integrating the following system of equations.

$$\frac{dx_{p,i}^N}{dt} = u_{p,i}^N \qquad i = 1\ldots3 \quad \wedge \quad N = 1\ldots N_{particles} \quad (1)$$

$$\frac{du_{p,i}^N}{dt} = \frac{3\,\rho_F c_D}{4\,\rho_p D_p^N}\left(u_{F,i} - u_{p,i}^N\right)\left|\overrightarrow{u_F} - \overrightarrow{u_p^N}\right| + g_i \qquad i = 1\ldots3 \quad \wedge \quad N = 1\ldots N_{particles} \quad (2)$$

Equation 1 solves the particle trajectory explicitly while Equation 2 calculates the particle velocity. This is directly related to some physical parameters such as the fluid and particle specific gravities and mainly of the relative velocity between the particle and the fluid.

Solving these equations in a predetermined flow field leads each particle to have a deterministic behaviour in the control volume. Therefore, to introduce turbulence into the system, the fluid velocity is changed, in consecutive time steps and at the same position, according to Equation 3.

$$u_{F,i}^{n+1} = u_{F,i}^{n} R_p + \left|u_{F,i}^{n}\right| \sqrt{1 - R_p^2} \times N\left(0,1\right) \tag{3}$$

The parameters associated with turbulence are taken into account in the variable R_p which is bounded to $[0, 1]$. As a short explanation of the impact of this variable in the final fluid velocity field, if R_p has a value near one, the velocity of the fluid in the next step has a strong correlation to the previous step, so the turbulence is low and the fluid velocity has almost a deterministic behaviour. However, if R_p has as value near zero, the velocity of the fluid in the next step has almost no correlation to the previous step, implying a strong turbulent flow and consequent almost random behaviour of the fluid velocity between consecutive time steps.

After obtaining the particles' trajectories in turbulent flow, a statistical criteria proposed by Sommerfeld [2001] is used to determine if a collision occurs between two particles or not. In the case where a collision occurs, using a momentum criteria the decision is made whether the result of the collision is an agglomerate or how the collision affects the velocities of the two particles. The formation of an agglomerate is determined by a number of parameters but has high dependency on the relative velocities of each particle. The process repeats itself, analysing all the binary interactions, until the final time of interaction is reached. No simultaneous three-particle or higher level interactions are considered.

The results of this part of the model are the final number distribution, which has stored the resulting number of particles after interaction (in their respective original class diameter), and the particle agglomeration history, which contains the time evolution of each resulting diameter.

2.2 Final particle decomposition

After obtaining the final number distribution the purpose is to follow the time dependent history of each of the resulting particles and/or agglomerates, taking in account that each agglomerate is a result of at least two particles, in order to build the particle size distribution that the cyclone actually "sees".

By using the information on the constitution of each new particle and of the final number of particles, an information matrix can be obtained, which allows to follow the path of each initial particle until the final agglomerates, and to calculate (backtrack) the effective efficiency of each class of initial particles.

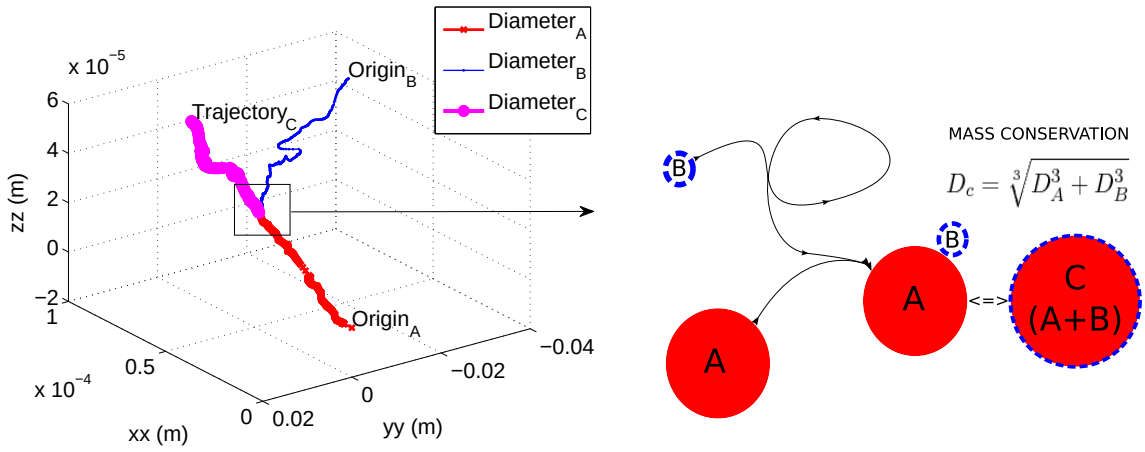
Equation 4 presents the new class efficiency using the information matrix which is obtained from the final number distribution. This matrix (referred as **INFO**) has dimensions $N_{classes} \times N_{diameters}$ and each $N_{diameters}$ has a corresponding efficiency η_j calculated by the Mothes and Loffler [1988] model for the cyclone or by the Salcedo et al. [2007] model for the recirculating system, whatever is the case.

$$\eta_i^{new} = \frac{\sum_j \mathbf{INFO_{ij}} \times \eta_j}{\sum_j n_{ij}}, \qquad i = 1 \ldots N_{classes} \quad \wedge \quad j = 1 \ldots N_{diameters} \tag{4}$$

3 Results

In this section we present some results obtained using the proposed model. All the results were obtained with the cyclone geometry proposed by Salcedo and Candido [2001], with internal diameter = 447 mm and inlet mean velocity of 30 m/s, without partial recirculation of gases and particles. The trajectories of some particles in a turbulent flow are first presented followed by the effect of the agglomeration in terms of the number and mass distribution, ending with the presentation of a sensitivity analysis of some parameters of the model.

By solving Equations 1, 2 and 3 to obtain the trajectories of each particle and using this information, their behaviour is calculated inside the control volume. Figure 2 presents some of the basic steps of the model as an example of two intersecting trajectories and the corresponding generation of an agglomerate.



(a) Trajectories of two colliding particles and of generated agglomerate

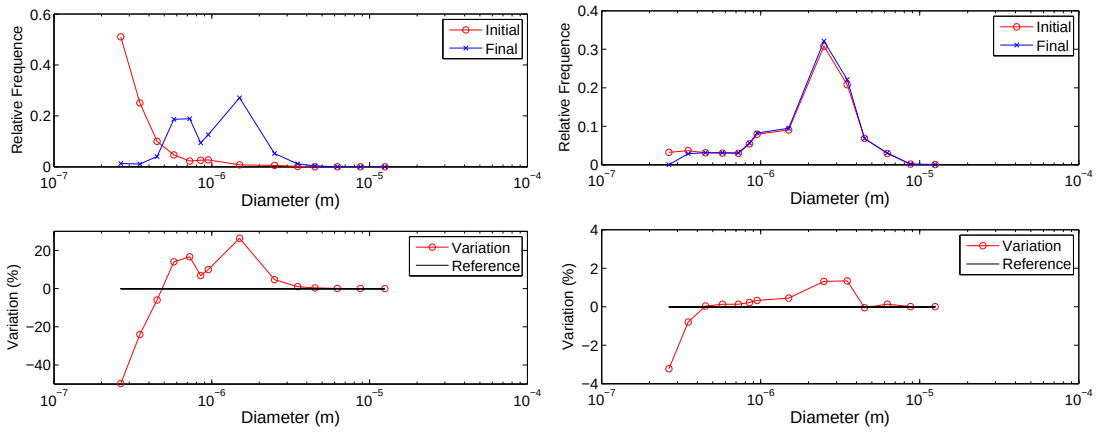
(b) Diagram of formation of a new particle with mass conservation

Figure 2: Trajectories and agglomeration effect in two particles

Figure 2a presents the trajectories of two particles with different diameters. The larger particle has a more deterministic trajectory while the smaller particle has a more random trajectory, which is a direct result of solving the system of equations presented by Equations 1 and 2. In this case, the particles collide in their trajectories and the result is a formation of a new agglomerate. The trajectory of this new agglomerate is calculated solving the momentum equations, and the resulting particle has a tendency to follow the trajectory of the larger particle.

To better understand the process of formation of new particles, we present in Figure 2b one scheme to illustrate the calculation of the new diameter of the agglomerate. This calculation takes into account the mass conservation of the particles.

The mass distribution is an input to the model. After some pretreatment, the model converts the information stored in this distribution to a number distribution. After completing the part of the model presented in Section 2.1, the model calculates the final number distribution and recalculates the corresponding mass distribution. Figure 3 shows the initial and final number and mass distributions before and after particle interaction/agglomeration.



(a) Number Distribution

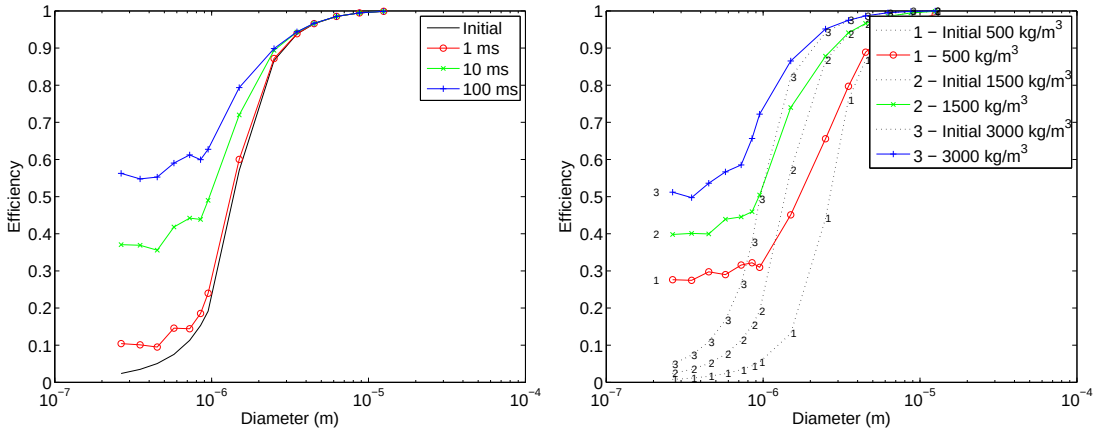
(b) Mass Distribution

Figure 3: Changes in the each distribution

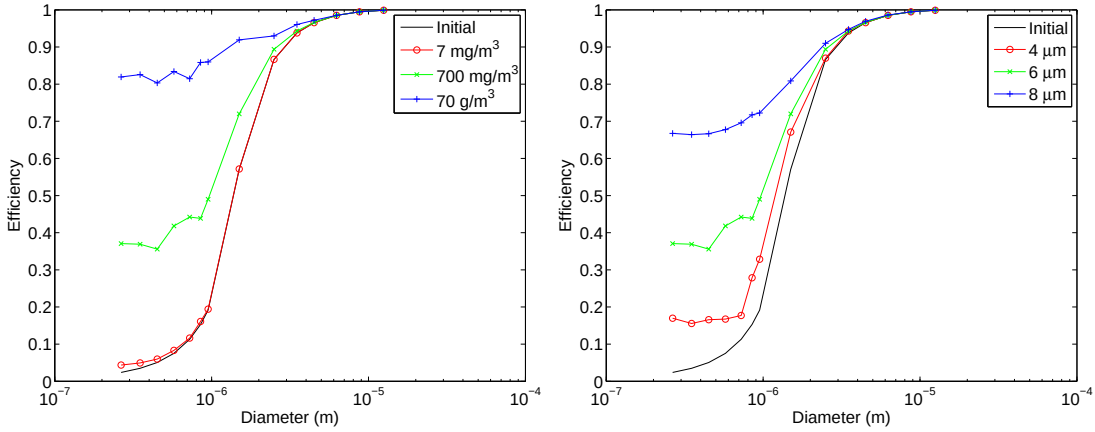
Figure 3a shows that the modal class in the beginning corresponds to the first class (corresponding to a

diameter around 0.3 μm). Analysing the result of the model, there is a displacement of the finer particles towards diameters both below and above 1 μm. This proves that the smaller particles are disappearing (the variation of the first three classes is negative) and indicates that there is formation of larger particles (the variation of the next five classes is positive).

Figure 3b shows the corresponding implications for the initial and final volume (mass) distributions. The reduction in the mass of the smaller particles and the increase in the mass of the particles above 1 μm is clearly seen.



(a) Time of interaction: 6 μm, 1500 kg/m^3, 700 mg/m^3 **(b)** Specific Gravity: 10 ms, 6 μm, 700 mg/m^3



(c) Concentration: 10 ms, 1500 kg/m^3, 6 μm **(d)** Cut-Diameter: 10 ms, 1500 kg/m^3, 700 mg/m^3

Figure 4: Sensitivity analysis of some of the parameters of the model

Figure 4 shows the grade-efficiency curves and the sensitivity to some model parameters. The chosen parameters were the time of interaction, the particle specific gravity, the particle concentration and the cut-diameter of the initial distribution, viz, the maximum allowable particle present in the original distribution. In each situation, the reference case has the following values: time of interaction (**10** ms), particle specific gravity (**1500** kg/m^3), cut-diameter (**6** μm), concentration (**700** mg/m^3).

Synthesising the information obtained in the sensitivity analysis of the model, we can observe that as the time of simulation increases (Figure 4a), higher efficiencies are obtained for the smaller particles.

Figure 4b presents the initial efficiency without agglomeration varying the particle specific gravity. The prediction of the Mothes and Loffler [1988] model increases as expected, as we increase the particle specific gravity. In terms of agglomeration, the agglomeration model leads to higher efficiencies as we increase this parameter, due to the initially higher theoretical efficiency for all the diameters.

Another important parameter of the model is the particle concentration, and Figure 4c gives the effect of this parameter. If the concentration is very low, the collision and consequent agglomeration will be two phenomena with almost no significance due to the small number of particles present in the control

volume. Therefore, as expected with low concentration, the results after agglomeration are almost those initially predicted by Mothes and Loffler [1988]. On the other hand, for the higher concentrations, the agglomeration phenomena has increasing relevance, so the final efficiency of the smaller particles increases substantially over the base-case.

Figure 4d shows the influence of the cut-diameter on the initial distribution. This parameter determines directly the initial highest diameter available for collision and as this parameter increases, higher efficiencies are obtained for the smaller particles. This is justified by the fact that, as we increase the cut-diameter, we have more larger particles to interact, and injecting more quantity of larger particles implies that there are more particles available with collection efficiencies around 100 % to collect the smaller ones. In this case we can observe that the results are also much smoother, which may simply mean that the "noise" of the results has been reduced by injecting more particles in the control volume.

4 Conclusions

The agglomeration model presented in this work has yet some parameters which must be further studied, like the collision properties or the influence of the material under study, but at the present moment, the model can predict in qualitative manner the increase of the efficiencies of the smaller particles observed experimentally.

The agglomeration phenomena seems to be a good justification of the larger observed collection efficiencies obtained experimentally for fine particles using cyclones. After an initial sensitivity analysis, we conclude that this model may lead to results closer to reality.

This model is an improvement of the existing models developed to predict grade-efficiency curves in gas-cyclones being expected that, after further studying the parameters of the model, theoretical results qualitatively nearer to the experimental ones may be obtained, allowing a more correct optimisation of the design of gas-cyclones.

Topic: Advancing the chemical and biological engineering fundamentals.

Abstract

Anomalous normalised permeability as a ratio of permeability to square of particle size for snow, diatomite, kieselgel was considered using Kozeny-Carman model and tortuosity factor defined as the square of average tortuosity pathway. Since the Kozeny-Carman model is based on the geometrical models of a capillary tube, the model adopted for high porous media with shaped particles (often with fractal properties) becomes complex. To show how the problem of permeability may be complex, two types of particles are analysed in porous media: snowflakes and diatomite and kieselguhrs. Snowflakes are typical fractal particles, whereas diatomite and kieselguhr can form pores with fractal tortuosity. Based on theoretical investigation a model including fractal measurements for void and solid phases and dependence of tortuosity on packing porosity is proposed. The obtained results show that within the developed model we can describe a wide range of porous media with different fractality and tortuosity. Based on presented numerous examples it was concluded that further experimental investigation should be useful to improve the model and validate the application range.

1. Introduction

Highly porous media play a significant role in many practical applications including nanotechnology, biomedicine, fuel cells, catalysis etc. However, the interpretation of experimental permeability data is difficult whenever the particle shape or particle arrangement becomes significantly different of conventional granular packing.

In this case conventional Kozeny-Carman model (1) does not satisfy experimental conditions

$$k = \frac{\varepsilon^3}{K_0 \tau^2 (1-\varepsilon)^2 S^2} = \frac{d^2 \varepsilon^3}{36 K_0 \tau^2 (1-\varepsilon)^2} = \frac{d^2 \varepsilon^3}{72 \tau^2 (1-\varepsilon)^2} \quad (1)$$

where k is the permeability, 1/m; S is the specific surface area based on the solid volume; $d = 6/S$ is the equivalent spherical particle size; ε is the porosity; $K_0 \tau^2$ includes tortuosity τ (ratio of average pathway to the porous medium thickness) and K_0 - a coefficient dependent on the pore cross-section shape (for cylindrical pores K_0 = 2). In particular cases model (1) may be used in the form

$$k = (d^2 \varepsilon^3) / [180(1-\varepsilon)^2] \quad (1a)$$

As Kozeny-Carman model is based on the geometrical models of a capillary tube, then the model adopted for high porous media with shaped particles (often with fractal properties) becomes complex (see Figs. 1 - 2).

In some cases porous media with fractal wall surface do not have a fractal tortuosity of pore channels, as in Fig. 1 (a-b) or, in contrary, display a fractal dimension dependent

* Corresponding author. Tel + 351-25360-1191. E-mail: MMota@reitoria.uminho.pt

on a channel topology, as in Fig. 1 (c-e). In theses examples two fractal curves with different fractal dimension were used to built the pore channels: (a) von Koch snowflake curve, fractal dimension 1.26, has 4 levels of structure, each level with tortuosity τ_i = 4/3, and the overall tortuosity of the curve is $\tau \approx$ 3.16, Fig. 1a; the (b) curve has fractal dimension 1.5, 3 levels of structure, each level with a tortuosity τ_i = 2, and overall tortuosity of the curve is τ = 8, Fig. 1b. The case in Fig. 1 (a-b) corresponds to the symmetrical pore channel with fractal perimeter (contour) where a centreline geometrical tortuosity is equal to 1.

In the case of non-symmetrical pore channels, Fig. 1 (c) and (d), built by fractal curves of types (a) and (b), they have a centreline tortuosity of τ = 1.97 and 2.62 with a fractal dimension of 1.01 and 1.03. In turn, in case (e), tortuosity is much higher, τ = 8, and the fractal dimension of pore channel walls is 1.5. Moreover, the porous medium fractal dimension is dependent on porosity and on the particle shape.

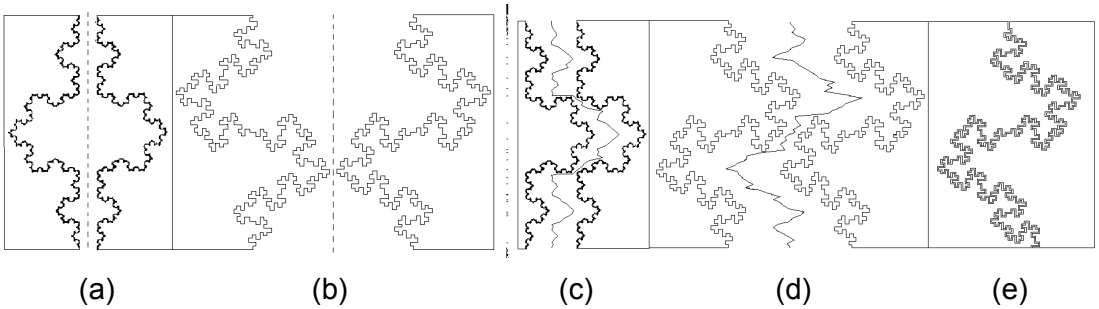

Figure 1. Two symmetrical pore channels built by fractal curves (See text) having the average geometrical tortuosity τ = 1.0, case (a) and (b). Non-symmetrical pore channels built by fractal curves, cases (c-d).

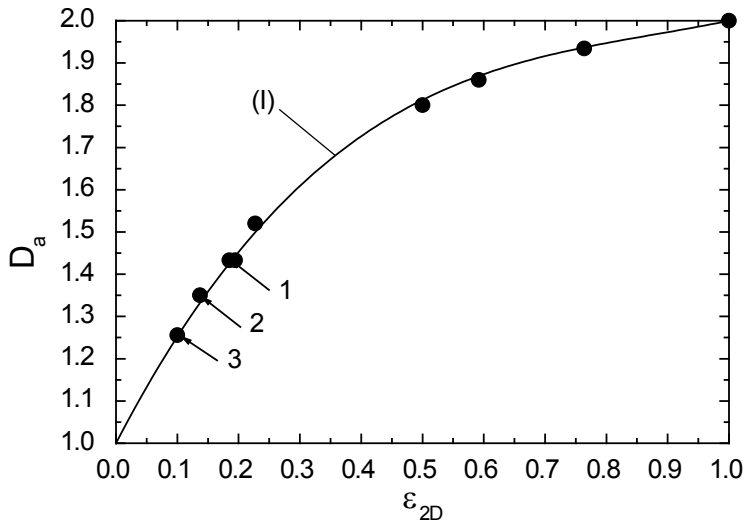

Figure 2. Fractal dimension D_a vs. ε_{2D} for regular packing of discs: 1 – square packing; 2 – hexagonal packing; 3 – discs square arrangement of two sizes (space between large size square packing filled by inscribed discs). I – correlation function.

Porous media porosity is one of the most important characteristics involved in all models of mass and heat transfer. Dependence of the 2D porous media fractal properties on porosity (ε_{2D}) is shown in Fig. 2, where a disc type porous structures are presented. Increasing porous media complexity (the structure deviates from uniformity)

renders the topological properties of the system (fractal dimension) dominant.

As can be seen, porosity and tortuosity are interrelated and both connected with fractal properties of porous media and properties interplay gives different results. For instance, a carbon felt (*Le Carbone Lorraine*, RVC 4002) for electrodes has the porosity 0.98 and tortuosity 5 – 6, (González-Garcia et al., 1999); α-alumina catalyst pellet, ε = 0.68, average tortuosity 4.0,(Dogu et al. ,1989); iron-based Fischer-Tropsch catalyst, ε = 0.628, tortuosity ~ 6.0, (Eaton et al. , 1995); mica (powdered) and vermiculite at porosity 0.85 – 0.9 have tortuosity over 2.0, (Currie ,1960).

2. Theoretical background

To show how the problem may be complex, two types of particles are considered below: snowflake and diatomite/kieselguhr.

Jordan et al. (1999) summarised and analysed published and own experimental data on snow permeability by using Kozeny-Carman model in the form (1a) and an approach of the form

$$k = 0.077 d^2 \exp(-0.0078 \rho_i (1-\varepsilon)) \qquad (2)$$

where ρ_i = 917 is ice density, kg/m^3.

Normalised experimental snow permeability k/d^2 together with models (1a) and (2) are shown in Fig. 3, where some data for low-density snow are below theoretical predictions for a granular bed (curve 1) as well as for a model (2), curve 2.

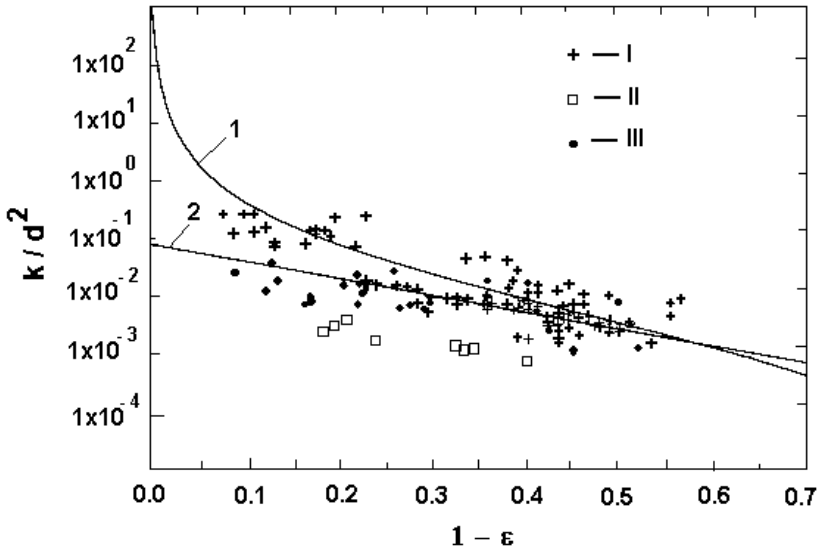

Figure 3. Reduced permeability k/d^2 vs. ice fraction $\phi = 1-\varepsilon$ as presented by Jordan (1999) in fig. 7. I – Shimizu, Ishido and Shimizu data; II – Sommerfeild and Rocchio data; III - Jordan data. 1 – granular bed model, equation (1a); 2 – approach, equation (2).

According to snow classification by solid fraction and permeability (Jordan , 1999), the main part of snow samples which does not fit to the above mentioned models belong to wind-packed (dense) and new snow (low density) which leads to consider particle shape as an important parameter of the permeability behaviour. However, in (2) we can speculate that $(1-\varepsilon)$ is accounted for in fractal properties as well.

For non-spherical particle the model (1) may be partially corrected by introducing a sphericity factor Φ of a particle as the ratio of the surface area of a sphere S (with the same volume as the given particle) to the surface area of the particle S_p, $\Phi = S/S_p$, hence, $d_p = 6/S_p = 6\Phi/S = \Phi d$. In this case, fractal behaviour may affect all or part

of variables (Xu and Yu, 2008): pore space (ε), solid ($1-\varepsilon$) or ratio $\varepsilon/(1-\varepsilon)$, and tortuosity ($\tau$).

In general, the tortuosity depends on porosity and may be presented in the form $\tau = a/\varepsilon^n$ ($n \geq 0$; $a \geq 1$, conventionally a = 1). By substituting τ and Φ in (1) and introducing the normalised permeability we have the following $k/d^2 = (\Phi^2/K_0)[\varepsilon^3/(36\cdot(a/\varepsilon^n)^2(1-\varepsilon)^2)]$. The value of K_0 depends on a pore cross-section configuration that, in turn, reflects the particles shape. Since the exact relations between Φ, K_0 and ε are unknown, complex $\Phi^2/(K_0 a^2)$ can be considered as the fitting coefficient $1/A$.

If we assume that in porous media structure particles are generated from sub-units of smallest scale, as shown in Fig. 4, then external and internal factors may yield substantial particle transformation. In the case of snow, primary snowflake melting results in porous media compaction and in structural degradation, with loss of fractal properties and an approach to granular packing.

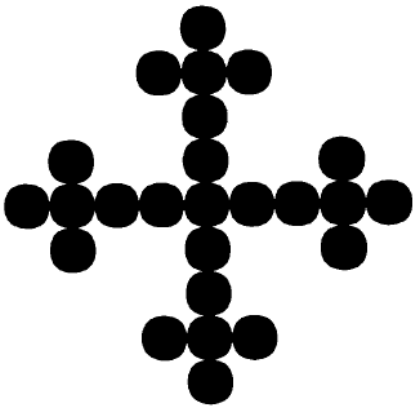

Figure 4. Simplified representation of a complex primary particle structure build by sub-units.

Structural properties based upon fractal analysis must be introduced in normalised permeability under the form of ΔD and $\Delta_1 D\cdot\varphi(\varepsilon)$ as fractal measures for void and solid phases, where $0 \leq \Delta D \leq 1$, $0 \leq \Delta_1 D \leq 1$, and $\varphi(\varepsilon)$ is a function accounting for deviation of porous media from granular packing. Finally, dependence of normalised permeability on porosity becomes

$$k/d^2 = \frac{\varepsilon^{3\Delta D}}{36A(1/\varepsilon^n)^2(1-\varepsilon)^{2\Delta_1 D\cdot\varphi(\varepsilon)}} = \frac{\varepsilon^{3\Delta D+2n}}{36A(1-\varepsilon)^{2\Delta_1 D\cdot\varphi(\varepsilon)}} \qquad (3)$$

3. Discussion

Two types of particles are presented in Fig. 5: snowflakes (shaded area occupied by data of Jordan et al. (1999)), diatomite (I), from Yoon et al. (1992) and kieselguhrs (II), Mota et al. (2000, 2003). Snow represents fractal particles, whereas diatomite and kieselguhr can form pores with a significant fractal tortuosity.

Application of relation (1a) and model (2) as proposed for the snow layer (Fig. 5), gives rise to curves 1 and 2, respectively. Ignoring dependence of τ on ε does not allow covering the whole region of experimental data. Conventional model (1) has as upper limit τ = 1.0 and curve 1′ is far from the experimental bounds.

The model (3) was accepted and deviation from granular packing $\varphi(\varepsilon)$ was assumed

to be $\varphi(\varepsilon) = 1 + \varepsilon_0 - \varepsilon$. The function $\varphi(\varepsilon)$ = 1 when $\varepsilon = \varepsilon_0$ where ε_0 has a value in the range 0.3 – 0.45 and is defined as a fitting parameter.

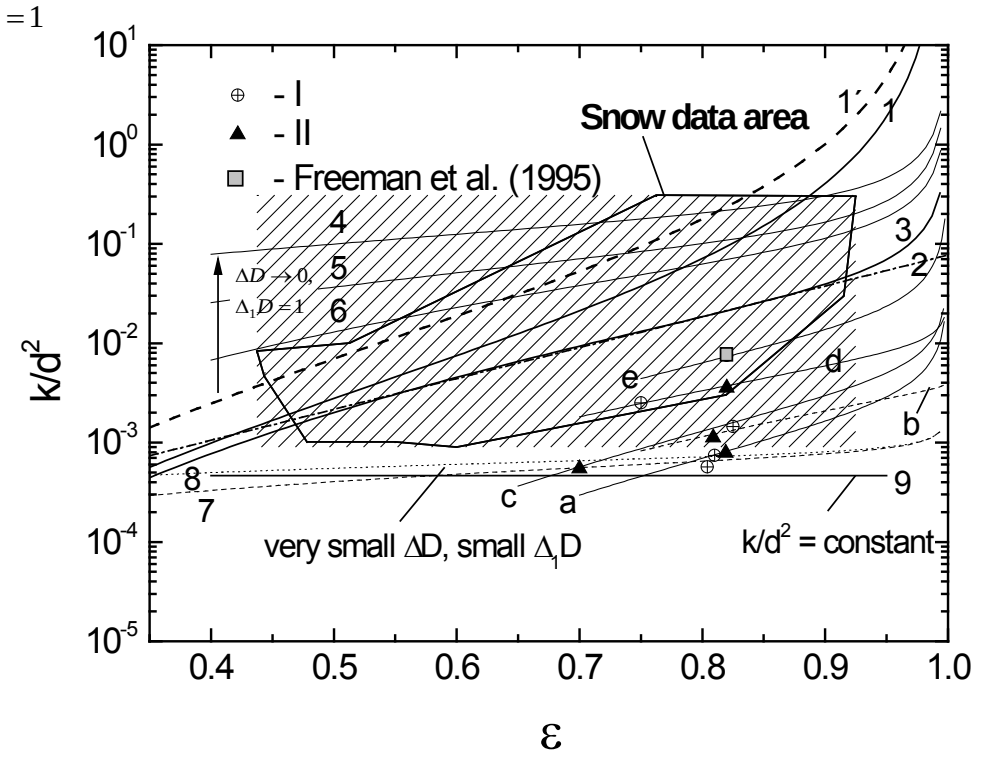

Fig. 5. Normalised permeability k/d^2 vs. porous media porosity. Shaded area is occupied by snow data of Jordan et al. (1999). 1 – equation (1a); 1´ – case (1) when τ = 1; 2 – relation (2); 3 – fitting relation (2) by model (3). Curves a – e are fitting data of mineral porous media: a - Kieselguhr fine; b – Kieselgel; c - Radiolite 600; d - Dialite UND; e – Kieselguhr. For curves 4 – 9 see the text.

Table 1. Coefficients of model (3) for curves presented in Figure 5

Curve	ΔD	$\Delta_1 D$	n	ε_0	A
4	0	1	0	0.42	1
5	0.1	1	0.1	0.45	2
6	0.3	1	0.5	0.4	2
3	0.69	1	0.6	0.4	5
Granular packing	1	1	0.4-0.5	$\varepsilon_0 = \varepsilon$	2
e	1	1	0.5	0.35	10.54
d	1	0.35	0.5	0.35	6.36
b	1	0.05	1	0.3	8.64
c	1	0.78	1	0.35	27.8
a	1	0.8	1	0.38	58.4
7	0.05	0.25	0.25	0.4	60
8	0.05	0.25	0.025	0.4	60
9	0	0	0	--	60

The obtained results show that within model (3) we can describe a wide range of porous media. In particular for snow, correlation (2), curve 2, is well fitted by model 3 (curve 3) with the following parameters: ΔD = 0.69, n = 0.6, A = 5, and ε_0 = 0.4. For new snow, in particular, a tendency (Fig. 5, arrow) to increase the permeability was found, when

$\Delta D \to 0$ and $\Delta_1 D = 1$. Curve 4 corresponds to the case $\Delta D = 0$, $\tau = 1$, when A = 1: $k/d^2 = 1/[36(1-\varepsilon)^{2(1.42-\varepsilon)}]$. Moreover, model (3) at $\varepsilon \to$ 1 gives $k/d^2 \to \infty$, whereas correlation (2) gives finite normalised permeability value. Examples of fitting data of mineral porous media by (3) are given by curves a – e and are also presented in Table 1: a - Kieselguhr fine; b – Kieselgel; c - Radiolite 600; d - Dialite UND; e – Kieselguhr.

Dependences 7 – 9 are hypothetic and simulate cases of very small ΔD. With decreasing ΔD and $\Delta_1 D$ we observe insignificant linear changes in k/d^2 and in limited case of ΔD and $\Delta_1 D$ equal zero dependence (3) becomes constant $k/d^2 = 1/(36A)$, as seen in Fig 5, bottom, curve 9. Even in the hypothetic case of A = 60 and a = 1 for Φ = 0.5 we have K_0 = 15. Assuming a = 1.5, K_0 becomes 6.7 and at a = 2 K_0 = 3.75. Formally, this situation is related with the degradation of porous media structure when tortuosity weakly depends on porosity, which is typical for non-granular porous media. For instance, when porous media contain homogeneous pores similar in length the porosity totally depends on number of pores on unit area of porous medium. Fractality behaviour of such systems is not enough investigated.

Model (3) allows simulating and predicting permeability or other parameters when experimental data are scarce.

4. Conclusion

Obtained results form the modified Kozeny-Carman model show that application of the fractal approach to the porous media void space as well as to solid phase enables to extend the model to highly porous media. The obtained results show that within the developed model we can describe a wide range of porous media with different fractality and tortuosity. In spite of the numerous examples presented, further experimental investigation will be useful to improve the model and validate its application range.

Abstract

Inertial particle motion in a stirred vessel with no baffle plate was observed experimentally and numerically at low Reynolds numbers. Several particles were captured on a torus orbit within one of the IMRs and kept traveling around the impeller. The particles captured in the IMRs enhance the exchange of material with the outside active mixing region.The primary and secondary circulation flow directions were defined ϕ- and θ-direction respectively. Initially, particle orbit obtained by Poincaré section showed that the particle motion covered the full surface of the torus orbit and the ratio of the period for one round of a particle in ϕ-direction to that in θ-direction, P_θ / P_ϕ, was irrational, while after a long time, the circular orbit on the Poincaré section converges on three discrete points and P_θ / P_ϕ was rational. Numerical simulation revealed that even after a particle seemed to have almost settled on a final orbit, the diameter of secondary circulation was not constant. After a particle has been captured, the drag force frequently works on the surface of the particle since the particle always exists near the impeller.

1 Introduction

Mixing is one of the most important unit operations in chemical and biochemical industries. Stirred vessels commercially available in a wide variety of sizes and impeller configurations are the most frequently used to homogenize different substances, to conduct chemical reactions and to enhance mass transfer between different phases. Owing to their versatility, stirred vessels can be operated under a wide range of conditions. Although turbulent flow is efficient for mixing, some situations require laminar mixing, e.g. for high viscosity fluids and shear-sensitive materials. Koiranen *et al.* (1995) proposed specific principles for effective mixing in laminar flow mixing regimes for highly viscous liquids or shear-sensitive materials. In the laminar flow mixing regimes, however, global mixing is inefficient due to the existence of isolated mixing regions (IMRs). Much attention has been paid to how to eliminate IMRs at low Reynolds numbers. Lamberto *et al.* (1996) and Yao *et al.* (1998) demonstrated that IMRs could be eliminated by using an unsteady rotation method.

The authors (Nishioka *et al.*; 2007) found that particles released at the liquid surface were captured by the recirculation of IMRs. This phenomenon may conceivably affect laminar mixing characteristics in a stirred vessel. Futhermore, solid-liquid two-phase flows in stirred vessels are often encountered in industrial processes.The present work, therefore, observed inertial particle motion in a stirred vessel with no baffle plate experimentally and numerically at low Reynolds numbers.

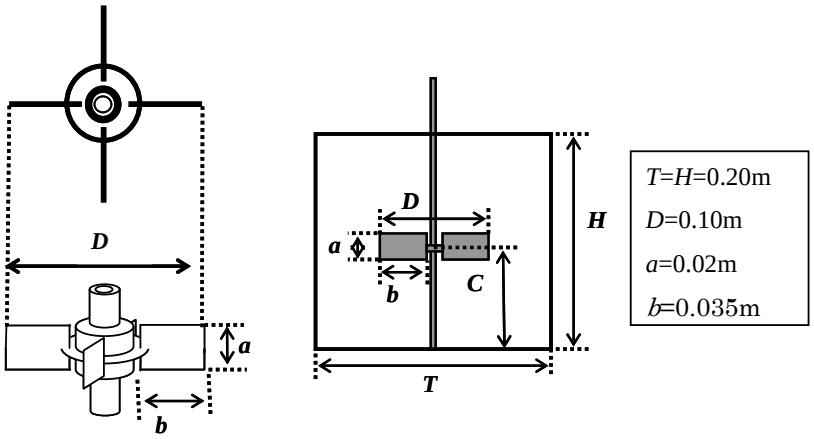

Fig. 1 Schematic of stirred vessel

2 Experiment and Numerical Simulation

In this study, inertial particle motion in a stirred vessel was investigated experimentally and numerically at low Reynolds numbers (*Re* = 10, 30). The mixing system consists of a cylindrical flat-bottom vessel without baffle and a 4-bladed Rushton turbine, as shown in Figure 1. In order to reduce photographic distortion, the cylindrical vessel was immersed in a square vessel of acrylic resin filled with the same glycerine solution. The ratio of impeller off-bottom clearance to the tank diameter *C*/*T* was 0.5. The working fluid was glycerine (ρ = 1260 kg/m^3, μ = 1.4 Pa·s).

Fluorescent pH-sensitive neutrally-buoyant green dye was used as a passive tracer to observe the mixing process. The working fluid was initially made basic by a small amount of basic solution consisting of 0.5 N NaOH and glycerine. After the turbine reached a certain rotational speed, a small amount of acidic solution consisting of 0.5 N HCl and glycerine was carefully added at the top of the vessel so as to decolorize the green dye by a neutralization reaction.The trajectories of resin particles having the density of 1377–1663 kg/m^3 and the diameter of 5 mm were analyzed using image processing. After a steady state was achieved, 10 particles were released on the upper surface at 1 or 5 cm away from the impeller axis.

The commercial CFD code RFLOW (Rflow Co, LTD) was used for the simulation of the motion of a particle. This numerical code is based on the finite volume method and makes it possible to simulate particle motion by a particle tracking method. All numerical conditions except particle size and particle density were the same as those for the experiment. The number of computational mesh is 60×60×60 in radial, circumferential and axial directions, respectively. Particle size and particle density were changed from 1.0×10^{-6} to 1.0×10^{-3} m and from 1200 to 1300 kg/m^3, respectively. Each particle was generated at the top of the device. At the first step, flow fields were obtained by solving the three-dimensional Navier-Stokes equations and the mass conservation for incompressible fluid in cylindrical coordinates, as shown in Eqs (1) –(4).

$$\rho\left(\frac{\partial v_r}{\partial t}+v_r\frac{\partial v_r}{\partial r}+\frac{v_\theta}{r}\frac{\partial v_r}{\partial \theta}-\frac{v_\theta^2}{r}+v_z\frac{\partial v_r}{\partial z}\right)=-\frac{\partial P}{\partial r}+\mu\left[\frac{\partial}{\partial r}\left\{\frac{1}{r}\frac{\partial}{\partial r}(rv_r)+\frac{1}{r^2}\frac{\partial^2 v_r}{\partial \theta^2}-\frac{2}{r^2}\frac{\partial v_\theta}{\partial \theta}+\frac{\partial^2 v_r}{\partial z^2}\right\}\right]+\rho g_r \quad (1)$$

$$\rho\left(\frac{\partial v_\theta}{\partial t}+v_r\frac{\partial v_\theta}{\partial r}+\frac{v_\theta}{r}\frac{\partial v_\theta}{\partial \theta}+\frac{v_r v_\vartheta}{r}+v_z\frac{\partial v_\theta}{\partial z}\right)=-\frac{1}{r}\frac{\partial P}{\partial \theta}+\mu\left[\frac{\partial}{\partial r}\left\{\frac{1}{r}\frac{\partial}{\partial r}(rv_\theta)+\frac{1}{r^2}\frac{\partial^2 v_\theta}{\partial \theta^2}+\frac{2}{r^2}\frac{\partial v_\theta}{\partial \theta}+\frac{\partial^2 v_r}{\partial z^2}\right\}\right]+\rho g_\theta \quad (2)$$

$$\rho\left(\frac{\partial v_z}{\partial t}+v_r\frac{\partial v_z}{\partial r}+\frac{v_\theta}{r}\frac{\partial v_z}{\partial \theta}+v_z\frac{\partial v_z}{\partial z}\right)=-\frac{\partial P}{\partial z}+\mu\left\{\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial v_z}{\partial r}\right)+\frac{1}{r^2}\frac{\partial^2 v_z}{\partial \theta^2}+\frac{\partial^2 v_z}{\partial z^2}\right\}+\rho g_z \quad (3)$$

$$\frac{1}{r}\frac{\partial(rv_r)}{\partial r}+\frac{1}{r}\frac{\partial v_\theta}{\partial \theta}+\frac{\partial v_z}{\partial z}=0 \tag{4}$$

Then the particles were tracked by solving Eq. (5),

$$\rho_p\frac{d\mathbf{V}_p}{dt}=\frac{3}{4d_p}C_D\rho_f\left|\mathbf{V}-\mathbf{V}_p\right|\left(\mathbf{V}-\mathbf{V}_p\right)+\rho_f\frac{D\mathbf{V}}{Dt}+\frac{1}{2}\rho_f\left(\frac{D\mathbf{V}}{Dt}-\frac{D\mathbf{V}_p}{Dt}\right)+\left(\rho_p-\rho_f\right)\mathbf{g} \tag{5}$$

where $\mathbf{V}_p$ is the velocity of the particle, $\mathbf{V}$ is the velocity field of the fluid, d_p is the particle diameter, ρ_p is particle density, ρ_f is fluid density, $\mathbf{g}$ is gravitational acceleration and C_D is the drag coefficient. The Basset history force, which is important in the initial motion of a particle starting from rest under certain conditions, was neglected.

3 Results and Discussion

As shown in Figure 2, when particles were released on the surface at 1.0 cm away from the impeller, several particles were captured on a torus orbit within the lower IMR and kept traveling around the impeller, while the rest of the particles sunk to the bottom of the vessel. On the other hand, when particles were released on the surface at 5.0 cm away from the impeller, several particles were captured on a torus orbit within the upper IMR (not shown in Figure 2). Initially, two IMRs clearly can be seen in Figure 2 a), After 18 h, the upper IMR is still visible, while the lower IMR is decolorized as shown in Figure 2b). This result indicates that particles caputured in the IMRs enhance the exchange of material with the outside active mixing region.

In our previous works (Ohmura *et al.*, 2003; Nishioka *et al.*, 2007), the primary and secondary circulation flow directions were defined as ϕ- and θ-direction respectively and the period for one round of a particle in ϕ-and θ-direction were also defined as P_ϕ and P_θ. This work also followed the above manner and investigated the relation between P_θ and P_ϕ of the particle captured in the IMRs. In order to clarify particle orbit within IMR, this work constructed Poincaré sections corresponding to an arbitrary plane cutting a torus orbit transversally in the manner of nonlinear dynamics. Particle orbit obtained by Poincaré section obtained particle obit initially shows that the particle motion covers the full surface of the torus orbit and P_θ/P_ϕ of the particle is irrational, as shown in Figure 3 a).

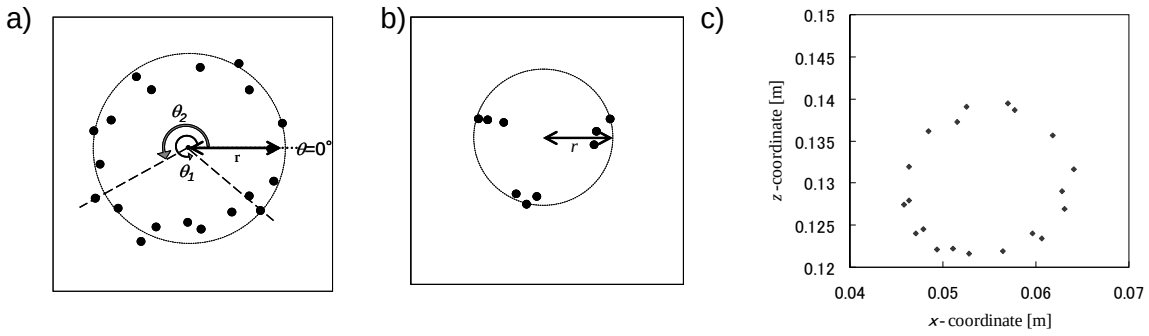

Fig. 3 Poincaré sections of particle orbit; a) experimental (30 min), b) experimental (120 min) and c) numerical (30 min)

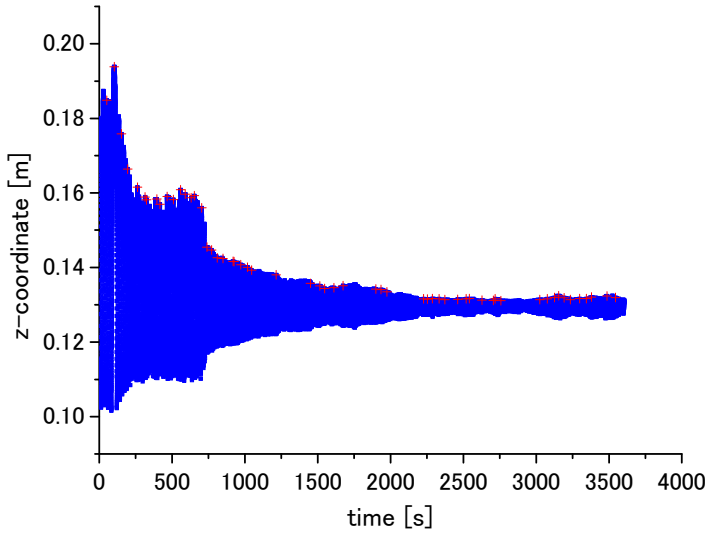

Fig. 4 Numerically obtained time trace of particle position in *z*-component (Re = 10, d_p = 8 mm, ρ_p = 1200 kg/m^3)

On the other hand, a circular orbit on the Poincaré section converges on three discrete points as shown in Figure 3b).This indicates that P_θ / P_ϕ is rational and the particle motion becomes phase-locked on the torus. Ohmura *et al*. (2003) revealed that the ratio of the time period for one round of a filament around the core IMR in θ-direction to the time for one round of a tracer particle in the filament in ϕ-direction is rational. It can thererfore be considered that particles initially move on the surface of the core torus and finally move in a filament within IMR. The particle trajectories obtained by numerical simulation show good agreement with the results of the experiment, as shown in Figure 3 c). However, no phase-locked orbit could be observed in numerical simulations so far.

Figure 4 shows numerically obtained time trace of particle position in *z*-component. This figure shows that the diameter of particle rotation orbit decreases stepwise with time. As can be seen during 250 and 750 s, even once a particle has settled on a certain orbit, the diameter flactuates. Furthermore, even after a particle seems to have almost settled on a final orbit (after 2000 s), the diameter is not constant. This particle motion may contribute to enhancement of material exchange with the outside active mixing region, as previously shown in Figure 2 b). The effects of particle diameter and particle density on particle motions were investigated by extracting local maximum values of particle position in *z*-component.

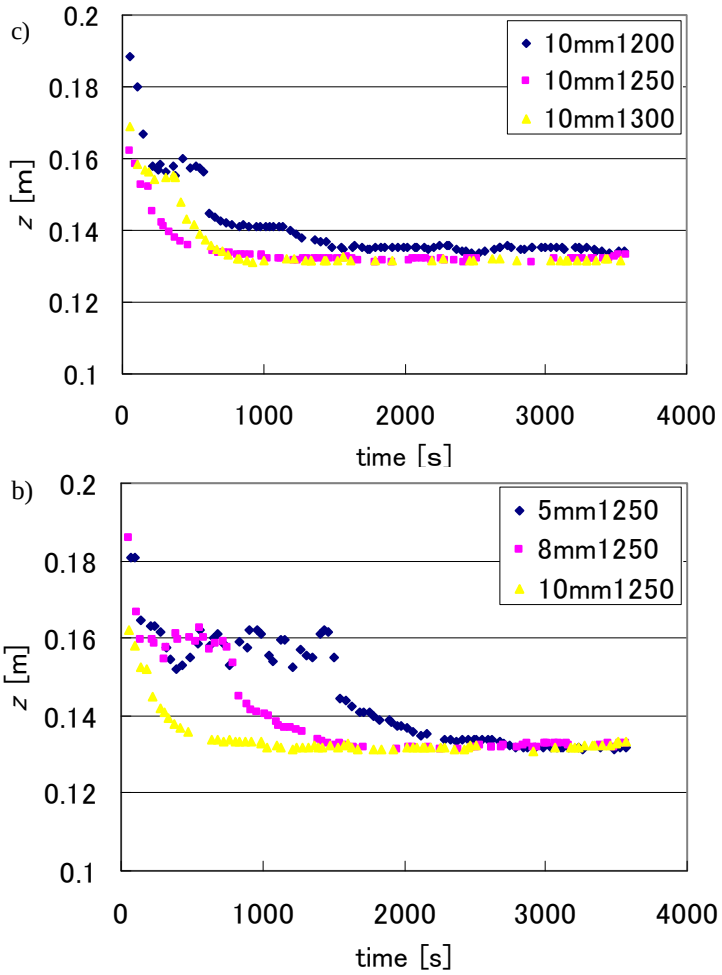

Figure 5 local maximum values of particle position in z-component against time

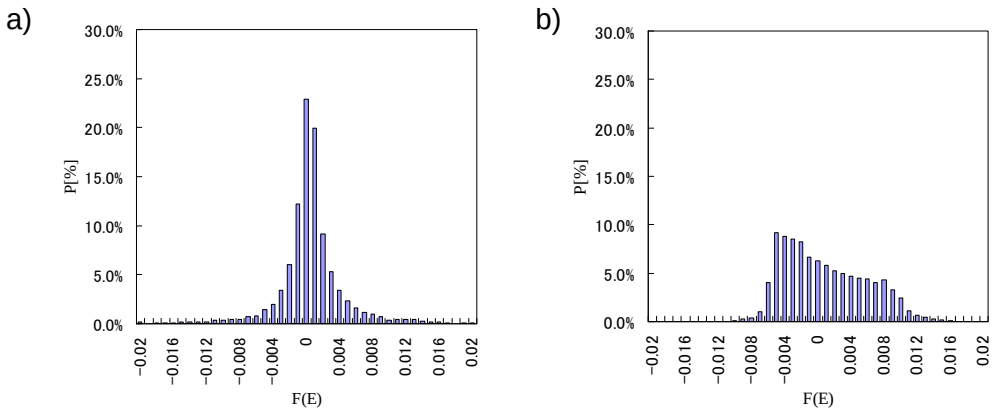

Fig. 6 Distribution of drag force on particle in *r*-direction; a) 0–25 min (before the convergence) and b) 25–60 min (after the convergence)

Figure 5 shows the tendency that the larger and heavier the particle is, the faster it converges. When the diameter is 5 mm, however, the heavier particle does not always converge faster.

Figure 6 shows that the drag force on particle in *r*-direction has drastically changed after particles are captured by the recirculation of IMRs. The drag force arises from the velocity difference between fluid and particles. Before a particle has been captured, it circulates through the whole region in the vessel. While the particle circulates through a tank apart from the impeller, the particle hardly receives the influence of accelerating flow discharged from the impeller. This means that the drag force does not work on the particle during this circulation. On the other hand, after the particle has been captured, the flow around the particle is repeatedly accelerated and decelerated by the impeller, because the particle always exists near the impeller. This indicates that the drag force frequently works on the surface of particle. The term of drag force on the particle is closely related to the mass transfer between partcle and liquid. Hence, mass transfer might be enhanced when a particle is within an IMR. In future work, the authors will investigate mass transfer between paticle and liquid in IMRs.

4 Conclusion

In this study, inertial particle motion in a stirred vessel with no baffle plate was observed experimentally and numerically at low Reynolds numbers (*Re* = 10, 30). Several particles were captured on a torus orbit within one of the IMRs and kept traveling around the impeller. Which IMR particles are captured depends on the position of particles when released. Initially, particle orbit obtained by Poincaré section showed that the particle motion covered the full surface of the torus orbit and P_θ / P_ϕ of the particle was irrational, while after a long time, the circular orbit on the Poincaré section converged on three discrete points. This indicates that P_θ / P_ϕ is rational and the particle motion becomes phase-locked on the torus. Numerical simulation revealed that even after a particle seemed to have almost settled on a final orbit (after 2000 s), the diameter of secondary circulation was not constant. This particle motion may contribute to enhancement of material exchange with the outside active mixing region. After a particle has been caputured, the drag force frequently works on the surface of the particle since the particle always exists near the impeller and the flow around the particle is repeatedly accelerated and decelerated by the impeller. This effect may enhance mass transfer between particle and liquid in IMRs.

Key words: wine, tartaric stability, saturation temperature; mini-contact test

Topic: Sustainable process-product development through green chemistry.

Abbreviations: ED: electrodialysis; MCT: mini-contact test; DD: deionization degree; KHT: potassium hydrogen tartrate; RT: refrigerator test; T_{Sat}: saturation temperature.

Abstract

The development of electrodialysis (ED) as a robust industrial technology for wine tartaric stabilization is interlinked to the mini-contact test (MCT) as a mean of predicting the correct deionisation degree (DD) that should be carried out to guarantee the treated wine tartaric stability. The objective of this work is to quantify, for different type of wines, the influence of the key-parameters of the MCT - running time and granulometry of the seeding KHT crystals on the predicted DD and to determine the best values of these parameters that ensure that the ED treated wine is stable according to the refrigerator test (RT), which is widely used in the wine industry. The ED experiments were carried out in a bench scale ED apparatus using white, rosé, red and liqueur wines in batch mode. The DD varied from 0 to 30%. The MCT was performed for each wine during a maximum running time of 65 h. The tartaric stability of the raw and partially deionised wines was assessed by the RT and by the saturation temperature (T_{sat}). For the type of wines investigated, the MCT predicts a DD required for stabilizing the wine that is strongly dependent on the running time of the test. The RT exhibited a very good reliability for the wines tested. The MCT can predict an accurate DD that ensures the tartaric stability of the ED treated wine, provided its key-parameters (e.g. running time) are adjusted empirically for each type of wine.

1. Introduction

In winemaking it is usually necessary to reduce the concentration of potassium hydrogen tartrate (KHT) of the wine, to avoid the precipitation of this salt in the bottles, which adversely affects the percepted quality of the product. The conventional process for the tartaric stabilization of wine does not allow a precise control of the final KHT concentration and may also decrease the wine quality due to the simultaneous precipitation of polysaccharides and polyphenols together with the KHT salts (Maujean 1994, Moutounet et al. 1997, Ribereau-Gayon et al. 1998, Benítez et al. 2003).

A more recent process developed to overcome the previous drawbacks in tartaric stabilization is electrodialysis (ED) (Strathman 1986, Moutounet et al 1994, Gonçalves et al 2003). With this process and under an applied electric potential, the KHT is transferred from the wine to an aqueous solution that is separated from the wine by ion exchange membrane.

The degree of deionization (DD) (defined by the relative decrease of the wine conductivity) required to stabilize a wine by ED, must be determined with accuracy before the wine treatment. The DD has been determined with recourse to the mini-contact test (MCT), (Ribéreau-Gayon et al. 2006, Benítez et al. 2004). The difference between conductivity at the beginning and at the end of the time period gives an estimative of the DD required to stabilize a wine by ED. It is crucial, for the widespread of this more recent technology, to confirm experimentally for different types of wines if the DD predicted by the MCT if sufficient to ensure that the treated wine passes the common quality control tests that are used to monitor the tartaric stability of the wine.

The traditional method to verify if a wine is stable, which is widely used by many wine producers is the refrigerator test (RT). The method, basically, consists in verifying if crystalline sediments appear in a sample stored at low temperature, for red wines, and bellow the freezing temperature, for other types of wines. At best of our knowledge, there are no established standard protocols for this test and each wine producer uses its own. The stability of wines has been assessed also by the measurement of the saturation temperature (T_{Sat}) (Würdig et al. 1982). At the T_{Sat}, the wine attains the equilibrium concentration of KHT and, for this reason, T_{Sat} is a good indicator of the wine saturation level in KHT (Santos et al. 2002).

The development of ED as a robust industrial technology for wine tartaric stabilization is interlinked to the MCT as a mean of predicting the correct DD that should be carried out to guarantee the treated wine tartaric stability.

The aim of this work is to quantify, for different type of wines, the influence of the key-parameters of the MCT – running time and granulometry of the seeding KHT crystals – on the predicted DD and to determine the best values of these parameters that ensure that the ED treated wine is stable according to the RT.

2. Material and methods

2.1 Wine Samples. The ED experiments were carried out with wine samples that were supplied by José Maria da Fonseca Vinhos SA, Azeitão, Portugal. The white, rosé, red and liqueur wines were produced from grapes harvested in 2006, 2006, 2005, and 2001, respectively. The summary analysis of the wines used is presented in Table 1.

Table 1 Physico-chemical characterization of the wines.

Parameter	Red wine	White wine	Rose wine	Liqueur wine
pH	3.48	3.20	3.11	3.41
Conductivity (20ºC) ($\mu S.cm^{-1}$)	2040	1920	2140	878
Ethanol (%v/v)	13.4	12.0	10.4	17.4

2.2 Analytical methods. The ethanol concentration was determined by the reference method of the Office International de la Vigne et du Vin, 1990. The wine conductivity was measured with a conductivity meter, model GPL32 from CRISON (Barcelona, Spain), using a conductivity cell with a constant of 1 cm^{-1}.

2.3 ED experiments. The several wines were processed by the bench scale ED unit EUR2C-7P18 from Eurodia Industrie, S.A, France. The ion exchange membranes were supplied by TOKUYAMA SODA, Japan and the ED stack had seven cells constituted by 7 anionic membranes (type CMXSb) and 9 cationic membranes (type CMXSb). Each membrane had an effective area of 2 dm^2. A sample of 3.0 L of wine was processed at room temperature using a constant electric potential difference of 1.5 Volt/cell, corresponding to the maximum value recommended by the equipment manufacturer. The concentrate compartment was initially filled with 3.0 L of an aqueous solution of 0.2 mol/L of KHT (pro analysis grade from Riedel-de Haën) acidified at pH 3 with nitric acid (65% from Panreac). The electrodes were rinsed with 3.0 L of an aqueous solution of 0.2 mol/L of K_2SO_4 (pro analysis grade, from Scharlau, Germany). The flowrate of the concentrate, diluate and electrode rinsing solution were 180 L/h, 250 L/h and 400 L/h, respectively. Both the conductivity and pH of the wine were measured during the experiments.

2.4 Mini-contact test. The conductivity of a wine sample of 100 mL with 4 g/L of very fine KHT crystals seeds, was measured and registered in a computer during 65 hours. The wine sample was continuously agitated with a magnetic stirrer at 700 RPM and the wine temperature was controlled at -4º for white, rose and red wines and at -8ºC for liqueur wine. The required degree of deionization (DD) was estimated by the relative variation of the wine conductivity after a given running time.

2.5 Saturation Temperature (T_{Sat}). The experimental saturation temperature of a wine was determined by measuring electrical conductivity in a two-step experiment, using a set-up described elsewhere (Santos et al. 2002). In the first experiment, the wine was brought to 0ºC in a thermostat-controlled bath equipped with sources of heat and cold. The temperature was then raised to 30ºC with 0.5ºC/min increments and the wine's conductivity measured continuously. In the second experiment, the same wine was brought to 0ºC, 4.0 g/L of KHT crystals were added and the temperature was once again raised to 30ºC in 0.5ºC/min increments. In both experiments the wine was agitated continuously with a magnetic stirrer at 700 rpm and its conductivity was measured every second. The T_{sat} of any wine is given by the intersection of the two experimental curves of the variation of the conductivity versus temperature. KHT pro analysis grade from Riedel-de Haën was used in this test.

2.6 Refrigerator Test. Before the refrigeration, the wine samples were first filtrated to remove suspended mater. The filtration was performed with 2.5 μm Whatman Paper filter number 22, with a pre-coating of filter aid Fibroklar L (Reinhardt Kellereibedarf, Germany), to assured that particles that may act as crystallisation seeds are kept to a minimum value for all the wines in order to increase the reproducibility of the test. For the case of the white, rose and liqueur wines, 100 mL glass screw cap bottles from ISOLAB (Germany) were filled with wine and then were placed in a refrigerator at -20 ºC until the wine freeze. After that, the glass bottles were placed in room temperature water to unfreeze the wine and, as soon as there was sufficient liquid wine, the bottoms of the bottles were inspected at naked eye to determine if crystals had precipitated. The wine was considered unstable if crystal were detected and stable, otherwise. For the case of the red wine, and following the same practice used by some wine producers in Portugal, the visual inspection of the existence of KHT crystal was performed after maintaining 100 mL of a wine sample at -4 ºC during 6 h without stirring.

3. Results and discussion

3.1 Mini-contact test. The DD for the different wines predicted by the MCT depends strongly on the running time of the test, as shown in Table 2 for all the types of wine. These results indicate that the running time of the MCT must be optimised in order to predict accurately the DD required stabilizing the wine.

Table 2. Deionization degree predicted by the mini-contact test at different running times.

	DD (%) for running time of			
Wine type	18 min	4h	24h	65h
White	6.98	13.7	17.8	20.1
Rose	19.0	23.8	26.7	28.1
Red	0.00	0.23	3.66	7.09
Liqueur	3.46	11.9	17.7	20.8

3.2 Tartaric stability analysis of the wines deionised by ED. The tartaric stability of the different wines deionised by ED was accessed by the RT for different DD, ranging from 0 to 30%, and the results are displayed in Table 3. According to this test, the untreated red and liqueur wines were already stable, but the white and the rosé wines were only stable after a DD of 5% and 30%, respectively. It has been claimed (Ribéreau-Gayon et al. 2006, Benítez et al. 2004) that the RT suffers from poor reproducibility and is not always reliable, nor easily repeatable due to the complex phenomenon of spontaneous, non-induced crystallization. Nevertheless, with the protocol used in the present work, the RT exhibited a very good reliability for the wines tested.

Table 3. Tartaric stability state[1] of the different wines vs. the DD, according to the refrigerator test.

		Wine tartaric stability state of			
	DD (%)	Red wine	White wine	Rose wine	Liqueur wine
wine samples filtered with 2.5 μm paper filter + Fibroklar L	0	S	U	U	S

	20	S	U	U	S
	25	S	S	U	S
	30	S	S	S	S

[1)] S - stable wine; U - unstable wine

In fact, as it can be seen in Table 4, the RT gave always the same result below and above the required value of the DD, for all the different of wines tested. For the different DD, Table 4 displays also the tartaric stability state of the different wines predicted by the MCT for running times of 18 min, 4 h, 24 h and 65 h. With this test, a wine is considered stable if the predicted DD of the MCT is lower that the real DD of the wine. It is noteworthy to observe that both the RT and the MCT, at a running time of 65 h, predict the same tartaric stability state for the white, rosé and red wines, for all the values of DD, except for the red wine without deionization. For the liqueur wine, the MCT is in agreement with the RT only for a running time of 18 min. This wine exhibits a good tartaric stability at low DD values, despite of the fact of being thermodynamically unstable.

For the white and rosé wines, the discrepancies between the predictions of the RT and the ones of the MCT, increase when the running time of the MCT decreases. For a running time of 4 h, the MCT strongly under-predicts the DD required for stabilizing the wine. When the running time increases to 24 h, the under-prediction is not higher than 5%. If an error of this magnitude is considered acceptable for the DD imposed to the ED of the wine, the time required to perform the MCT may be reduced from 65 h to 24 h. Further reduction of the running time to 4 h must be done with caution and taking into account that the true DD required for wine stabilization may be substantially higher that the predicted value.

Table 4 Tartaric stability state[a] predicted by different methods and saturation temperature for the different wines vs. the DD.

	15	S	S	S	U	U	14.0
	20	S	S	S	S	U	[c)]
	25	S	S	S	S	S	[c)]
	30	S	S	S	S	S	[c)]

[a)] S - stable wine, U - unstable wine.

[b)] The wine was considered stable because the predicted DD was not higher than 5%.

[c)] The test was irreproducible.

The T_{Sat} of the different wine samples is also displayed in Table 4. For the white and rosé wines, the T_{Sat} decreases almost linearly with the DD in a similar way as observed already in a previous work for the other type of wines (Gonçalves et al. 2003). For the white wine with a DD of 25%, which is considered stable by the RT and by the MCT at 65 h, the T_{Sat} is 9.0 ºC.

According to Maujean et al. (1985, 1986), for white and rosé wines with alcohol content of about 11%v/v, the spontaneous crystallization temperature is equal to the T_{Sat} minus 15ºC. With this criterion, the white wine with a DD equal to or higher than 25% is stable at the temperature of the MCT, which is -4 ºC. In the case of the rosé wine, and using the Maujean criterion, the rosé wine is stable for a DD equal to or higher than 15%. These results show that the Maujean criterion gives results compatible with the RT for the white wine, but not for the rosé wine. For the case of the red and liqueur wines, the Maujean criterion is not applicable by default, due to their higher alcohol content.

4. Concluding remarks.

For the type of wines investigated, the MCT predicts a DD required stabilizing the wine that is strongly dependent on the running time of the test. With the protocol used is present work, the RT exhibited a very good reproducibility for the wines tested. Both the RT and the MCT, at a running time of 65 h, predict the same tartaric stability state for the white, rosé and red wines, for all the values of DD, except for the red wine without deionization. For the liqueur wine, the MCT is in agreement with the RT only for a running time of 18 min. This indicates that the MCT at 65 h is a very robust method to predict a DD that ensures that the ED treated wine is always stable. The MCT can predict a less severe and more precise DD that ensures the tartaric stability of the ED treated wine, provided its key parameters (e.g. running time) are adjusted empirically for each type of wine. The fine-tuning of the MCT key-parameters for different types of wines contributes to increase the ED reliability and robustness for wine tartaric stabilization.

Characterization of a Microporous Titanosilicate AM-3 Membrane – Pure gas permeation

Patrícia F. Lito, Sara B. Barros, Chunfang Zhou, João Rocha, Zhi Lin, Carlos M. Silva[1]

University of Aveiro, Department of Chemistry, CICECO, 3810-193 Aveiro, Portugal

Keywords: AM-3, Titanosilicates, Microporous Membranes, Gas permeation.
Topic: Advancing the chemical and biological engineering fundamentals.

Abstract

In this work, two microporous AM-3 membranes were studied. Thin AM-3 films were hydrothermally crystallized on porous α-alumina supports by seeded hydrothermal technique, and were subsequently characterized by measuring pure N_2 permeation flux. The enhancement in the N_2 fluxes observed after an heating/cooling cycle confirms the hydrophilic character of AM-3 crystals. The flux of N_2 in both membranes depends linearly on the transmembrane pressure drop, evidencing the absence of viscous flow. Permeances found were 6.84×10^{-7} mol/(m^2sPa) and 8.42×10^{-7} mol/(m^2sPa) for one membrane, and 1.03×10^{-7} mol/(m^2sPa) and 1.23×10^{-7} mol/(m^2sPa) for the second membrane, which are well inside typical values for microporous membranes. Accordingly, results suggest that good quality membranes were obtained.

1. Introduction

Membrane processes are very attractive methods to separate a variety of gas mixtures due to their relatively low energetic consumption and high selectivities observed in comparison with more conventional processes (Xomeritakis and Tsapatsis, 2001). Accordingly, the interest in the application of membrane technology in gas separation and purification processes has been intensified.

Microporous inorganic membranes are promising materials due to their high thermal and chemical stability, and resistance to high pressure differences. Among them, a variety of zeolite membranes have been successfully synthesized and applied in the separation of different mixtures, including azeotropic and other difficult ones (Kita et al., 1995; Coronas et al., 1997; Giroir-Fendler et al., 1996; Xomeritakis et al., 2001).

Titanosilicate membranes belong to the microporous inorganic group. Similarly to zeolites, these materials exhibit a crystalline structure with molecular dimensions and are able to separate mixtures based on differences in affinity and sieving effect (Poshusta et al., 1998). In addition, they comprise benefits over more classical zeolite membranes (Lin et al., 2004), namely: they can be synthesized without organic templates, avoiding subsequent calcination treatments which often causes irreversible defects and/or loss of active surface groups; they are prepared under moderate pH conditions, reducing chemical attack of the support surfaces; and they exhibit novel possibilities of isomorphous framework substitution, allowing for fine-tuning of catalytic and adsorption properties.

Only a small number of microporous titanosilicate membranes have been recently synthesized and characterized, mainly reporting to ETS-4 (Guan et al., 2001; Braunbarth et al., 2000; Guan et al., 2002). Preparation of ETS-4 films on porous alumina and titania supports by secondary growth method was described by Yilmaz et al. (2006), however only crystals orientation were investigated. Hetero-epitaxial growth of ETS-10 on ETS-4 has been

[1] Corresponding author. Tel +351 234 401549. E-mail:carlos.manuel@ua.pt

accomplished, but no permeation or separation results have also been published (Jeong et al., 2002). Preparation and characterization of ETS-10 membranes were presented for the first time by Lin et al. (Lin et al., 2004) and subsequently by Tiscornia et al. (2005, 2007). Sebastían et al. (2005, 2006) reported the synthesis, characterization, and separation properties of a Ti-Silicate umbite membrane (AM-2) by seeded hydrothermal synthesis. Reported results suggest the potential of titanosilicate membranes for water/organic compounds, and gas mixtures separations.

AM-3 is a synthetic microporous titanosilicate analogue of mineral penkvilksite $Na_4Ti_2Si_8O_{22}.5H_2O$ (Lin et al., 1997, 2006; Rocha and Anderson, 2000). Its structure consists of SiO_4 tetrahedra connected by individual TiO_6 octahedra forming a three-dimensional framework of 6-ring channels (Lin et al., 2006), and contrarily to most titanosilicates, it does not contain Ti–O–Ti linkages. In a previous work (Lin et al., 1997) it was shown that AM (Aveiro-Manchester) materials adsorb water in relatively large amounts. In addition, AM-3 was demonstrated to be stable up to ca. 600 ºC, loosing water and rehydrating back after being kept in air for a few hours at room temperature. A detailed morphological characterization of AM-3 was reported first by Lin et al. (1997) and later by Rocha and Anderson (2000). At the moment, no publications have been presented concerning the preparation and characterization of AM-3 membranes. Only its ability to sorb radioactive cobalt-60 using an ion-exchange batch-type method has been studied (Koudsi and Dyer, 2001).

Membranes characterization is a fundamental test before their use in a mixture separation. In addition to its structure determination, it is essential to study permeation properties, which are directly related to the density and size of defects. With this information, ideal preparation and operation conditions can be established in order to obtain a defect-free membrane, and so a good quality membrane. Permeation of certain molecules, such as nitrogen, can be used to detect the presence of rough defects in the zeolite structure. Accordingly, over enhanced N_2 permeances evidence the presence of defects.

In the present work, two thin AM-3 films were hydrothermally crystallized outside a porous α-alumina support by seeded hydrothermal technique (Lovallo and Tsapatsis, 1996). Subsequently, the existence of rough defects or cracks in both membranes was investigated by means of single N_2 permeation runs.

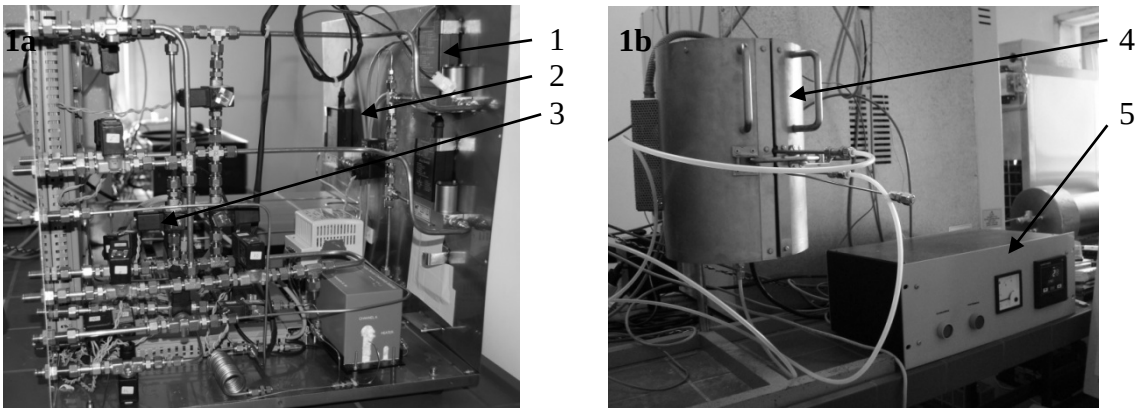
2. Experimental Section

The experimental set-up used for the permeation measurements is shown below in Figures 1a and 1b. Membrane features of both synthesized AM-3 membranes may be found in Table 1.The presence of adsorbed compounds, like water from air humidity, affects the results; therefore a previous heating/cooling cycle up to ca 200ºC was performed before the permeation measurements. Experiments were conducted with a transmembrane pressure difference providing the driving force for permeating and no sweep gas was used.

A stainless-steel module containing the membrane was placed inside an oven with temperature control (TC). Viton o-rings were used to seal the membrane inside the module. The flow rate of feed gas was fixed by means of a mass flow controller (MFC) and the permeate flow rate was measured by a mass flow meter (MFM) until the equilibrium be reached. The permeate side was kept at atmospheric pressure; the feed side pressure was measured in this work with a back pressure regulator (BPR). During the experiments the feed flow rate was varied between 10 and 300 cm^3(PTN)/min and the temperature was kept at 298 K.

Table 1: Features of AM-3 membrane.

Membrane material	AM-3
Support material	α-alumina
Membrane pore diameter, 10^{-9}m	direction a: 0.3x0.3 direction b: 0.4x0.25
Support pore diameter, 10^{-9}m	3000
Membrane diameter, 10^{-2}m	1.0
Membrane length,10^{-2}m	5.6



Figures 1a and 1b – Experimental set-up used for permeation measurements. Legend: 1 – MFM; 2 – BPR; 3 – MFM; 4 – Oven; 5 – TC.

3. Results and discussion

Figure 2 shows nitrogen permeation flux as function of transmembrane pressure drop for both synthesised membranes, before and after the heating/cooling cycle; calculated permeances, corresponding to the slop of linear fittings to the experimental data, are also included in the figure. Permeances found were 6.84×10^{-7} mol/(m^2sPa) and 8.42×10^{-7} mol/(m^2sPa), for one membrane, and 1.03×10^{-7} mol/(m^2sPa) and 1.23×10^{-7} mol/(m^2sPa), for the other one. Generally, single N_2 permeances in microporous membranes have values in the range of 1×10^{-7} and 1×10^{-6} mol/(m^2.s.Pa); over-enhanced values denunciate the existence of rough defects in the membrane. Accordingly, results suggest good quality membranes. It is important to note that permeances depend on the membrane thickness, which explains the difference observed in the permeance values of both membranes.

As may be observed, the N_2 fluxes are enhanced after the heating/cooling cycle; such behaviour supports the hydrophilic character of AM-3 crystals. Besides, the flux of N_2 in both membranes depends linearly on the transmembrane pressure drop, which evidences that viscous flow may be neglected. In fact, for non-adsorbable gases the permeation flux in micro and mesopores is directly proportional to the pressure gradient. Therefore, it may be anticipated that our synthesized membranes do not exhibit macropores or other rough defects.

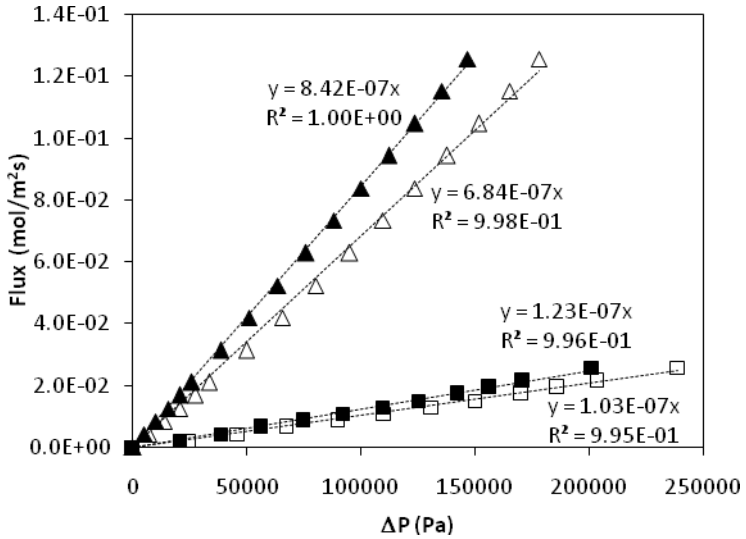


Figure 2: N_2 permeation flux plotted as function of transmembrane pressure. Symbols: ▲ and △: membrane 1; ■ and □: membrane 2. Open and full symbols: before and after the heating/cooling cycle, respectively. Lines: correlations.

3. Conclusions

In this work two microporous AM-3 membranes were characterized by measuring pure N_2 permeation flux. The enhancement of the N_2 fluxes observed after the heating/cooling cycle confirms the hydrophilic character of AM-3 crystals. The flux of N_2 in both membranes depends linearly on the transmembrane pressure drop, evidencing negligible viscous flow contribution. Furthermore, permeances found are well inside typical values for microporous membranes. In the whole, results suggest that good quality membranes were obtained.

Abstract

In this work, solubilities in pure solvents of some drugs measured in the temperature range from 298.2 K to 315.2 K are presented. Measurements were performed using the standard shake-flask method, followed by compositional analysis by HPLC. Theoretical work was essentially focused on the application of the NRTL-SAC model, with a very satisfactory agreement between experimental data and predicted values. The *reference solvent approach* was also addressed but the results were worst, although still fair.

1. Introduction

New drugs are always under development during the establishment of new therapies. Solubility is important both for drug production and in its therapeutic use. Many separation processes in the pharmaceutical industry are based on the solubilities in different solvents, while solvation is important in each stage of drug transport and delivery. Properties like lipophilicity, hydrophilicity, the ability to establish hydrogen bonds and other interactions of the molecules with the surrounding media play an important role in the solvation process. Although some thermodynamic tools can be used to predict drug solubility, the availability of experimental data is still fundamental for appropriate model development and evaluation. However, there are inherent complexities with experimental measurements: accuracy and reliability are difficult to achieve, and experiments are time consuming. So, efficient methods to predict solubilities are a main research subject, with high value for drug design.

In spite of drugs being so complex molecules, with several functional groups, having different structures or isomers, or even different solid structures, a few methods were proposed to represent their solubility. In this work, two approaches are addressed. The Nonrandom Two Liquid–Segment Activity Coefficient (NRTL-SAC) model (Chen and Song, 2004) which is a modification of the original NRTL model (Prausnitz et al., 1999), and has been widely applied to correlate and predict phase equilibria of highly nonideal systems. It is, in fact, one of the most successful models for the representation of drug solubility. Alternatively, Abildskov and O'Connell (Abildskov and O'Connell, 2003) proposed the *reference solvent approach* to predict the changes of solubilities with solvent composition. This methodology is also focused in this work.

In this study, solubilities of some drugs, such as paracetamol, budesonide, furosemide and allopurinol, were measured in the temperature range from 298.2 K to 315.2 K, in water, and in a set of organic solvents (ethanol, acetone, n-hexane, ethyl acetate and carbon tetrachloride), at 298.2 and 310.2 K. Measurements were performed using the shake-flask method for generating the saturated solutions, followed by compositional analysis by HPLC or gravimetry. Concerning the theoretical work, it was possible to find a very satisfactory agreement for correlation of the solubility data measured.

2. Experimental

All the solubility experiments were carried out using the isothermal saturation shake-flask method. The aqueous solubilities were measured at five different temperatures 298.2, 303.2, 310.2, 313.2 and 315.2 K, while for the other solvents (ethanol, acetone, ethyl acetate, carbon tetrachloride and n-hexane), the solubilities were only obtained at 298.2 and 313.2 K. Saturated solutions were prepared mixing an excess of solute and solvent, stirring for 2 days and then allowing to settle for 1 day. The temperature was maintained constant by a circulating water bath and with an air bath (composed by an acrylic box, a resistance, an electric fan and a temperature controller) and monitored by platinum resistance probes connected to a data acquisition unit. Samples from the saturated liquid phase were removed with isothermal syringe filtration and the drug composition determined from liquid chromatography (HPLC). To verify the accuracy of the chromatographic method, some measurements were also done by the gravimetric method.

Melting data (melting temperature and enthalpy of fusion) of the pure drugs were obtained by differential scanning calorimetry (DSC) to provide a broader understanding of the solubilization process, as well as for modeling purposes.

3. Modeling

Considering that the heat capacity difference between the liquid and the solid phases is negligible (Prausnitz et al., 1999), the temperature dependence of solubility can be described by the following general equation:

$$\ln x_2 = -\frac{\Delta_{fus}H}{R}\left(\frac{1}{T}-\frac{1}{T_m}\right)-\ln\gamma_2 \tag{1}$$

where x_2 is the mole fraction of the solute, $\Delta_{fus}H$ is its enthalpy of fusion, R the ideal gas constant, T the absolute temperature, T_m the melting temperature, and γ_2 is the solute activity coefficient.

The NRTL-SAC model (Chen and Crafts, 2006; Chen and Song, 2004) is a modification of the original NRTL equation, where the combinatorial term (γ_I^C) is calculated from the Flory-Huggins approximation for the combinatorial entropy of mixing. The residual term (γ_I^R) is set equal to the sum of the local composition interaction contributions for each segment:

$$\ln\gamma_I = \ln\gamma_I^C + \ln\gamma_I^R \tag{2}$$

$$\ln\gamma_I^C = \ln\frac{\phi_I}{x_I} + 1 - r_I\sum_J\frac{\phi_J}{r_J} \tag{3}$$

with

$$r_I = \sum_i r_{i,I} \tag{4}$$

$$\phi_I = \frac{r_I x_I}{\sum_J r_J x_J} \tag{5}$$

$$\ln\gamma_I^R = \ln\gamma_I^{lc} = \sum_m r_{m,I}\left[\ln\Gamma_m^{lc} - \ln\Gamma_m^{lc,I}\right] \tag{6}$$

$$\ln \Gamma_m^{lc} = \frac{\sum_j x_j G_{jm} \tau_{jm}}{\sum_k x_k G_{km}} + \sum_{m'} \frac{x_{m'} G_{mm'}}{\sum_k x_k G_{km'}} \left(\tau_{mm'} - \frac{\sum_j x_j G_{jm'} \tau_{jm'}}{\sum_k x_k G_{km'}} \right) \quad (7)$$

$$\ln \Gamma_m^{lc,I} = \frac{\sum_j x_{j,I} G_{jm} \tau_{jm}}{\sum_k x_{k,I} G_{km}} + \sum_{m'} \frac{x_{m',I} G_{mm'}}{\sum_k x_{k,I} G_{km'}} \left(\tau_{mm'} - \frac{\sum_j x_{j,I} G_{jm'} \tau_{jm'}}{\sum_k x_{k,I} G_{km'}} \right) \quad (8)$$

with

$$x_j = \frac{\sum_J x_J r_{j,J}}{\sum_I \sum_i x_I r_{i,I}} \quad \text{and} \quad x_{j,I} = \frac{r_{j,J}}{\sum_i r_{i,I}} \quad (9) \text{ and } (10)$$

where I and J are the component indices, while i, j, k, m and m' are the segment based species indices, r_I is the total segment number, ϕ_I is the segment mole fraction, x_j is the segment based mole fraction of segment species j, x_J is the mole fraction of component J, $r_{m,I}$ is the number of segment species m contained in component I, Γ_m^{lc} is the activity coefficient of segment species m and $\Gamma_m^{lc,I}$ is the activity coefficient of segment species m contained only in component I. G and τ are local binary quantities related to each other by the NRTL nonrandomness parameter α:

$$G = \exp(-\alpha\tau) \quad (11)$$

To account for several interactions, predefined conceptual segments were proposed, along with their corresponding segment-segment binary parameters: one hydrophobic that represents the molecular surface area unlike to form hydrogen bonds; two polar (one repulsive and one attractive) that represent the surface area with interactions characteristic of an electron donor or acceptor; and one hydrophilic that represents the area with interactions characteristic of a hydrogen-bond donor or acceptor. The essence of this model consists on the use of these conceptual segments, which is different, for example, from group-contribution approaches which build molecules from a large set of predefined functional groups based in their chemical structure. Since for most of the solvents used in the pharmaceutical industry the parameters are already available (Chen and Crafts, 2006), the experimental data measured here are useful to estimate the solute parameters. After, the model can be applied to predict solute solubility in other solvent systems.

The *reference solvent approach*, proposed by Abildskov and O'Connell (2003, 2004, 2005), is a simplified methodology that allows the prediction of differences in solubilities of sparingly soluble chemicals when the solvent is changed, based on a limited set of experimental data. The method can not be applied if there are phase transitions in the solid phase, as long as, some compounds can have more than one metastable solid forms. If we have an activity coefficient model and know the solubility of the solute in one pure solvent *j*, the solubility in another pure solvent *i* can then be directly calculated according to:

$$\ln x_{2i} = \ln x_{2j} + \ln \gamma_{2j} - \ln \gamma_{2i} \quad (12)$$

where *i* and *j* are subscripts refering to the solvents and 2 to the solute. This equation is useful because no pure solute properties are needed. However, it requires the selection of a reference solvent *j*. The optimal reference solvent is one for which: (Abildskov and O'Connell, 2005, 2004, 2003)

$$\ln x_{2j} + \ln \hat{\gamma}_{2j} = \sum_{i=data} \frac{\ln x_{2i} + \ln \hat{\gamma}_{2i}}{N} \quad (13)$$

where the circunflex denotes a calculated value and the mole fractions are experimental solubility data of solute 2 in solvent *j* and *N* are the number of experimental solubility data points.

4. Results and Discussion

Among the studied drugs, only for paracetamol data are available in the literature (Bustamante et al., 1998; Granberg and Rasmuson, 2000, 1999; Hojjati and Rohani, 2006). In general, the agreement between the data measured in this work and that published in the literature is good, showing the adequacy of the experimental method for drug solubility measurements.

The melting properties have an important role in the solubilization of solids in liquids, and are also necessary for modeling purposes. Furosemide decomposes at melting, and like that, its melting properties had to be calculated by a group-contribution method (Marrero and Gani, 2001). For all the other drugs, DSC measurements were carried out, but only for paracetamol it was possible to find literature data (NIST Chemistry Webbook, 2007) to compare, showing a very good agreement.

To apply the NRTL-SAC model, the selection of the solubility measurements to be carried out for solute parameter regression involves the careful choice of solvents to cover the four types of distinctive surface interaction characteristics. Alkanes are hydrophobic compounds; ketones and esters are polar molecules with varying degrees of hydrophobicity; alcohols are hybrids of hydrophobic and hydrophilic segments. In this way, n-hexane, carbon tetrachloride, acetone, ethyl acetate and ethanol were used as representative solvents, with distinctive surface interaction characteristics. The solute model parameters were regressed using the solubility data in these pure solvents, melting data and the solvent parameters (Chen and Crafts, 2006). Once these model parameters were regressed, the model can be used to predict the solubility of the same solute in different solvents. Experimental and modeling results for the drugs solubility in water are presented in Figure 1. It can be seen that NRTL-SAC is an appropriate tool for the solubility modeling of aqueous solutions of these complex molecules.

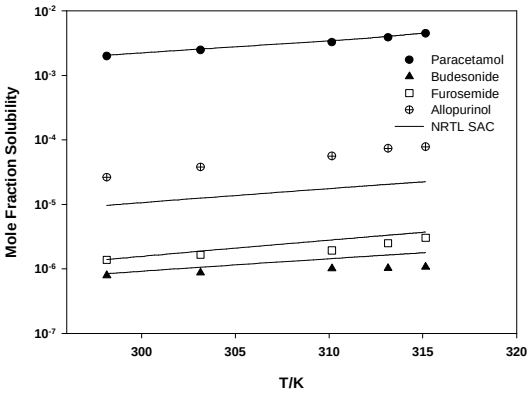

Figure 1. Experimental and NRTL-SAC calculated aqueous solubilities of the studied pharmaceuticals.

The model parameters based on the pure solvents regression can also be used to predict the solubility of these solutes in some mixed solvent systems. For paracetamol, data available in the literature for mixtures of water/acetone (Granberg and Rasmuson, 2000), ethanol/water and ethanol/ethyl acetate (Romero et al., 1996) were checked, and the prediction results showed to be very satisfactory. For the other studied drugs, no data were available. Thus, the solubilities of allopurinol and budesonide, at 298.2 K, in the extremely non-ideal system acetic acid/1-butanol; and the solubility of furosemide, at 298.2 K, in a binary mixture methyl

acetate/methanol were measured. These solvents are not included in the database for solute parameter estimation, even though the alcohol group and the ester groups were considered. The results were very satisfactory. For allopurinol a good prediction was obtained, with a root mean square deviation (RMSD), in the logarithm of mole fraction, of 0.191; for budesonide, the model overpredicted the solubility (RMSD of 0.561); and for furosemide, the prediction values were lower than the experimental values (RMSD of 0.697). Figure 2 shows the experimental data against the predicted results for allopurinol in the mixed system acetic acid/1-butanol, at 298.2 K.

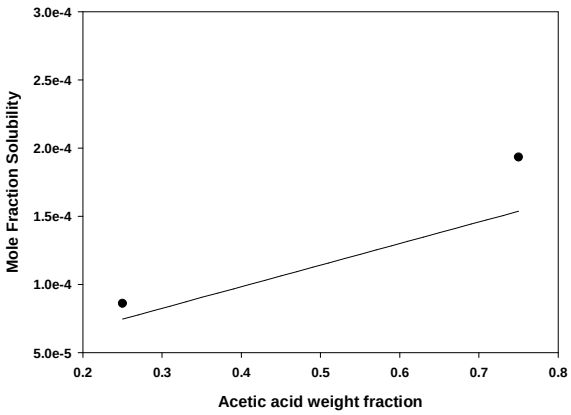

Figure 2. Measured and predicted (NRTL-SAC) allopurinol solubility in the mixed system acetic acid/1-butanol (acetic acid weight fraction in allopurinol free basis).

To apply the *reference solvent approach*, the NRTL-SAC model was used (Chen and Crafts, 2006) to calculate the activity coefficients. The solute parameters used were those obtained from the previous correlation. The reference solvents found were: water for paracetamol and furosemide, and carbon tetrachloride for allopurinol and budesonide. For paracetamol and budesonide, the prediction results were very satisfactory (RMSD of 3.075 and 2.875), but for the other two compounds the results presented considerable scattering. The results for all compounds can be observed from Figure 3.

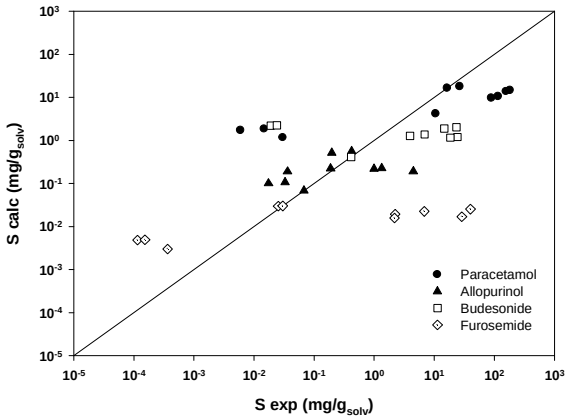

Figure 3. Measured and predicted (*reference solvent approach*) drug solubility in pure solvents.

5. Conclusions

Solubilities of some pharmaceutical compounds in pure water were measured, at five different temperatures, ranging from 298.2 to 315.2 K, and in other organic solvents (ethanol, acetone, carbon tetrachloride, ethyl acetate and n-hexane) at 298.2 K and 310.2 K, using the shake-flask method coupled with HPLC analysis. The aqueous solubility follows the general

increasing trend with temperature. Besides solubility data, melting temperatures and enthalpies of fusion were also measured, providing a broader knowledge about the solubilization process of these molecules. The NRTL-SAC model and the reference solvent approach were applied to calculate solubilities. For the NRTL-SAC, the solubility data in pure solvents were used to estimate the solute parameters which were used in the prediction of the solubility of these compounds in pure water as a function of temperature and also in mixed solvent systems. This model showed to be an appropriate tool to represent the solubility of these molecules. With the reference solvent approach, the predicted results were very scattered. This methodology was used with the NRTL-SAC model to obtain the solute activity coefficients. To improve the results, further studies should be accomplished such as the use of another activity coefficient model, explicitly considering other specific interactions.

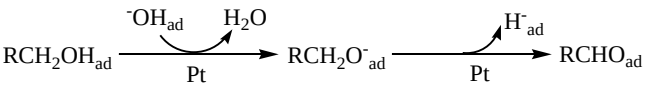
Topic: Sustainable process-product development through green chemistry

Abstract

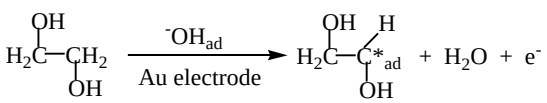
Gold catalysts supported on activated carbon (Au/AC) are investigated for the liquid phase oxidation of alcohols with molecular oxygen under atmospheric pressure. This work focus on two issues: 1) The role of basicity in the reaction; and 2) the way by which molecular oxygen participates in the reaction. The first issue was investigated by changing the initial reaction conditions and by using promoters with different basicity. The results suggest that promoters with strong basicity favor the reaction, and their role is to supply OH^- anions to Au, to form Au-OH^- active sites where H-abstraction from alcohol takes place. The second issue was addressed by comparing the catalytic performance of gold catalysts on carbon supports with different amounts of oxygen-containing functional groups. The results indicate that the amount of oxygen-containing species relates closely to the catalyst activity, and increases largely after the reaction, suggesting that an interaction between molecular oxygen and the carbon support occurs, so that molecular oxygen participates in the reaction via the carbon support. The unchanged oxidation state of gold (detected by XPS) before and after reaction suggested that the interaction between gold and molecular oxygen did not occur, supporting the above proposal.

1 Introduction

The liquid phase oxidation of alcohols with molecular oxygen is an attractive route for the synthesis of fine chemicals. Carbon supported metal catalysts are particularly useful in this context, since carbon materials are stable in acidic and basic media (Figueiredo et al., 1999; Rodriguez-Reinoso, 1998), while gold seems to be a more promising catalyst than other noble metals (such as Pt and Pd), as it is more resistant to deactivation (Biella et al., 2002; Comotti et al., 2005; Prati and Porta, 2005). As a result, gold supported on carbon received much attention in this field and many interesting results have been obtained (Mallat and Baiker, 2004). It is generally accepted that the dehydrogenation of alcohol is the first step of reaction and proceeds on the interface of noble metals, see reaction (1) and (2), followed the removal of hydrogen by oxidation with molecular oxygen and the regeneration of the catalyst (Beltowsk-Brzezinska et al., 1997; Dijkgraaf et al., 1988).



(1)



(2)

However, it is surprising to find that no work regarding the actual role of basicity (OH^-) or the way by which oxygen participates in the reaction has been reported. All the published reports

* Corresponding author. Tel + 351-225-081663. E-mail:feupzjj@fe.up.pt

just mention that the presence of basicity is necessary (especially for gold catalysts) and that the role of oxygen is to remove the adsorbed hydrogen, while no evidence and sound explanation for this assumption is normally given.

Thus, the aim of our work is to investigate the role of basicity and how molecular oxygen participates in the reaction, in order to provide better insight about the reaction mechanism. Herein, we used 1wt. % Au/AC as catalyst and benzyl alcohol as substrate, and NaOH as promoter for investigation.

2 Experimental

2.1 Materials

$HAuCl_4 \cdot 3H_2O$ (99.99% ACS, Au ≥ 49.5%) was purchased from Alfa Aesar, Polyvinyl alcohol (PVA) (> 99%), $NaBH_4$, NaOH, benzyl alcohol from Sigma-Aldrich, Decane from Fluka, Toluene from Panreac and Activated Carbon Aerosorb LR4 (BET: 875 m^2/g) from Degussa.

2.2 Modification of carbon supports

The original activated carbon (AC0) was first treated by 5% O_2/N_2 at 400 ºC for 10 h (denoted as: AC5), subsequently treated in inert atmosphere (N_2) at 650, 735, 820 and 910 ºC for 1 h, respectively. The obtained carbon supports were, accordingly, denoted as AC5_T (T = 650, 735, 820 and 910).

2.3 Preparation of catalyst

Gold supported on activated carbon (loading: 1wt. %) catalysts were prepared by gold sol method similar to that reported by Onal et al (2004). Here, $HAuCl_4 \cdot 3H_2O$ was used as the gold precursor; PVA and $NaBH_4$ were used as the protective and reductive agent, respectively. The samples obtained were finally treated by N_2 at 350 ºC for 3h, followed by reduction with H_2 at 350 ºC for 3h. According to the treatment temperature of the carbon supports, the gold catalysts were named as: Cat0, Cat5 and Cat5_T (T = 650, 735, 820 and 910).

2.4 TPD experiments

The TPD profiles were obtained with an Altamira equipment (AMI-200). The helium carrier gas was passed over 0.1 g sample at a flow rate of 25 cm^3/min, with a heating rate of 5 ºC/min. The amounts of CO and CO_2 desorbed from the carbon samples were monitored with a quadrupole mass spectrometer. For the analysis of samples after reaction, the samples were first filtered, washed with water several times, and dried in an oven at 100 ºC for 2h before the experiment.

2.5 Oxidation procedure

Alcohol oxidation was carried out at atmospheric pressure and 80 ºC, in a 30 mL, three-necked batch reactor fitted with a reflux condenser, oil bath, thermocouple and magnetic stirrer. A mixture of 40 µL NaOH, 20 µL benzyl alcohol, 10 µL decane (used as internal standard) and 0.05 g catalyst in toluene (20 mL) was prepared. The flask was then heated to 80 ºC and flushed with O_2 (or O_2/N_2) at a rate of 50 cm^3 min^{-1} , under vigorous stirring. The products of reaction were analyzed by GC (DANI 1000) with a flame ionization detector, using a CP-Sil 8 CB column and N_2 as carrier gas.

3 Results and discussion

3.1 Role of Basicity

It is generally accepted that basicity is necessary to increase the activity of supported gold catalyst in selective alcohol oxidation (Biella et al., 2003; Carrettin et al., 2003). Conversion was rather modest in the absence of any promoter (Zheng and Stucky, 2007). To better understand the role of each intervening species (O_2, catalyst and NaOH), we performed a series of exploratory experiments as described in Fig. 1: (a) with catalyst (Cat0) and O_2; (b) with catalyst (Cat0) and NaOH; (c) with O_2 and NaOH (homogeneous reaction); and (d) with (Cat0), O_2 and NaOH (Zhu et al., 2008a). At point (a), where NaOH was not added, only a

very low yield was obtained, indicating that the reaction is difficult to proceed in the absence of alkali. The selectivity increased abruptly when NaOH was added, no matter there is O_2 or not – points (b) and (c) – suggesting that basicity is necessary for benzyl alcohol oxidation. Only low conversion was observed at point (b), since O_2 was not bubbled into the reaction to oxidize benzyl alcohol. This indicates that it is not a stoichiometric reaction between benzyl alcohol and NaOH, and O_2 must take part in the oxidation process. (Activity at this point derives from the residual O_2 in toluene, the free space of the flask before reaction or the oxygen in the oxygen-containing species on the carbon support). Interestingly, a moderate conversion was observed at point (c), where catalyst was not present. It means that a homogeneous reaction occurs in the presence of NaOH. In all, these results indicate that the presence of either O_2, NaOH or Au/AC are beneficial for the reaction, but only two of these factors are not enough for the reaction to be carried out with satisfying results. Expectably, a significant improvement both in selectivity and conversion was achieved when all of them were presented – point (d). Comparing the results at points (a) and (d), one can easily conclude that basicity is necessary and is crucial in promoting the activity of Au/AC catalyst for the selective oxidation of benzyl alcohol.

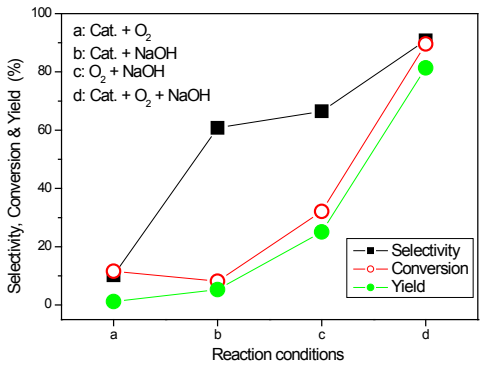


Fig.1: Benzyl alcohol oxidation on 1wt.%Au/AC under different initial conditions (NaOH/alcohol = 1 except for (a)) (Zhu et al., 2008a)

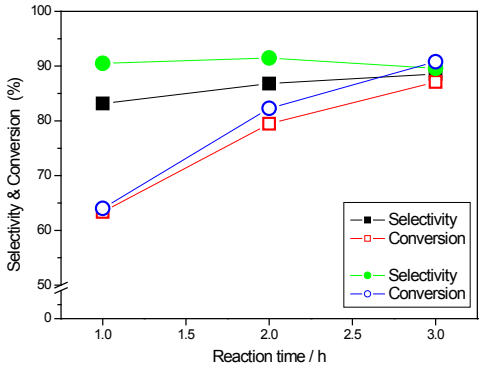

Fig.2 Benzyl alcohol oxidation on 1wt.%Au/AC: 1) OH^- physical loading (squares) and 2) adding NaOH solution (circles) (Zhu et al., 2008a)

To investigate whether the promotion of activity is caused by the basicity, we compared the effect of promoters with different basicity (neutral, weak and strong basicity) on the activity, and the results are listed in Table 1 (entries 1-3, 7). It is obvious that the activity is in sequence of $NaNO_3$ < Na_2CO_3 < NaOH ≈ KOH, which suggests that the promotion is indeed caused by basicity. For neutral $NaNO_3$, both the conversion and the selectivity are low, indicating it is not a suitable promoter. For alkalescent Na_2CO_3, which has the possibility to produce OH^- anion, the increase is small in conversion but is large in selectivity. This shows that weak basicity can improve selectivity satisfactorily, but not the conversion (Note: because the solubility of Na_2CO_3 is low, a 5 M solution cannot be prepared at room temperature, so we used a concentration of 2.5 M and a volume of 2x40 μL). As expected, addition of strongly basic NaOH/KOH improves greatly both the conversion and the selectivity, indicating that basicity indeed plays an important role in the reaction.

Optimizing the NaOH amount was then performed and the results are also listed in Table 1 (entries 4-8). Obviously, the conversion increases with NaOH amount up to a molar ratio of NaOH:alcohol equal to 1:1. We recall that this is not a stoichiometric reaction between $C_6H_5CH_2OH$ and NaOH, as explained above (see point (b)). Moreover, when we used solid NaOH in the reaction, we observed that there was still a large mass of NaOH remaining after the reaction (with ~80% conversion), indicating that it is indeed not a stoichiometric reaction and NaOH will not be dissolved in toluene. So, we advance the idea that NaOH supplies OH^- to Au, in order to form an Au-OH^- active site where H-abstraction from alcohol takes place, which is difficult to be accomplished by gold alone.

Furthermore, when we used a catalyst washed with a 5M NaOH solution and filtered (to physically load OH^- on Au surface); it showed similar activity to that of adding NaOH solution

(see Fig.2). This supports the idea that the addition of NaOH is indeed to form the Au-OH^- site required for H-abstraction from alcohol. When the NaOH amount was further increased (NaOH/alcohol = 1.5), the activity was a little lower than that measured at NaOH/alcohol = 1, indicating that the optimum value is at molar ratio of NaOH/alcohol = 1.

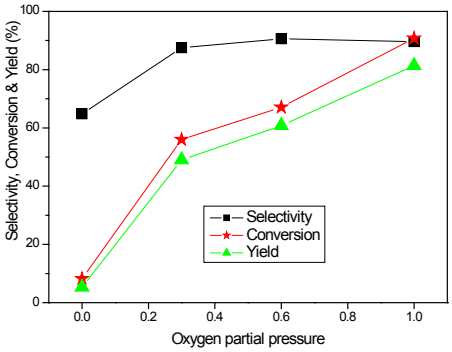

Fig.3 Effect of oxygen partial pressure on the reaction (P/A = 1.0)

3.2 Oxygen pathway

In subsequent experiments, it was found that the oxygen partial pressure affects greatly the reaction (Fig.3), which prompted us to study how oxygen participates in the reaction.

In a previous work (Figueiredo et al., 1999), it was shown that gas phase oxidation changes both the texture and surface chemistry of carbon materials (i.e. AC0 vs. AC5), while thermal treatments under inert atmosphere do not produce significant textural changes with respect to the parent materials (i.e. AC5 vs. AC5_T). So, this section is based on the catalytic performances of Cat5 and Cat5_T, in which the texture of the carbon supports is similar, and the major difference is the type and amount of oxygen-containing species on their surfaces.

Fig.4 shows the TPD results of AC5 and AC5_T. it is seen that the total amount of oxygen-containing species decreased with increasing treatment temperature. For CO desorption, a significant decrease was observed when the treatment temperature increased from 735 to 820 ºC, and only a very small CO desorption peak was observed for sample AC5_910. For CO_2 desorption, the area also decreased with increasing temperature, no CO_2 signal being observed for samples AC5_820 and AC5_910.

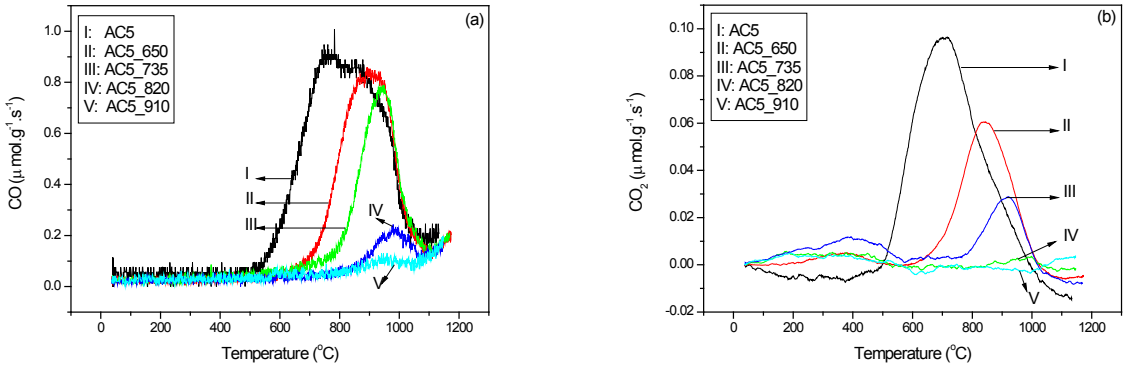

Fig.4 TPD spectra of AC5 and AC5_T: (a) CO evolution; (b) CO_2 evolution (Note: the CO_2 desorption profiles were smoothed due to the strong noise generated). (Zhu et al., 2008b)

Fig.5 shows the alcohol conversion observed with Cat5 and Cat5_T. It is seen that the conversion decreased with the increase in the carbon support treatment temperature, i.e., Cat5 > Cat5_650 > Cat5_735 > Cat5_820 > Cat5_910, which is the same sequence as the amount of oxygen-containing species of the carbon supports (see Fig.4). This means that the conversion has a close relation to the amount of oxygen-containing species in the catalyst. It may be possible that the carbon support has some activity of its own due to the presence of some type of oxygen functional group, such as observed in the oxidative dehydrogenation of ethylbenzene, where quinone groups were identified as the active sites (Pereira et al., 1999).

We do not exclude this possibility. However, the present results show that the activity decreases irrespective of the type of oxygen-containing species being removed. On the other hand, as it is known that the alcohol dehydrogenation step proceeds on the surface of the active phase (i.e. Au) and oxygen dissociation on gold surface is difficult, we propose that the contribution of oxygen-containing species is to offer a place for oxygen adsorption and dissociation (O_2 → 2O), which subsequently reacts with the hydrogen left on the gold surface to regenerate the OH^- anion ($H + O + e^- \rightarrow OH^-$)

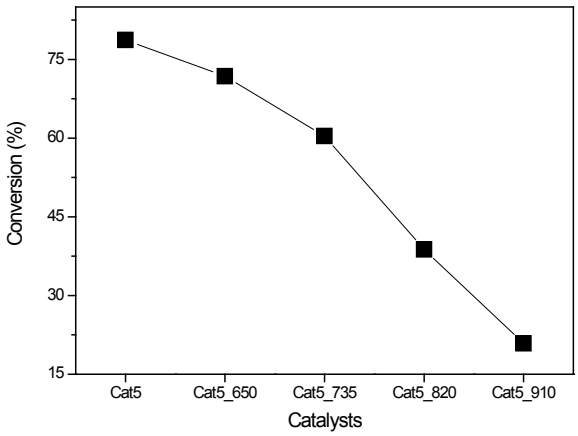

Fig.5 Alcohol conversion tested from Cat5 and Cat5_T (T = 650, 735, 820 and 910) (Zhu et al., 2008b)

In order to support the above idea that an interaction between molecular oxygen and oxygen-containing species occurs during the reaction, TPD experiments for Cat5 before and after reaction were carried out. The results in Fig.6 indicate that the amount of oxygen-containing species increased greatly after reaction, suggesting that an interaction between oxygen and the carbon support has indeed occurred, some of the oxygen entering the carbon support as a new oxygen-containing species.

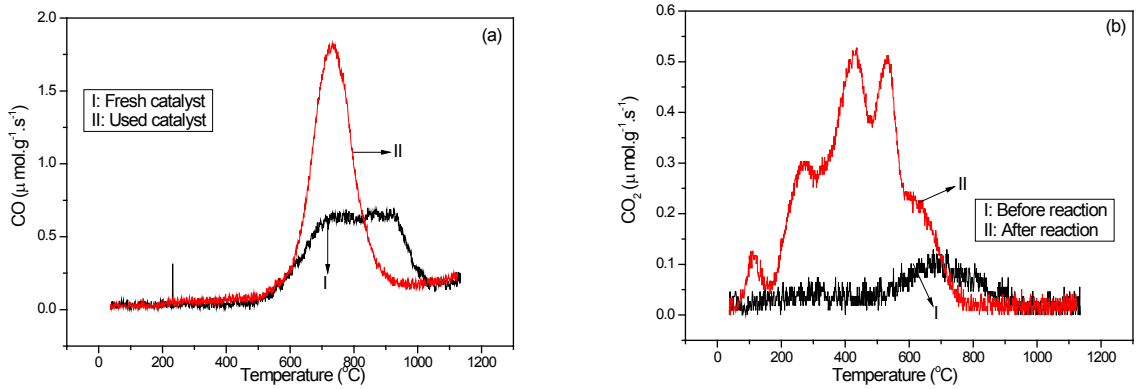

Fig.6 TPD spectra of fresh and used Cat5: (a) CO evolution; (b) CO_2 evolution (Zhu et al., 2008b)

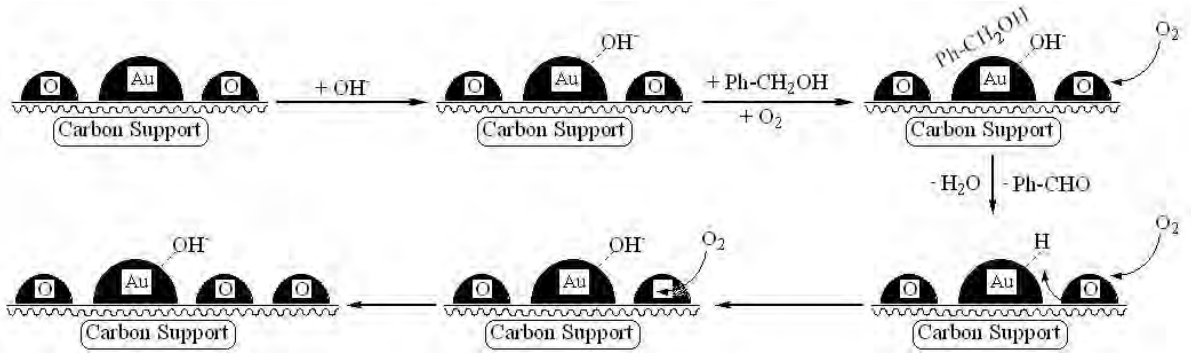
On the other hand, according to previous results (Figueiredo et al., 1999), we propose that, for the catalyst after reaction, the CO_2 desorption (T < 600 ºC) results from carboxylic or lactone groups, while CO desorption (T = ~720 ºC) is from carbonyl or quinone groups, all of them containing a C=O group. Based on this result and the fact that it is difficult to adsorb and dissociate oxygen on the gold surface (XPS results, which were not shown here, indicate that the oxidation state of gold before and after reaction is zero), we therefore propose that the pathway for oxygen participating in the reaction is through the carbon support, as shown in Scheme 1.

Scheme 1: Suggested pathway for molecular oxygen participation in the reaction (Zhu et al., 2008b)



Because molecular oxygen cannot react directly with hydrogen, it must be dissociated into atomic oxygen before participating in the reaction. This may occur by interaction with the carbon support, since oxygen dissociation on gold is difficult. However, as the carbon support, unlike metal oxides, does not have oxygen vacancies (sites for oxygen dissociation), we thus suggest that the carbon support should be activated (interaction between H and O in Scheme 1) before oxygen dissociation proceeds. After activation (i.e. removal of initial oxygen), a site for molecular oxygen adsorption is created, on which the oxygen dissociation proceeds, accompanied by the oxidation of an adjacent carbon atom (the amount of oxygen-containing species increased after the reaction, see Fig.6).

4 Conclusion

In summary, this work suggested 1) the role of basicity in gold catalyzed alcohol oxidation is to supply OH^- to the gold surface, to form an Au-OH^- active site, where H-abstraction takes place; 2) molecular oxygen participates in the reaction through the carbon support, by exchanging oxygen with the oxygen-containing species on surface.

Topic: Advancing the Chemical and Biological Engineering Fundamentals

Abstract

A plastisol is a dispersion (suspension) of fine particles of poly(vinyl chloride) with a plasticizer that is normally applied over a substrate, by spreading or coating, The selection of the type of emulsion polymer to obtain the desired rheology and the quality of the final product plays a major importance. Although several factors can affect the rheological properties, this work is concerned with the particular impact of different anionic surfactants that are used during the polymerization reaction. Namely, the effect over the aging period and, additionally, their physical properties correlated with the final viscosity level of the plastisol.

Introduction

Considering the several types of poly(ethylene), poly(vinyl chloride) (PVC) is the second world consumed thermoplastic. Although the vast majority of homopolymer and copolymer products are produced in a suspension system, a particular type is produced by the emulsion or microsuspension processes, making the so called dispersion grades (Saeki and Emura, 2002). These types of PVC products are normally fine powders of spherical particles (0.1-15 μm) that are mixed with a plasticizer to produce a dispersion (suspension), normally referred as paste or plastisol. Industrially, the said dispersion is applied over a substrate, by spreading, coating or molding, before the gelification and fusion into the final commercial products, such as: films, sheets, paper coatings, mats, flooring, life preservers and roof tops (Sarvetnick, 1972; Nakajima and Harrel, 2001).

Depending on each application type, the shear stress applied over the plastisol during the production stage makes the study of the paste's rheological behaviour a very important factor to determine and fine tune all process conditions and formulations (Marcilla *et al*, 1997). Also, in the particular case of the emulsion PVC polymers, the conditions during the free radical polymerization, as well as the process conditions of the industrial spray-dryer and the subsequent milling of the powder, can have a great influence over the final properties (Nakajima and Harrel, 2001).

The emulsion polymers are normally made up in the presence of a surfactant and a free radical initiator, to produce a polymer that can have different particle sizes and surface characteristics. Also, depending on the production process, an aggregation effect is normally observed, affecting the size and size distribution of the final powder. Nevertheless, during the plastisol formation, these agglomerated particles are not sufficiently strong to resist to the high shearing mixing conditions, together with the solvating plasticizer effect over the polymer. This effect is normally translated by an increase of the plastisol viscosity with time, in a process normally called "viscosity aging" (Nakajima and Harrel, 2005). The aging rate and the rheological behaviour of the plastisols are also sensitive to the type of surfactants used during the polymerization process, type and quantity of plasticizer and to other

* Corresponding author. Tel + 351-234-811212. E-mail: arnaldo.tomas@cires.pt

additives used in the final formulation, such as fillers, pigments and thermal stabilizers (Sarvetnick, 1972, Alsopp and Vianello, 2003).

Considering the final application of the plastisol, the applied surfactant during the polymerization can play a fundamental role on the product characteristics, namely, for distinct applications of vinyl foams or films and sheets (Sarvetnick, 1972). Thus, the surfactant should be carefully selected for the final application which, normally, undergoes several trials to get sufficient knowledge of the type and quality of the obtained final product. Although the rheology of the plastisols has been quite studied, the effect of the surfactants, over the type of the particles aggregates and the correspondent effect in the viscosity aging, are normally kept within the know-how of the industrial producers and their product developers.

The application of a developed laser diffraction spectroscopy's technique (LDS) to evaluate the particle size distribution of the initial polymer's powder, as well as its evolution on the plastisols, allows very significant information of the aggregates dimension during the aging period, correlating with the paste's viscoelastic response (Rasteiro and Antunes, 2005).

The present study was aimed at identifying the effect of three selected anionic surfactants on the rheological behaviour of the pastes. For that we have fixed the plastisol formulation, having varied the main surfactant type during the emulsion polymerization.

Experimental

Materials

Emulsion PVC samples from *Companhia Industrial de Resinas Sintéticas, CIRES, S.A.:* produced in a 5L pilot reactor according to a standard emulsion polymerization recipe using the same dosage of different types of main surfactants. The free radical initiator used was ammonium persulphate. All standard procedures for the reaction are described in the literature (Burgess, 1982; Butters, 1982).

Surfactants: commercial grades of Sodium Lauryl (C_{12}-C_{14}) Sulphate (SLS) and Sodium n-Alkyl (C_{10}-C_{13}) Benzene Sulfonate (SABS) from Cognis Iberia. Sodium Alkyl (C_{15}) Sulfonate (SAS) from Leuna Tenside GmbH.

Plasticizer: Di-isodecyl Phtalate (DIDP), trade name Palatinol® 10P from BASF GmbH.

Thermal stabilizer: Mark BZ505 (Barium-Zinc) from Crompton Vinyl Additives GmbH.

Organic solvent: n-Heptane (commercial grade).

Plastisol samples preparation

Commercial formulations of 70 phr (parts of plasticizer per hundred parts of polymer) of DIDP were considered, with a common heat stability additive (Barium-Zinc) (2 phr) and the emulsion PVC samples. The preparation of the plastisols was carried out in a planetary mixer during 15 min to obtain a homogeneous final paste. While ageing proceeded, the paste was kept in a closed chamber at constant temperature (23ºC) and relative humidity (≈35%).

Particle Size Distribution

Laser diffraction spectroscopy technique (LDS): Mastersizer 2000, Malvern Instruments, UK.

LDS was used to measure the particle size distribution of the dry PVC powder in a diluted dispersion with n-heptane. Regarding the plastisol samples, according to the already published method by Rasteiro and Antunes (2005), the dilution procedure was made with n-heptane.

Rheology Measurements:

Rheological measurements: Controlled stress rheometer, Model RS1, Haake.

The rheological tests were carried out in a controlled stress rheometer, with a sensor system Z34 DIN that comprises one rotor and one beaker, with a connected thermocontroller (constant temperature 23ºC). The spindle used had 20,00 mm (radius) at a clearance to bottom 7,2 mm. For the plastisol samples, flow and dynamic tests were performed.

Zeta Potential
Zetasizer NanoZS, Malvern Instruments.
The Zeta potential is normally applied to access the charge stability of colloidal systems. In practice, the Zeta potential of the dispersion is measured by applying an electric field across the mixture. Particles, within the referred dispersion, will migrate toward the electrode of opposite charge with a velocity proportional to the magnitude of the zeta potential. A higher zeta potential will confer stability, i.e. the dispersion will keep original properties. In the particular case of the PVC powder, the Zeta potential will give an indication of the degree of packing of the particles within the aggregates.

Results and Discussion

Polymer Properties

The emulsion PVC samples are listed on table 1, including the known type of main surfactant used during polymerization, average molecular weight, polydispersity and commercial K value (inherent viscosity method ISO 1628-2). The main physical properties of the plasticizer DIDP used in the plastisol formulations are also given in Table 1.

Table 1: Main physical properties of all PVC samples and DIDP.

PVC sample	Surfactant	Mn Da	Mw Da	Polydispersity Mw/Mn	Inherent viscosity ml.g-1	K value
E-PVC 1	SLS	49223	94079	1.91	102.28	72.3
E-PVC 2	SABS	51069	92566	1.81	104.06	73.0
E-PVC 3	SAS	49752	93646	1.88	102.79	72.5
DIDP	Molecular weight (g/mol)		Density (kg/cm^3)		Viscosity 20ºC (mPa s)	
	446		962		120	

Considering the data from table 1, with the exception of the surfactant type, there is no significant difference in the polymer properties from the free radical polymerization. Also, from the dilute viscosity method (inherent viscosity method ISO 1628-2), it is possible to calculate the Fikentscher “K value”, normally used for industrial purposes.

Table 2 shows the main properties of the powder samples, namely the zeta potential and the particle size distribution (PSD), including the median size (d_{50}), the distribution ratios d_{90}/d_{10} and $(d_{90}-d_{10})/d_{50}$.

Table 2: PVC powder properties

PVC sample	Zeta (mV)	d_{50} (µm)	d_{90}/d_{10}	$(d_{90}-d_{10})/d_{50}$
E-PVC 1	-53.2	31.22	4.7	1.8
E-PVC 2	-52.1	24.72	4.5	1.6
E-PVC 3	-54.1	28.52	4.0	1.4

Considering all the samples, there is only a slight difference in all the PSD parameters, although E-PVC 3 has the lowest ratio d_{90}/d_{10} and $(d_{90}-d_{10})/d_{50}$, which corresponds to a lower fraction of aggregates and a narrower distribution. E-PVC 1 has the highest d_{50} and a broader PSD type.
The Zeta potential of the powder gives an indication of the effect of each surfactant over the packing stability of the aggregates. In fact, it is possible to access some differences between

the three samples, namely the higher value of E-PVC 2, which induces a stable behavior of the aggregates.

Plastisol's PSD Properties During Aging

Considering the stated experimental procedure, table 3 summarizes the PSD distribution of the plastisols during the aging time from 1h to 168h (7 days) after preparation.

Table 3: Particle size distributions of Plastisols during aging.

	d_{50} (µm)						d_{90}/d_{10}						$(d_{90}-d_{10})/d_{50}$					
Plastisol	1h	3h	24h	48h	120h	168h	1h	3h	24h	48h	120h	168h	1h	3h	24h	48h	120h	168h
P1	18,72	19,15	18,17	18,29	18,49	18,43	10,8	9,7	8,6	8,6	8,2	8,8	3,1	3,0	2,7	2,7	2,6	2,8
P2	17,37	19,61	18,49	19,58	18,67	18,64	11,9	11,6	10,5	11,1	10,9	10,6	2,8	2,6	2,5	2,5	2,6	2,6

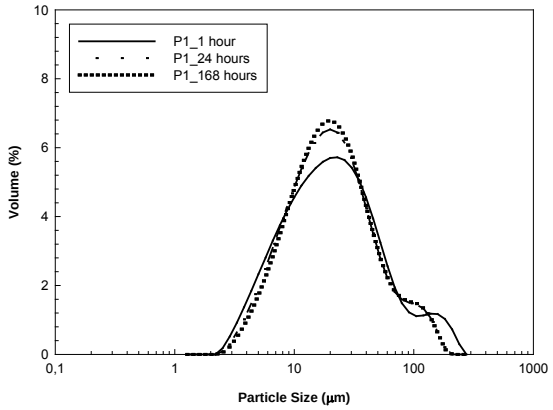
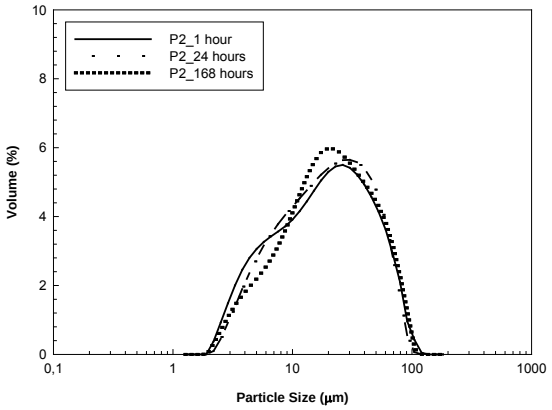
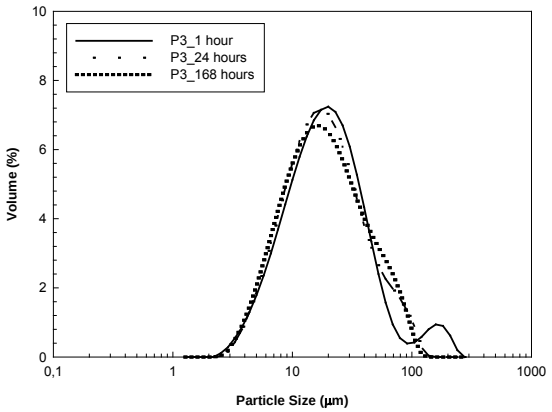
Comparing with the PSD results from the powder samples (Table 2), there is a general decrease on d_{50} just 1h after the plastisol's preparation. This fact is directly correlated with the plasticizer solvent effect over the particle's aggregates during the aging period. Also, for all samples, the ratio d_{90}/d_{10} decreases from 1 to 24h, indicating the destruction of the loose agglomerates in an earlier stage.
The size distribution, analysing the ratio $(d_{90}-d_{10})/d_{50}$, indicates a constant relative width of each sample through the aging period. With the exception of P3, there is a general decrease in that item, in tune with the justification made to d_{90}/d_{10}.



a) P1_1, 24 and 168h



b) P2_1, 24 and 168h



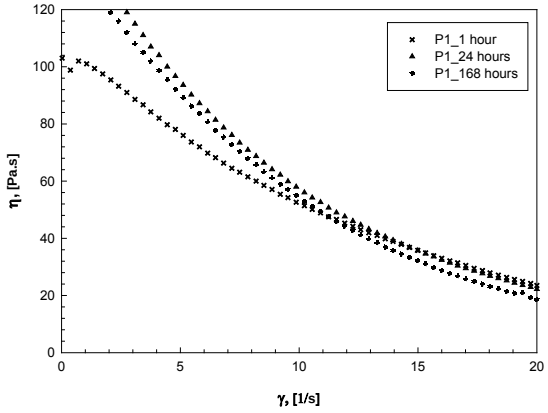
c) P3_1, 24 and 168h

Figure 1: PSD distributions (from LDS) of plastisol's samples P1, P2 and P3 at 1, 24 and 168h.

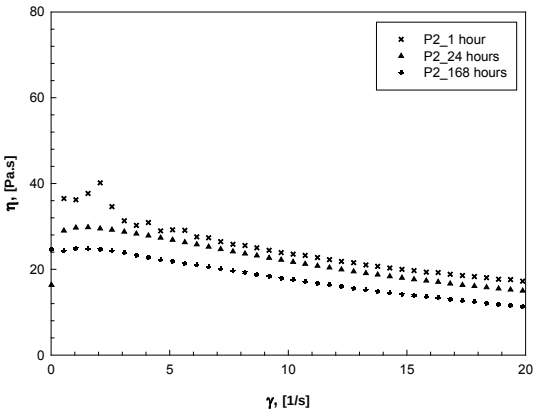
Adding to the data shown in table 3, in fig. 1 it is possible to analyse the PSD evolution (from 1 to 168h) in all plastisol samples. Again, more clearly, the early destruction of the large aggregates of P1 and P3 (fig. 1a),b)) and the almost stable behaviour of P2 (fig. 1c). This fact is consistent with the findings from the zeta potential analysis of the powder samples.

Plastisol's Flow Properties During Aging

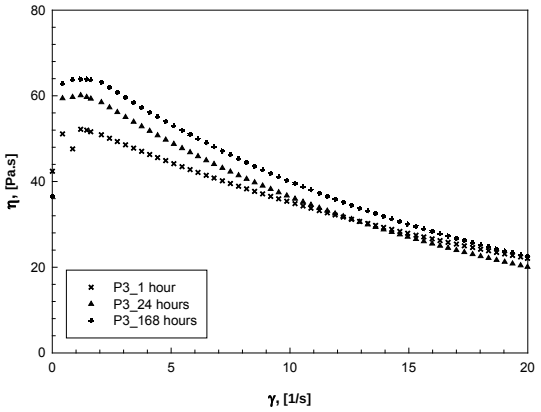
The viscosity *vs* shear rate of all plastisol samples are shown in Fig. 2. Considering the aging period at 1, 24 and 168h over the applied shear rate, there are significant differences between the samples. With the respect to the rheological behaviour, all plastisols have a markedly pseudoplastic behaviour, although P2 (fig. 2b) has a significant lower viscosity for the same shear rate (mainly for the lower shear rates) and a lower yield stress. P3 (fig. 2c) exhibits a tyxotropic effect at low shear rate followed by a steady decrease in viscosity. The aging effect is observed in P1 and P3. Nevertheless, for P2 the viscosity level tends to decrease slightly through the aging period. This unusual behaviour can only be explained by the difference in the used surfactant nature. Considering some possibilities advanced by Collins and Hoffmann (1979), the effect of the interparticle repulsion can decrease with the progressive swelling of the plasticizer by the polymer particles, suppressing the normal aging profile. Also, for low shear rates, the applied stress can not overcome the electrical and van der Waals forces between the particles layers, inducing an abrupt increase in viscosity. This effect is slightly observed in P2 and markedly in P3, inducing the reported tyxotropic behaviour in the initial stage.



a) P1_1, 24 and 168h



b) P2_1, 24 and 168h



c) P3_1, 24 and 168h

Figure 2: Viscosity (η) *vs* shear rate (γ) of plastisol's samples P1, P2 and P3 at 1, 24 and 168h.

Besides the small changes in the PSD curves (see fig. 1), the narrower PSD of P3 agreeing with the higher viscosity values observed, the major differences in the flow properties can be only justified by the different surfactant on the surface of the particles. Thus, for a control shear rate of 5 s^{-1}, the overall viscosity tends to decrease from P1>P3>P2. Therefore, for the considered formulation, the anionic surfactant SABS, present in E-PVC 2, provides a lower viscosity level together with a steady decrease through the aging period. Besides the given general theories, other properties of surfactants can be correlated, namely the critical micelle concentration (cmc), deeply linked to the alkyl chain and anionic nature (Myers, 2006). Thus, SLS has a cmc of 0,38 $g.L^{-1}$ (E-PVC 1), SAS has 0,50 $g.L^{-1}$ (E-PVC 2) and SABS has 1,00 $g.L^{-1}$ (E-PVC 3) (Myers, 2006). That is, for the tested conditions, it becomes quite acceptable that a higher cmc value induces a lower plastisol viscosity.

Conclusions

The effect of the particle size and size distribution of the dispersion PVC grades have been quite studied and, generally, elected as the most important factor for controlling the flow behaviour of the commercial plastisol formulations. However, it becomes clear that the surfactant type used during the emulsion polymerization plays a crucial role in the plastisol rheology and in the aging characteristics.

From the differences in the plastisol rheology from the tested surfactants, it is possible to achieve a low viscosity level with SABS that can, for instance, lead to a further decrease in the plasticizer concentration or other improvement in the formulation.

Furthermore, upon the results, it seems that the cmc data can be correlated with the achieved plastisol viscosity. Nevertheless, due to the low number of tested surfactants, further confirmation studies are required to have a deeper understanding of the interaction mechanism associated with the surfactant type over the (inter)particles surface layer and the plasticizer.

Topic: Advancing the chemical engineering fundamentals.

Introduction

In the last few years, atom transfer radical polymerization (ATRP) of acrylate and methacrylate monomers in the presence of a small amount of cross-linker has been investigated in order to produce branched polymers and gels with applications in microelectronics, coatings industries or biomedicine (Wang and Zhu, 2005; Gao et al., 2007). In this context, it is being explored the production by ATRP of branched/crosslinked polymers with a lower degree of heterogeneity than that obtained by conventional free radical polymerization (FRP). This work reports an experimental study on the ATRP of methyl methacrylate (MMA) + ethylene glycol dimethacrylate (EGDMA) initiated by MBPA (methyl α-bromophenylacetate) and mediated by copper bromide (CuBr) ligated with HMTETA (1,1,4,7,10,10-hexamethyltriethylenetetramine). The synthesized copolymers were analyzed by size exclusion chromatography (SEC) with simultaneous detection of refractive index (RI) and multi-angle laser light scattering (MALLS) signals. Important details of the molecular architecture of these materials can therefore be measured, namely absolute molecular weights and *z*-average radius of gyration. Different experimental runs were performed in order to investigate the influence of the operating conditions (e.g. temperature and initial molar ratios MMA/EGDMA/MBPA/CuBr/HMTETA) on the structure of the products.

In conventional radical polymerization (FRP), the expected life time of a radical t_l is very short (of the order of 1 s) owing to the termination reaction according to Eq. (1):

$$t_l = \frac{R}{r_t} \simeq \frac{1}{2k_t R} \tag{1}$$

In this equation, R represents the concentration of radicals, r_t the rate of termination and k_t the correspondent rate coefficient. However, with ATRP the expected life time of a radical can attain several hours, since it is determined by the dynamic equilibrium between activated and deactivated states according to

* Corresponding author. Tel. +351-273-303088. E-mail: rdias@ipb.pt.

Eq. (2):

$$-\mathrm{P}^{\bullet} + \mathrm{X} - \mathrm{M}_{\mathrm{t}}^{\mathrm{n}+1} - \mathrm{Y/Ligand} \underset{k_{act}}{\overset{k_{deact}}{\rightleftharpoons}} -\mathrm{P} - \mathrm{X} + \mathrm{M}_{\mathrm{t}}^{\mathrm{n}} - \mathrm{Y/Ligand} \tag{2}$$

Here, $-\mathrm{P}^{\bullet}$ represents a radical in a polymer molecule, $\mathrm{X} - \mathrm{M}_{\mathrm{t}}^{\mathrm{n}} - \mathrm{Y/Ligand}$ a transition metal complex (e.g. $\mathrm{Cu(I)Br/HMTETA}$), $\mathrm{X} - \mathrm{M}_{\mathrm{t}}^{\mathrm{n}+1} - \mathrm{Y/Ligand}$ the correspondent oxidized metal complex (g. $\mathrm{Cu(II)Br_2/HMTETA}$) and $-\mathrm{P} - \mathrm{X}$ a dormant radical. This intermittent exchange reduces the concentration of growing radicals and therefore minimizes the termination reactions (usually less than 5% of the total polymer chains undergoes termination in ATRP). The more usual applications of the almost "living" character of ATRP are the synthesis of low polydispersity linear polymers and of block copolymers. Nevertheless, it will be shown next that it is also useful for the controlled production of well defined hyperbranched polymers and comparatively much more homogeneous networks than those achieved by conventional radical polymerization, as the effect of intramolecular reactions is decreased.

Experimental Part

Polymerization runs were carried our using a $2.5\ \mathrm{dm}^3$ maximum capacity stainless steel reactor (Gonçalves et al., 2007). Anisole at 99% purity, N,N-dimethylformamide at 99.8% purity, toluene at 99.7% purity, MBPA at 97% purity, HMTETA at 97% purity, Cu(I)Br at 98% purity, MMA stabilized with 10 to 100 ppm monomethyl ether hydroquinone at 99% purity and EGDMA stabilized with 100 ppm monomethyl ether hydroquinone at 98% purity have been purchased from Sigma Aldrich and used as received. MMA, EGDMA, solvent(s), CuBr and HMTETA were premixed at 60 °C for at least 30 min in a volumetric flask. This mixture was charged to the reactor (previously purged with argon) and brought up to the desired temperature. The initiator (MBPA) was rapidly added to the system and its introduction is used to define the zero reaction time $t = 0$. Argon was bubbled in the reactor during the whole polymerization. At prescribed polymerization times, samples of polymer were withdrawn from the reactor and analyzed by SEC/RI/MALLS. A poor solubility of copper species in the polymerization system was observed when toluene was used as solvent. This difficulty was not eliminated by extending the mixing period, increasing the temperature or using a higher initial molar ratio HMTETA/CuBr. Better results could be obtained by excluding toluene (therefore using bulk MMA) or adding DMF as a solvent (Pascual et al., 1999) even in a small amount (10%). Good solubility could also be achieved by using anisole (Xia and Matyjaszewski, 1997) + DMF as a co-solvent.

Kinetic Modeling

As described in previous works (Costa and Dias, 2007, 2005; Dias and Costa, 2007, 2006), it is possible to obtain the generating functions (GF) of molecular size distributions (MSD) of the rate equations of formation of polymer species by chemical reactions ($G_{\mathcal{R}_P}$, $G_{\mathcal{R}_S}$ and $G_{\mathcal{R}_{H_n}}$). The insertion of these GF in the population balance equations (PBE) of a non-steady state perfectly mixed continuous stirred tank reactor (CSTR) yields PBE in terms of the GF of size distributions of mole concentrations of polymer degrees of polymerization, sequences and pendant chains, $G(\mathbf{s})$, $U(\mathbf{s})$ and $G_n^H(\mathbf{s}^-, \mathbf{s}^+)$, respectively:

$$\frac{\partial G}{\partial t} = G_{\mathcal{R}_P} + \frac{G_F(t) - G}{\tau} - \mathcal{R}_v G; \qquad G_{|t=0} = G_0\left[\mathbf{s_0}(t, \mathbf{s})\right] \tag{3}$$

$$\frac{\partial U}{\partial t} = G_{\mathcal{R}_S} + \frac{U_F(t) - U}{\tau} - \mathcal{R}_v U; \qquad U_{|t=0} = U_0\left[\mathbf{s}_0(t, \mathbf{s})\right] \tag{4}$$

$$\frac{\partial G_n^H}{\partial t} = G_{\mathcal{R}_{H_n}} + \frac{G_{n\ F}^H(t) - G_n^H}{\tau} - \mathcal{R}_v G_n^H; \qquad G_{n\ |t=0}^H = G_{n\ 0}^H \left[\mathbf{s_0}^-(t,\mathbf{s}^-), \mathbf{s_0}^+(t,\mathbf{s}^+)\right] \qquad (5)$$

Eqs. (3)-(5) are non-linear first order partial differential equations solvable by the method of the characteristics. These master equations allow the prediction of the MSD, SSD (sequence size distribution) and RG (radius of gyration) distributions for general irreversible non-linear polymerizations. For the present chemical system, modeling studies were carried out considering a kinetic scheme comprising a total of 22 species and 44 different chemical reactions, as summarized in Table 1. Due to its generality, this method can be applied to different chemical systems and reactors (e.g. semi-batch), as recently shown for conventional (Gonçalves et al., 2007) and nitroxide-mediated non-linear radical copolymerizations.

Complex metal/ligand and deactivator.	
Solvent and correspondent primary radical.	

Results and Discussion

Figure 1(a) compares experimental observations and predictions for monomer conversion in ATRP copolymerizations of MMA/EGDMA at different temperatures. A good agreement between predictions and measurements is observed using kinetic parameters available in literature for linear polymerizations (e.g. Al-Harthi et al. (2007), Zhang and Ray (2002) and references therein). Notice that the reactivity of pendant double bonds of EGDMA have a minor impact in the global monomer conversion but strongly affects the gelation phenomenon, as will be discussed below. Figure 1(b) compares experimental measurements and predictions of $\overline{M}_n$ and $\overline{M}_w$ in linear ATRP polymerizations of MMA at different temperatures. Good agreements are also observed at low temperatures but major deviations are identified at 90 °C possibly due to side reactions and loss of termination control which is known to occur in ATRP at high temperatures.

Figure 1(c) shows the RI chromatograms of ATRP synthesized polimethylmethacrylate (PMMA) samples at different polymerization times. The living character of this polymerization is confirmed by the observed growth of the molecular weight (MW) without a concomitant raise of polydispersity index (PDI). Figure 1(d) shows the good control of the molecular architecture achieved with ATRP for linear polymerization systems.

Predicted and observed time evolution of $\overline{M}_w$ in linear and crosslinked polymers obtained in the ATRP copolymerization of MMA/EGMDA are compared in Figure 1(e). Here a system with a mole fraction of EGDMA of 0.5% was considered. From Figure 1(e) it is clear the influence of a small amount of crosslinker in the properties of the resulting materials, namely in comparison with the linear analogs. It is also shown the possibility of synthesize soluble hyperbranched polymers (without gelation) using living polymerization instead of conventional radical polymerization (FRP). A good agreement is also observed between predictions and measurements of $\overline{M}_w$ in the non-linear polymerization system. Nevertheless, it should be mentioned that the most important kinetic parameter governing the crosslinking process is the

reactivity of the pendant double bonds (PDB) of EGDMA. In the present work this parameter was used to fit the experimental data and the reactivity ratio between PDB of EGDMA and MMA double bonds, $r = k_p^*/k_{p11} = 0.45$ was estimated. The decrease in the reactivity of PDB here estimated is consistent with other measurements neglecting the effect of intramolecular cyclizations in diluted systems (see for instance Gonçalves et al. (2007) and references therein) but is not in agreement with findings for bulk polymerizations stating the equal reactivity of PDB and double bonds of monovinyl monomers (Ide and Fukuda, 1997). This means that the reactivity ratio here estimated is likely an apparent value affected by the neglected influence of intramolecular cyclizations which may become appreciable already for the 50 % dilution used in our experiments. Similar findings about the importance of cyclizations have been recently reported by Matyjaszewski group in the synthesis of polyacrylate networks by ATRP (Gao et al., 2008). Complementary studies concerning reaction runs in bulk should yield a more complete assessment on the possibilities of this synthetic method to prepare well defined hyperbranched polymers and networks devoid of intramolecular loops.

Figure 1(f) shows the predicted and experimentally observed influence of the temperature on the *z*-average radius of gyration ($\overline{R}_g$) in ATRP copolymerizations of MMA/EGDMA with constant mole fraction of crosslinker ($y_{EGDMA} = 0.5\%$). Predictions were obtained with the same set of kinetic parameters used for the computation of molecular weights. The good agreement between experimental measurements and predictions confirms the ability of the proposed kinetic approach to obtain some details of the molecular architecture of non-linear polymers.

Figure 2(a) shows bimodal chromatograms due to the formation of a polymer population at a low concentration but high molecular weight in ATRP of MMA/EGDMA. Notice that this observation is only possible using a SEC/RI/MALLS system. Time evolutions of the molecular architectures of highly branched samples are compared in Figure 2(b). In this figure it is possible to observe the gradual shift of the molecular architecture of branched copolymers away from the one of linear polymers. It is also possible to conclude that erroneous interpretations of chromatograms of non-linear polymers will result from using molecular weight calibrations based upon linear polymers, as before shown in the framework of FRP systems (Gonçalves et al., 2007).

Conclusions

It is shown that important features of the molecular architecture of ATRP synthesized MMA/EGDMA branched copolymers can be measured using a SEC/MALLS system. A general kinetic approach was also used to predict some structural properties of these materials, namely their *z*-average radius of gyration. The experimental results of this work agree with those found in a comparable research on polyacrylate networks (Gao et al., 2007, 2008) which have also detected the effect of intramolecular cyclizations at a comparable dilution ratio. Reaction runs in bulk are planned to be carried out at a short term and they should yield a more complete assessment on the possibilities of this synthetic method to prepare well defined hyperbranched polymers and networks with few intramolecular loops. The interest of such polymers as building blocks for advanced materials with applications in electronics and in biomedicine/pharmacy is one of the main driving forces for such efforts. The availability of the computing tools to predict the formation and final structure of these complex materials (such as the radius of gyration in sol) despite the huge number of reactions strongly enhances the possibilities of better design of the involved products and processes.

Abstract

Thermal degradation of high and low density polyethylene (LDPE) (HDPE) in an inert atmosphere was studied using simultaneous thermogravimetry (TG) and differential scanning calorimetry (DSC) at four different heating rates: 5, 10 ,20 and 40ºC/min. The products obtained in depolymerisation reaction were analyzed by gas chromatography. In this work a kinetic model has been developed that allows a simultaneous correlation of the signals obtained from TG and DSC, under dynamic conditions at different heating rates and allows further insight into the chemical process that is taking place. Fitting this model to the all experimental results made possible to estimate several kinetic parameters. It was also shown that the simultaneous use of TG and DSC information allows the measurement of the reaction rate before any gas-phase products can be observed.

1 Introduction

The consumption of plastic materials has been growing progressively. Consequently, increase amounts of waste plastics are causing serious pollution problems. Reduction of polymer waste is important both from environmental and energetic aspects. In this way, pyrolysis can be considered as a sustainable solution for urban waste polymer recycling (Aguado et al. 2007). During this process, the polymers are heated in an inert atmosphere, leading to cracking of their backone (Dong et al 2007 and Demirbas et al. 2004). The light hydrocarbons formed can be used either as fuels or as feed stock in the petrochemical and chemical production (Demirbas et al. 2004). Polyethylene is the most commonly used plastic worldwide which explains why many studies on the pyrolysis of polyethylene have appeared in literature in the last few years

Thermal behaviour of polymers can be improved by the knowledge of their thermal degradation kinetics and this can be done using dynamic techniques, such as TG/DSC, coupled with gas phase products analysis. Different techniques have been considered to investigate the reaction, but due to the nature of the process, thermogravimetric analysis (TGA) is widely considered as a useful technique to study polymers decomposition processes, including their kinetics (Kayacan et al. 2008, Ceamanos et al. 2002 and H. Bockhorn et al. 1999). Kinetic models used to describe the pyrolysis of polymers are basically based on the analysis of weight loss curves obtained during thermal gravimetric analysis of the polymeric samples. However, with this technique the reaction will only be

* Corresponding author. Tel + 351-239-798700. E-mail: francisco.lemos@ist.utl.pt

detect after it has occurred, when the products became sufficiently small to evaporate into the gas phase thus leading to the decrease of the observed polymer mass. Nevertheless, it is possible to follow the reaction from the very start, by measuring the heat involved in the breaking of the polymer bonds, for example using DSC. In this work, we have developped a model that makes use of the combination of the DSC and TG signal to give a more complete picture of the reaction.

2 Experimental

Polymers Investigated

The polymers studied in this work were pure, high density and low density polyethylenes used without any type of additivation. The high density polyethylene samples (HDPE) show an average molecular weight Mw~300 000 (Mw/Mn~20) and the low density polyethylene ones (LDPE) a Mw~390 000 (Mw/Mn~21).

Degradation of PE

All TG/DSC experiments were carried out in a TA Instruments SDT 2960 simultaneous DSC-TGA apparatus. The PE samples were placed in an alumina TG pan and their thermal degradation was analyzed. The initial sample mass was about 10 mg. The run was performed under nitrogen, with a continuous flow rate of 80 ml/min, and heating rates of 5,10,20 and 40 ºC/min temperature increase rate from room temperature up to 600 ºC; this temperature was maintained for an additional 10 min. At the end of each run, the oven was cooled and a second run was performed with the same pan arrangement to obtain the baselines, particularly for the DSC signal, which is very sensitive to the layout of the pans inside the oven. The gas phase products of the thermal and catalytic degradation of the polymers were collected and analysed by GC Shimadzu GC-9A chromatograph equipaded with a flame ionization detector (FID) and a capillary KCl/Al_2O_3 PLOT column.

3 Results and Discussion

DSC and TG Analysis

As shown in Figures 1b and 2b, there is a displacement of the maximum of the heat-flow curves to higher temperatures with increasing heating rate, due to the kinetics of the process itself and to dynamic effects of the equipment being used. For lower heating rates the time taken to heat up to a certain temperature is longer that at higher heating rates and, thus, the conditions for the appearance of the maximum occur at lower temperatures. The effect of heat transfer also becomes more important as the heating rates increase and the dynamics of the equipment itself may also become important for very high heating rates (Conesa et al 1996). From table 1, it is possible verify that the degradation temperature increased as the increasing heating rate.

The same table also shows that the thermal degradation of LDPE tends to occur at lower temperatures than that observed for HDPE.

Table 1. Degradation temperatures for the polymer samples obtained from TGA/DSC results.

Sample	$T_{degrad.}$ (ºC)
HDPE 5ºC/min	470.9
HDPE 10ºC/min	483.2
HDPE 20ºC/min	493.2
HDPE 40ºC/min	511.7
LDPE 5ºC/min	459.7
LDPE 10ºC/min	475.3
LDPE 20ºC/min	494.8
LDPE 40ºC/min	511.0

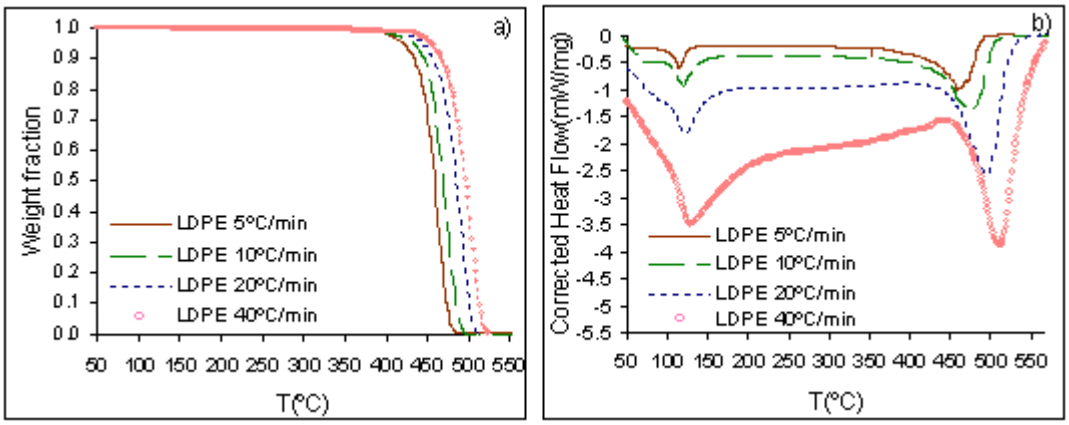

Fig. 2.TG (a) and Heat Flow (b) curves obtained in the degradation of LDPE at different heating rates.

Kinetic Model

The degradation process takes place by a succession of bond breakages. For each bond broken, a certain amount of energy is required and this should be seen directly in the heat flow signal. On the other hand, the TG signal only registers mass losses and not all the bond breakages are accompanied by losses of mass. In fact only when relatively small molecules are formed they will leave the system in the gas flow and a mass loss will be detected. The initial bond breakages will lead to quite large molecules which will not be volatile. Only the combination of TG and DSC analysis will be able to describe adequately the degradation processes.

The kinetic model developed was based on the material balance in respect to the number of bonds in the sample at each time, coupled with the energy balance. If we assume that the polymer molecules are very long chains of alkanes, the number of C-C bonds per unit mass, N, will be given, for a very large n, by the limit of the expression

$$N = \frac{n-1}{14n+2} = \frac{1}{14} \qquad \text{(Eq. 1)}$$

where n is the number of carbon atoms in the molecule. When n is very large, the number of C-C bonds will be close to 1/14 and we assume that this is the bond density at the beginning of the run. As mentioned above, C-C bonds will be lost in two ways: the first one will be due to the cracking reactions, either thermally induced or promoted by a catalyst, if present; however, when relatively small molecules are formed they will evaporate into the gas phase, carrying with them a certain number of unbroken bonds; this corresponds to the second way that bonds will be lost from the sample. We will note the average number of bonds lost to the gas phase, per unit mass of evaporated material, at a given moment, by α. Thus, the balance to the number of bonds in the sample will be:

$$\frac{dN}{dt} = -k(T)N + \frac{dm}{dt}\alpha \qquad \text{(Eq. 2)}$$

where dm/dt is the rate of mass loss. We assumed that the bond breaking process is first-order in relation to bond concentration and k(T) is the corresponding temperature-dependent rate constant, which will be taken as being described by the Arrhenius law.

$$k(T) = k_{ref}\, e^{-\frac{E_a}{R}\left(\frac{1}{T}-\frac{1}{T_{ref}}\right)} \qquad \text{(Eq. 3)}$$

where T_{ref} is a reference temperature chosen within the range of significant weight loss (573 K in this case), E_a is the activation energy of reaction and k_{ref} is the kinetic constant at the reference temperature (T_{ref}). With this information,it will now be possible to estimate the heat flow that will be measured by the apparatus, by performing an energy balance to the pan:

$$\text{Heat Flow} = -mCp\frac{dT}{dt} - k(T)N\Delta H_{\text{C-C}} + \Delta H_{vap}\frac{dm}{dt} \qquad \text{(Eq. 4)}$$

where m is the weight of the sample at any given time, Cp is the average heat capacity, $\Delta H_{C\text{-}C}$ is the average C-C bond enthalpy and ΔH_{vap} is the average vaporization enthalpy per unit mass.

This model was fitted, within the range of temperatures where degradation occurs, to the experimental Heat Flow curve. The average number of bonds in the evaporated material, α, was taken as independent of time. In addition to these equations, we had to assume that the response time of the heat flow sensor was finite and a first order dynamics was assumed for the sensor, for which the corresponding time constant was also estimated in the fitting procedure.

The differential Equation 2 was solved numerically, using the Euler method, for each run, and the model parameters were obtained by a least-squares procedure, using the sum of the squares of the residues on the heat flow as the objective function (O.F.) to be minimized:

$$\text{O.F} = \sum_{\text{all data points}} \left[\left(\text{Heat Flow}\right)_{\text{exp}} - \left(\text{Heat Flow}\right)_{\text{computed}}\right]^2 \qquad \text{(Eq. 5)}$$

The optimization procedure was carried out using the “Solver” tool in an Excel (© Windows) spreadsheet.

Table 2. Model parameters obtained by fitting the kinetic model for the thermal degradation of HDPE and LDPE at different heating rates

Polymer	Heating Rates (ºC/min)	k_{ref} (min^{-1})	E_a ($kJ.mol^{-1}$)	$\Delta H_{C\text{-}C}$ ($kJ.mol^{-1}$)	ΔH_{vap} ($J.g^{-1}$)	α (Bond $mole.g^{-1}$)	C_p ($J.g^{-1}.K^{-1}$)
HDPE	5	7.01×10^{-4}	131	4.41	410	0.0092	1.86
	10	2.18×10^{-4}	143	4.77	284	0.0343	1.86
	20	3.32×10^{-5}	188	3.12	203	0.0421	1.87
	40	5.40×10^{-6}	202	7.49	114	0.0628	1.86
LDPE	5	8.42×10^{-4}	123	4.21	297	0.0139	2.21
	10	4.90×10^{-4}	138	2.79	222	0.0206	2.28
	20	7.83×10^{-5}	144	8.53	223	0.0582	2.25
	40	6.06×10^{-6}	189	5.13	202	0.0630	2.19

The values obtained for some of the parameters can be compared with estimates obtained from tabled data. Averaging tabled data for olefins from C2 to C10 (Lide, 2004-2005), we estimated ΔH_{vap} as being around 360 $J.g^{-1}$ and C_p as 2.18 $J.g^{-1}.K^{-1}$. Although the values estimated from the experimental data show some variation, they are in reasonable agreement with the average values thus computed.

Average bond and vaporization enthalpies are similar for the two polymers and the same can be said in relation to C_P values, which are averaged to 1.9 and 2.2 $J.g^{-1}.K^{-1}$ to the HDPE and LDPE, respectively.

In this work, the values of estimated apparent activation energies are consistent with other authors (Ceamanos et al. 2002). If we compare the results obtained for thermal processes of the HDPE and LDPE at four different heating rates, we can see that the estimated apparent activation energy for the process increases as the heating rates increase. Conversely the specific reaction rate at the reference temperature decreases with increasing heating rates.

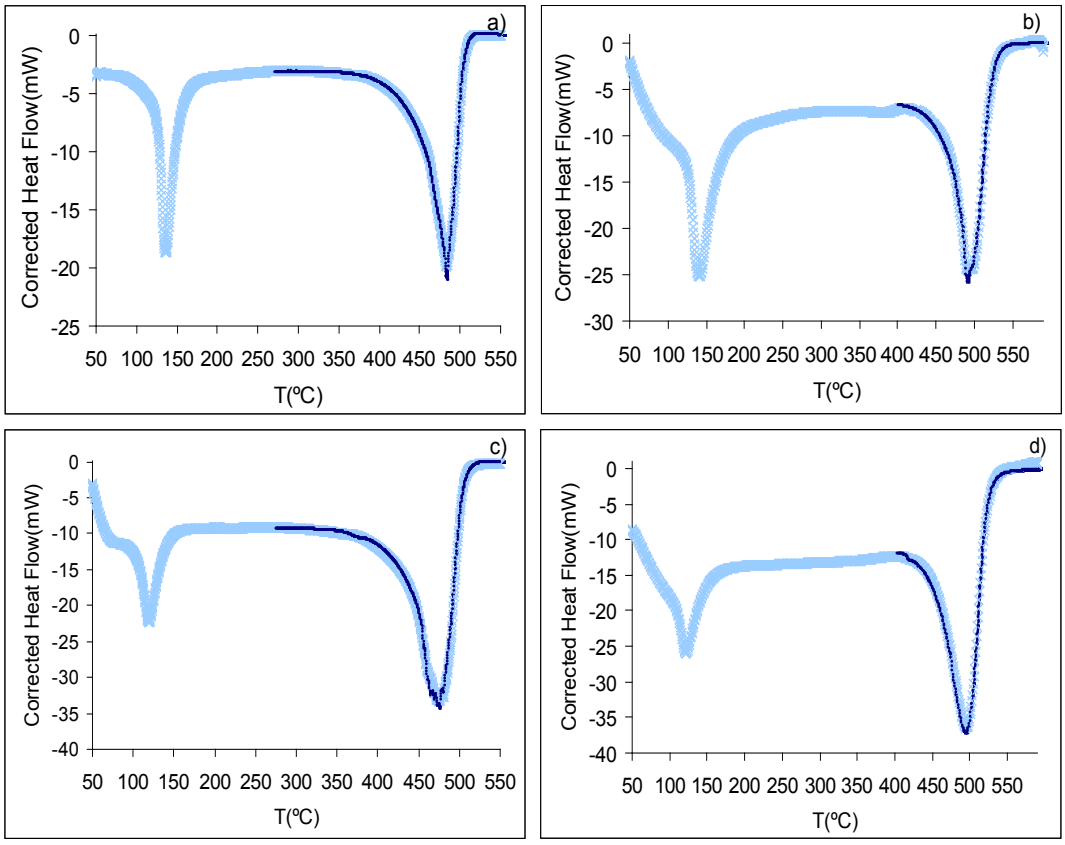

Fig. 3. Experimental (×) and calculated (—) heat flow curves - (a) HDPE 10ºC/min; (b) HDPE 20ºC/min; (c) LDPE 10ºC/min; (d) LDPE 20ºC/min.

Analysis of products

The products distributions (%molar) obtained in the thermal degradation of polyethylene at four different heating rates are shown in fig.5 (HDPE) and fig.6 (LDPE). Either for degradation of HDPE or for degradation of LDPE the products were mainly C2 (ethane, ethylene), C3 (propane, propylene) and C4 (butane, iso-butane, butene,…). As a general observation the amount of lighter products increases as the heating rate increases

This is likely to occur since the contribution of the reaction occurring at higher temperatures increases as the heating rate is increased and, thus, reactions with higher activation energy are favoured by this increase in the heating rate, justifying the observed increase in the estimated apparent activation energy (see table 2).

The use of lower heating rates leads to an increase in the production of the gasoline fraction whilst higher heating rates will tend to produce lighter fractions.

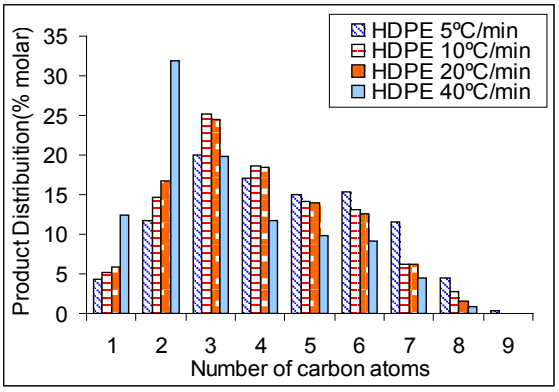

Fig. 5. Distribution of evolved products as a function of carbon number at different different heating rates with HDPE

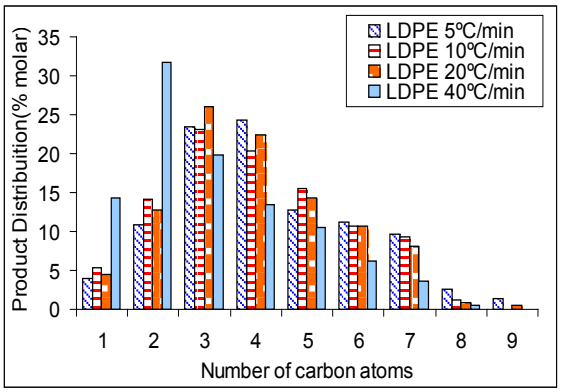

Fig. 6. Distribution of evolved products as a function of carbon number at different different heating rates with LDPE

Conclusions

The simultaneous use of DSC/TG together to GC analysis allowed us to have a clearer picture of the thermal degradation process. The model developed provides quite good fittings to the experimental data, and despite their simplicity allowed us to estimate kinetic and thermodynamic parameters, such as: bond energies, vaporization enthalpies and specific heat capacities wich are in accordance with published and calculated values.
The results also show that the product distribution depends on the heating rates.
In this way an increase in the heating rate leads to an increase of the amount of lighter products in accordance with the observed estimated apparent activation energy

Acknowledgements

The authors wish to thank Borealis for the HDPE and LDPE sample used in this work.

Topic: Advancing the chemical and biological engineering fundamentals

Abstract

The synthesis of decyl acetate, from the transesterification of vinyl acetate with decanol, was studied in a high-pressure experimental set-up, equipped with a variable volume batch reactor, operating isothermally at 35 ºC and 100 bar, using CO_2 in supercritical conditions as solvent, and *Candida antarctica* lipase B (CALB), immobilized on the macroporous resin Lewatit B (Novozym 435®), as catalyst. The enzymatic content was determined for each particle size of the catalyst. It was shown that the smallest particles have a larger specific amount of enzyme, and the results indicate that the enzyme is located in an external shell of the particle, following an "egg-shell" model type, with a thickness of ca. 60 μm (assuming a homogeneous distribution), independent of the particle size. Both external and internal mass transfer resistances were evaluated. External resistances were easily eliminated by stirring and internal diffusional limitations can be considered as negligible. The effect of the feed concentration of substrates on the initial reaction rate was also studied. It was observed that, above a certain concentration of decanol in excess relatively to vinyl acetate, the reaction is inhibited by the alcohol. On the contrary, the reaction is favoured when the reactor is fed with excess of vinyl acetate, with a significant enhancement of its initial rate. These results are consistent with a Ping-pong bi-bi type mechanism with competitive inhibition by the alcohol, commonly used in the description of enzymatic reactions of esterification/ transesterification.

1 Introduction

The growing interest in industrial biocatalysis and in the research concerning enzymatic catalysis opened a wide range of applications in the field of pharmaceuticals, (fine-) chemicals and intermediates, leading to an increasing number of industrial biotransformations (Rozzell, 1999). Simultaneously, increased concern for the environment led to awareness for environmental friendly production methods. In this field, supercritical (sc) fluids may play a major role as they can be used for the reduction of organic waste, with the additional benefit that separation after reaction is relatively simple, which offers several process advantages. Another useful characteristic of sc-fluids is their adjustable solvation ability and properties that facilitate mass transfer. Among the four most extensively studied sc-fluids (CO_2, ethane, ethene and water), there is a wide interest in the use of sc-CO_2 since it has several advantages like non-toxicity, non-flammability, availability in high purity and solubilities of solutes can be tuned by changing temperature and pressure. As sc-CO_2 has

the GRAS (generally regarded as safe) status, it can be used in food and pharmaceutical processes without major regulatory issues. The possibility to combine two sustainable technologies – biocatalysis and supercritical technology using green/natural solvents – allows to establish processes without environmental costs, and whose products are considered natural, resulting in a significant increase of their market value due to the present trends of such products.

In this work, the production of decyl acetate was studied. It is an ester with applications in the industry of fragrances where its floral odour is greatly appreciated. Since it mainly appears in nature in expensive oils, enzyme catalysis in a green solvent, such as CO_2, can be a valuable process for production of natural decyl acetate. The reaction studied was the transesterification of vinyl acetate with decanol, obtaining decyl acetate as the main product. *Candida antarctica* lipase B (CALB), immobilized on the macroporous resin Lewatit B (Novozym 435®), was chosen as the catalyst.

2 Materials and Methods

Catalyst. Novozym 435® (Candida antarctica lipase B (CALB) immobilized on the macroporous resin Lewatit B) was gently provided by Novozymes (Denmark). The catalyst particles were sieved in four size groups: >598, 425–500, 297–350 and 250–297 μm. The enzyme content of the Novozym 435® particles was determined by a modified Lowry method (Lowry et al., 1951). Measurements were made for each size group.

Chemicals. The reactor was fed with 1-decanol (>99 wt%, Aldrich), vinyl acetate (>99 wt%, Aldrich), n-decane (> 98 wt%, Fluka) and carbon dioxide (N45, Air Liquide). For GC calibration solutions, decyl acetate (> 98 wt%, Alfa Aesar) and n-hexane (> 99 wt%, Riedel – de Haën) were also used. For the modified Lowry method the following chemicals were used: sodium carbonate anhydrous (> 99.5 wt%, Fluka), potassium sodium tartrate (> 99 wt%, Riedel-de Haën), copper (II) sulphate pentahydrate (> 99 wt%, Riedel-de Haën), sodium hydroxide (Pronolab), Folin-Ciocalteau reagent (Merck) and Bovine Serum Albumin (SigmaDiagnostics).

Apparatus. A variable-volume stainless steel batch reactor equipped with a sapphire window and with loading and sampling valves was used. Details of the high-pressure apparatus and experimental technique have been given elsewhere (Fontes et al., 2001). All experiments were performed with a reaction mixture volume of ca. 22 mL.

Sample Analysis. The samples were analysed on a gas chromatograph (Trace 2000 series, Unicam) equipped with a flame ionization detector (FID) and an autosampler. The compounds were separated in a chiral capillary column with 30 m length, 0.25 mm inner diameter and 0.25 μm film thickness (BGB – 178, BGB Analytik AG). Helium N50 (2 mL/min) was used as the carrier gas. The injector and detector temperatures were set at 250 ºC. The oven temperature program was set as follows: 80-150 ºC ramp at 4 ºC/min, 150-170 ºC ramp at 6 ºC/min. n-decane (20 mM) was used as internal standard for GC analysis.

3 Results and Discussion

Enzyme distribution on the catalyst particles. The results of the specific enzyme content for the different size groups of the Novozym 435® particles are shown in Table 1.The values obtained for the enzyme content show that the specific enzyme loading (mass of enzyme/mass of particle) depends on the particle size and smaller particles have a higher specific enzyme loading than the larger ones. Garcia-Alles and Gotor (1998) already presented some experimental evidence suggesting that the specific enzyme loading varies with the particle size, being larger for smaller particles. A similar correlation was reported by van Roon et al. (2003) for immobilized Penicilin-G Acylase and such dependence of the specific enzyme loading with the particle size could be related to internal mass transfer limitations during the enzyme immobilization process. This is supported by the results

obtained more recently by Chen et al. (2007) with experimental evidence that, although the maximum attainable enzyme loading (saturation) is independent of the particle size, smaller particles will saturate with enzyme faster. Mei et al. (2003) studied the internal distribution of Novozym 435® using synchrotron infrared microspectroscopy, showing that for a particle size around 600 μm there is only an 80-100 μm thick enzyme layer in the outer portion of the particle, distributed heterogeneously. Several modeling studies were done in the eighties (Clark et al., 1985; Hossain et al., 1986) that associated this kind of intraparticle distribution with restricted diffusion conditions during the immobilization process since, as the immobilization proceeds, the pore size will be reduced by the adsorbed enzyme. More recently, Mei et al. (2003) suggested that restricted diffusion during the immobilization process is unlikely in the case of Novozym 435® since the enzyme molecules are ten times smaller than the average pore size of the support. Moreover, in their studies to regulate the thickness of the enzyme outer shell, these authors found that, by increasing the time for diffusion and the concentration of CALB, it was possible to obtain particles containing protein distributed throughout.

Table 1: Enzymatic content for each particle size group of Novozym 435®.

Particle diameter (μm)	Enzymatic content (mg enzyme/g particle)
> 598	54.09
425-500	61.94
297-350	84.13
250-297	89.18

The results obtained in this work also suggest that Novozym 435® has an egg-shell intraparticle distribution. Assuming a homogeneous distribution of the enzyme on the outer shell (i.e., the ratio volume of the outer shell/mass of enzyme is constant in each particle), the enzyme thickness should be independent of the particle size, since all of them are exposed to the same time for diffusion. In fact, we obtained an enzyme outer shell thickness of 60 μm, with an average error of ca. 3%. This thickness is less than the reported by Mei et al. (2003), as should be expected, since our calculation considers a homogeneous distribution of the enzyme.

In order to correctly account for the different specific enzyme loadings, care must be taken to express the reaction rate in terms of the mass of enzyme instead of the total mass of the catalyst particles, since when using the same amount of catalyst particles we are actually performing the reactions with different amounts of enzyme. As the particle size decreases, the amount of enzyme in the reactors will be higher, contributing to an enhancement in the reaction rate that is not directly related to the reduction of diffusion limitations.

External mass transfer studies. When working with immobilized enzymes, as with any other supported catalysts, in order to reach the enzyme molecules, the reactants must firstly diffuse from the bulk liquid to the surface of the particles, across a stagnant layer of fluid, and then inside its pores, where the enzyme is immobilized. When working with a batch reactor, the thickness of the stagnant film can generally be reduced by stirring the reaction mixture, minimizing, if not eliminating, the influence of this transport phenomenon in the overall reaction process. To ensure the absence of external diffusion limitations in all experiments, the stirring was gradually increased until it had no influence in the evolution of the observed concentrations of the reacting components, which occurred around 950 rpm. These experiments were performed keeping all the other conditions constant (temperature, pressure, amount of enzyme, particle size, initial substrate concentrations).

Internal mass transfer studies. The influence of internal mass transfer in a given heterogeneous catalytic process can be minimized by reducing the particle size and hence, shortening the diffusion path. If catalyst particles of different sizes are available, they can be used to assess the relative influence of internal diffusion in the overall process. Whenever internal diffusion limitations are present, a reduction in the particle size, usually leads to an enhancement of the reaction rate; when reducing the particle size has no further influence in

the reaction rate, internal diffusion is fast enough to be considered negligible and the process is controlled by the reaction. In order to assess the influence of internal diffusion, several reactions were performed using different particle sizes, but with the same amount of enzyme, the same initial substrate concentrations, the same stirring speed, temperature and pressure. The results obtained, in terms of the reactants conversion as a function of time and in terms of initial reaction rate (R^0), are presented in Figure 1a and 1b, respectively, and show that the size of the catalyst particles does not have a significant effect on the initial reaction rate (maximum relative difference of 4.5% between R^0). Therefore, the internal diffusional limitations can be considered negligible, and any size group of particles can be used without considering mass transfer resistances inside the particles. As mentioned previously, amongst the usually stated advantages of supercritical fluids as solvents for reaction processes are the reduction of mass transport resistances that arise from the high gas-like diffusivities.

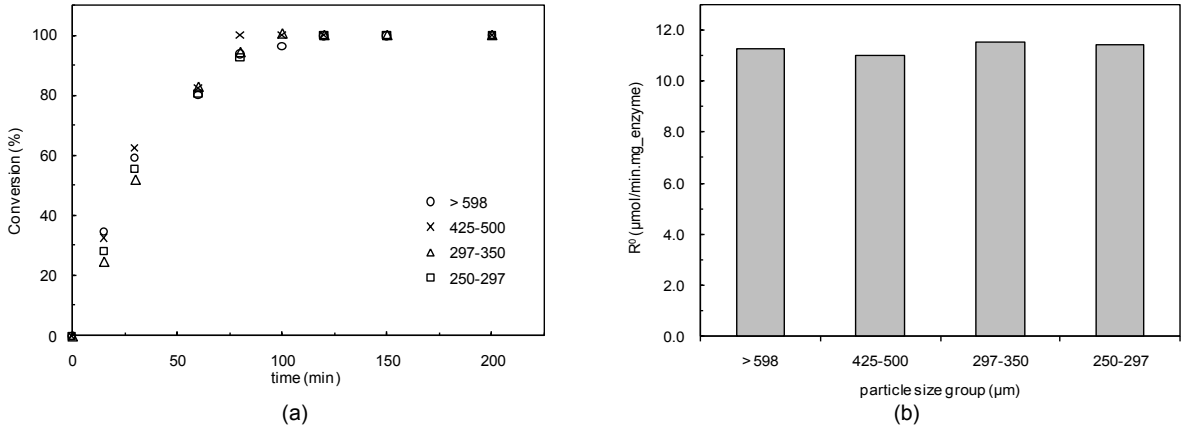

Figure 1: Effect of particle diameter on the: (a) reactants conversion as a function of time; (b) initial reaction rate. Equimolar feed (50 mM), 2.2 mg of enzyme, 35 ºC and 100 bar for all assays.

Effect of feed concentration. The effect of the feed concentration of substrates on the initial reaction rate was also studied. The Ping-pong bi-bi model is widely used to describe the kinetics of transesterification reactions (Yadav and Devi, 2004; Zhang et al., 2005). According to this ordered mechanism, the ester firstly binds to the active site of the enzyme, and the first product is released (bi-product), leading to the formation of a substrate altered enzyme complex. The alcohol then binds to this complex and the second product (main product) is formed and released, returning the enzyme to its native state. When vinyl acetate is used as a reactant, the first product formed is vinyl alcohol that quickly tautomerizes to acetaldehyde, making the overall transesterification irreversible, which is consistent with our experimental results where full conversions were always obtained. The Ping-pong bi-bi reaction rate equation can be simplified if the enzyme has a significantly higher affinity for some of the components or if there are large differences in their concentrations. When the affinity of the enzyme for the substrates is much higher than the affinity for the products, and if the concentration of the reactants is much higher than the concentration of the products, i.e. in the beginning of the reaction, the initial reaction rate can be described as:

$$R^0 = \frac{V_{max}}{\frac{K_{MA}}{[A]} + \frac{K_{MB}}{[B]} + 1} \quad (1)$$

where V_{max} is the maximum reaction rate, [A] is the concentration of vinyl acetate and [B] the concentration of decanol; K_{Mi} represents the Michaelis constant for component i. For transesterifications (and esterifications) reactions, an additional competitive inhibition step is usually added to the Ping-pong bi-bi kinetic mechanism since the alcohol can also compete with the ester (or acid) in binding to the enzyme in its native state but no product is formed:

$$R^0 = \frac{V_{max}}{\frac{K_{MA}}{[A]}\left(1+\frac{[B]}{K_I}\right)+\frac{K_{MB}}{[B]}+1} \quad (2)$$

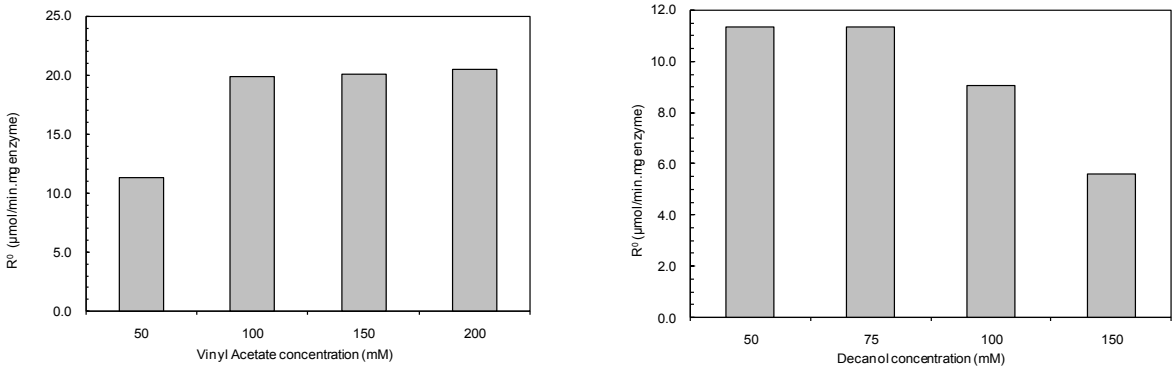
where K_I represents the competitive inhibition constant.

Equation (2) can be further simplified by raising the concentration of one of the reactants, eliminating the influence of the other substrate:

$$R^0 = \frac{V_{max}}{\frac{K_{MB}}{[B]}+1} \text{ for } [A]>>[B], \qquad R^0 = \frac{V_{max}}{\frac{K_{MA}}{[A]}+\frac{K_{MA}}{K_I}\frac{[B]}{[A]}+1} \text{ for } [B]>>[A] \quad (3a, 3b)$$

From Equation (3a), provided that the concentration of vinyl acetate is sufficiently larger than the concentration of decanol, the initial reaction rate becomes independent of the concentration of the reacting ester. On the opposite end, if the concentration of decanol is much larger than the concentration of vinyl acetate (Equation 3b), unless inhibition by decanol is negligible, the initial reaction rate will still depend on the concentration of both reactants.

The experimental results obtained while varying the concentration of each reactant individually (Figure 2a and Figure 2b) were qualitatively consistent with this model: (i) the reaction is enhanced by higher concentrations of vinyl acetate ([A] ≥ 100 mM); (ii) the reaction is inhibited by larger concentrations of the alcohol ([B] ≥ 100 mM). When fixing the concentration of decanol and increasing the concentration of vinyl acetate, R^0 increased ca. 83% (Figure 2a). Moreover, the concentration of vinyl acetate no longer influenced the initial reaction rate, as predicted by Equation (3a). As a result of the competitive inhibition by decanol, fixing the concentration of vinyl acetate and increasing decanol has an adverse effect in the initial reaction rate; in this case, as predicted by Equation (3b), the initial reaction rate remains a function of the concentration of decanol: R^0 decreased ca. 18%, relatively to the equimolar feed, for [B]=100 mM, and ca. 49% for [B]=150 mM (Figure 2b).



(a) (b)

Figure 2: Effect of the feed concentration of substrates on the initial reaction rate: (a) excess of vinyl acetate ([B]=50 mM, 35 ºC and 100 bar for all assays; 2.2 mg of enzyme for [A]=50 and 100 mM, 1.1 mg of enzyme for [A]=150 and 200 mM); (b) excess of decanol ([A]=50 mM, 2.2 mg of enzyme, 35 ºC and 100 bar for all assays).

4 Conclusions

The transesterification of vinyl acetate and decanol in sc-CO_2 by Novozym 435® was studied, with particular emphasis on the influence of enzyme distribution, internal diffusion and feed concentration of substrates. It was shown that the specific enzyme loading increases as the particle size decreases. As a consequence, care should be taken to ensure that this does not affect mass transfer studies by using the same enzyme amount instead of the same mass of catalyst particles. It was also shown that the enzyme is located in an external shell of the particle, following an “egg-shell” model type, with a thickness of ca. 60

μm (assuming a homogeneous distribution in this outer shell), independent of the particle size. Diffusion limitations were shown to be negligible. Finally, the experimental results obtained while varying the concentration of each reactant individually were qualitatively consistent with the Ping-pong bi-bi kinetic model with competitive inhibition by the alcohol: the reaction was enhanced by concentrations of vinyl acetate ≥ 100 mM, and inhibited by concentrations of decanol ≥ 100 mM.

Keywords: catalytic membrane reactors, hydrogenation, propylene purification

Topic: Advancing the chemical and biological engineering fundamentals

Abstract

The purification of propylene is a very energy demanding industrial separation. The present work analyses theoretically the performance of various Catalytic Membrane Reactor (CMR) arrangements with perfect mixing flow pattern. It is concluded that the best arrangement consists of two CMR in series. This arrangement allows reaching the same results as a conventional reactor, though with a lower Damköhler number.

1. Introduction

For the synthesis of polypropylene, the feed (propylene) stream should contain less than 10 ppm of propadiene and 5 ppm of propyne (Liu *et al*., 1997). However, typical industrial propylene produced by steam cracking contains about 2-5 % (mol) of alkynes and dienes (Liu *et al*., 1997, Fajardo *et al*., 1996). The traditional purification process consists in the selective hydrogenation of such impurities (Fajardo *et al*., 1996), carried out in a fixed-bed catalytic reactor (Liu *et al*., 1997). In this process, however, the over-hydrogenation of propylene to propane is a drawback to be avoided, beyond the high cost of the catalysts.

An alternative approach for propylene purification is the use of membranes, such as carbon molecular sieves or zeolites (Steel and Koros, 2003, Stoitsas *et al*., 2005). When functionalized, these membranes are highly selective towards propyne and propadiene (Padin *et al*., 2000).

The objective of this work is to perform a theoretical study combining the separation selectivity of membrane-based processes with the catalytic hydrogenation selectivity in a single process unit, showing synergetic performance. Indeed, it is expectable that using a selective hydrogenation catalyst, placed on the permeate side, one can increase the driving force and selectivity. For comparison purposes, we consider that the results obtained in a membrane reactor operating in the total flow-through configuration (total permeation condition, TPC, or no retentate stream) are equivalent to the ones obtained in a conventional catalytic reactor. “Conventional”, in the context of this work, means a catalytic gas-phase reactor with perfectly mixed flow pattern (CSTR) fed with the same stream, with the same reactions taking place at the catalyst surface and described by equivalent kinetic equations.

2. Model Development

The catalytic membrane reactor considered in this study has the general features of the one depicted in Figure 1. It consists of retentate and permeate perfectly mixed chambers with constant pressure, separated by a flat hypothetical composite membrane, highly selective towards alkynes, and supporting a catalytic layer on the permeate side. The hydrocarbon mixture (propyne and propylene) is fed at a higher pressure to the retentate chamber, while a low-pressure hydrogen stream is fed to the permeate side.

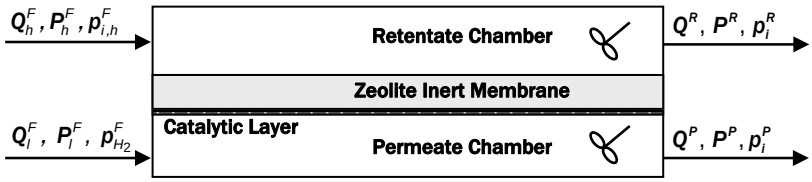

Figure 1 – Schematic diagram of the catalytic membrane reactor (CMR).

The model proposed for this reactor is based on the following main assumptions: (1) steady-state, ideal gas behavior and isothermal conditions; (2) the transport through the membrane is considered to be described by an “overall” permeability coefficient, constant for all the operating conditions; (3) homogeneous distribution of the catalytic nanoparticles throughout the catalytic layer, which is considered to be part of the permeate chamber. (4) the kinetic equations are considered valid for all the operating conditions.

The reaction considered is of the consecutive-parallel and irreversible type, describing the hydrogenation of propyne, $C_3H_4 + H_2 \rightarrow C_3H_6$, and propylene, $C_3H_6 + H_2 \rightarrow C_3H_8$. To describe the reaction kinetics, power-law type equations were considered, which simplifies the problem without compromising the main conclusions. In fact, some works report that simple power-law type rate equations represent well the experimental results for hydrocarbon catalytic hydrogenation reactions, sometimes even better than the Langmuir-Hinshelwood/Hougen-Watson models (Fajardo *et al*. 1996, Groschel *et al*., 2005). Based on a literature review (Brandão *et al*., 2007; Groschel *et al*, 2005; Bond and Sheridan, 1952; Bond and Wells, 1965), the following reaction rate equations were considered:

$$r_1 = k_1 p_{H_2} \left(p_{C_3H_4}\right)^{-0.25} \quad \text{(propyne hydrogenation)} \tag{1}$$

$$r_2 = k_2 p_{H_2} p_{C_3H_6} \quad \text{(propylene hydrogenation)} \tag{2}$$

The steady state mass balances are presented in the following sections in their dimensionless form. The variables were made dimensionless with respect to the feed conditions (Q_h^F , P_h^F) and to propylene species ($L_{C_3H_6}$).

2.1 Partial and Total Mass Balances for the Retentate Side

$$Q_h^{F*} p_{i,h}^{F\,*} = Q^{R*} p_i^{R*} + \Gamma L_i^* \left(p_i^{R*} - p_i^{P*}\right) \tag{3}$$

$$Q_h^{F*} P_h^{F*} = Q^{R*} P^{R*} + \Gamma \sum_i L_i^* \left(p_i^{R*} - p_i^{P*}\right) \tag{4}$$

2.2 Partial and Total Mass Balances for the Permeate Side

$$Q_l^{F*} p_{i,l}^{F\,*} = Q^{P*} p_i^{P*} - \Gamma L_i^* \left(p_i^{R*} - p_i^{P*}\right) + Da\left(\nu_{i,1} f_1\left(p_i^*\right) + \nu_{i,2} R_r f_2\left(p_i^*\right)\right) \tag{5}$$

$$Q_l^{F*} P_l^{F*} = Q^{P*} P^{P*} - \Gamma \sum_i L_i^* \left(p_i^{R*} - p_i^{P*}\right) + Da \sum_i \left(\nu_{i,1} f_1\left(p_i^*\right) + \nu_{i,2} R_r f_2\left(p_i^*\right)\right) \tag{6}$$

Where $f_1\left(p_i^*\right) = p_{H_2}^* \left(p_{C_3H_4}^*\right)^{-0.25}$, $f_2\left(p_i^*\right) = p_{H_2}^* p_{C_3H_6}^*$, $Da = \frac{k_1 \Re T P_{ref}^{-0.25}}{Q_{ref}}$, $\Gamma = \frac{A \Re T L_{ref}}{\delta Q_{ref}}$, $R_r = \frac{k_2}{k_1} P_{ref}^{0.25}$

i refers to the i^{th} component (C_3H_4, C_3H_6, C_3H_8, H_2); the superscripts *F*, *R* and *P* refer to feed, retentate and permeate conditions, respectively; the subscripts *h* and *l* refer to high (retentate) and low (permeate) pressure sides, respectively; L_i^* is the dimensionless permeability coefficient of the membrane (L_i/L_{ref}), p_i^* is the dimensionless partial pressure (p_i/P_{ref}) and Q^* is the dimensionless volumetric flow rate (Q_i/Q_{ref}). *Da* is the Damköhler number (based on the propyne hydrogenation reaction), Γ is the dimensionless contact time (ratio between the maximum possible flux across the membrane for the reference component, that is, permeation of pure species against null permeate pressure, and its molar feed flow rate) and R_r is the ratio of the reaction rate constants. ν is the stoichiometric coefficient, taken negative for reactants, positive for reaction products, and null for the components that do not take part in the reaction, *A* is the membrane surface area, *T* is the temperature, $\Re$ is the ideal gas constant and δ is the membrane thickness. It should be emphasized that the reaction rate constants include the catalyst amount.

3. Results and Discussion

The ranges of values for the model parameters are listed in Table 1. It is assumed that the permeability value for propyne is much higher than for the other components (which are considered all with the same value). The permeability range listed is based on several published reports (Steel and Koros, 2003, Padin *et al*. 2000, Olson *et al*., 2004). The volumetric feed flow rate of hydrogen (Q_l^{F*}) was set to a value so that its molar flow rate would be equal to propyne's molar flow rate. R_r values were chosen in accordance to some reported results (Groschel *et al*., 2005). Reference pressure was considered to be 1 atm.

Table 1 – Parameter ranges used in the simulations.

P^{P*}	0.005	Γ	0.01-TPC
Q_l^{F*}	4	*Da*	$1 - 10^5$
$L_{C_3H_4}^*$	$10 - 10^4$	R_r	0.001 – 0.1
$L_{C_3H_6}^*$, $L_{C_3H_8}^*$, $L_{H_2}^*$	1	$y_{C_3H_4}^F$	0.02

The catalytic membrane reactor (CMR) was compared with a conventional reactor and with an equivalent membrane system without catalyst, in terms of the outlet propyne concentration. It was assumed that a CMR operating in the total flow-through configuration (total permeation condition – TPC) with a nonpermselective membrane is loosely equivalent to the conventional catalytic reactor described above. This equivalence is discussed elsewhere (Sousa and Mendes, 2006). From this point on, this equivalent CMR will be named "ECSTR".

3.1 Equivalent Conventional Reactor (ECSTR)

Figure 2 shows the simulation results for the ECSTR. As it can be seen, this reactor is able to achieve the desired product purity with a reaction rate ratio (R_r) equal to or below 0.01. Propylene's overall yield (defined as the moles of propylene produced per mole of propyne fed) is very close to 1, so there is no deeper hydrogenation of propylene to propane, for this set of kinetic parameters. The minimum *Da* for this separation, when R_r is 0.01, is very high (around 20 000), which constitutes a downfall for the traditional approach.

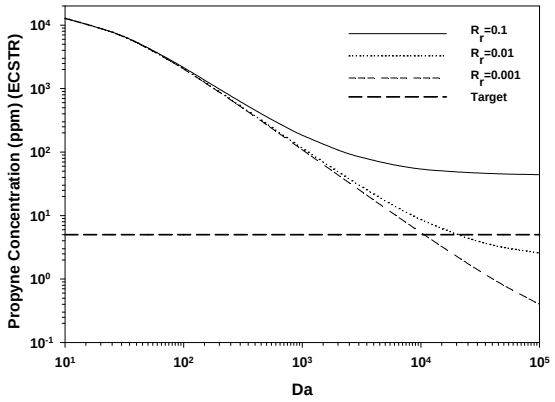

Figure 2 - Propyne outlet concentration (in ppm) as a function of the Damkhöler number, for different reaction rate ratios in a CMR ($L_i^* = 1, \Gamma = \Gamma_{TPC}$). The other parameters have the values reported in Table 1.

3.2 Membrane and Catalytic Membrane Reactor (CMR)

Figures 3 shows the results obtained for a membrane-based separation system (A), *i.e*., the CMR here considered with $Da = 0$ and for the CMR (B). In the second case the overall yield of propylene is again approximately 1.

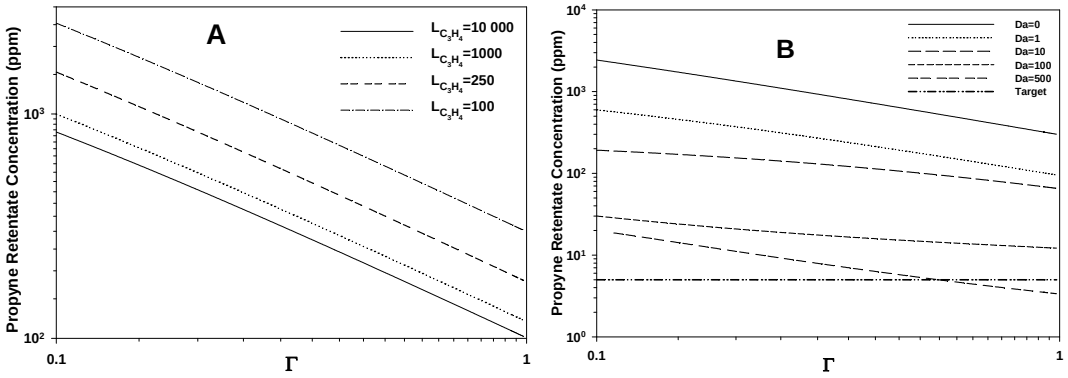

Figure 3 – Propyne outlet concentration as a function of the dimensionless contact time. (A) - membrane; (B) – CMR with $L^*_{C_3H_4}$=10 000 and R_r=0.01)

Figure 3A shows a decrease in the propyne outlet concentration when increasing the dimensionless contact time; an increase of Γ increases the stage-cut ratio (ratio between the flux across the membrane and feed flow rate), leading to retentate streams poorer on the most permeable components (which is the case of propyne, cf. Table 1). A membrane is unable to perform the desired separation (conc. < 5 ppm) even with very high membrane selectivities.

Figure 3B shows that a CMR achieves the desired product purity at relatively low Damkhöler values when compared with the ECSTR (Fig. 2), meaning that, for example, lower catalytic activity (lower mass of catalyst) is required. However, it requires very high membrane selectivities (a CMR with selectivity for propyne of 1000 is unable to meet the outlet stream concentration requirements) and high dimensionless contact time values (high membrane area requirements or low feed flow rates, for example).

3.3 Two Separation Units in Series (Membrane/CMR; CMR/CMR)

A CMR's advantage over a membrane is the enhancement on the driving force for propyne caused by its hydrogenation on the permeate side. This driving force enhancement is more significant when feeding a less concentrate stream. Placing a separation unit before the CMR in order to decrease the propyne concentration would then optimize the latter's performance. Two different strategies of combined separation

units were then tested: Membrane-based separation/CMR and CMR/CMR (Membrane/Membrane strategies require very high contact times). The first unit's retentate stream enters the feed/retentate chamber of the second unit, from where the final stream exits. For the case of two CMRs in series, the unreacted hydrogen from the first unit is fed to the second one. The hydrogen flow rate on the second unit was set so that its molar flow rate would equal propyne's molar flow rate entering the unit.

A qualitative optimization of the results was made. Reasonable membrane selectivies were used (100-1000) and the final retentate flow rate was maximized, for a maximum propyne concentration of 5 ppm. The combined separation units met the requirements for propyne concentration with a low catalytic activity of the catalyst, when compared to the ECSTR.

Figure 4 shows the results obtained with the Membrane/CMR and CMR/CMR assemblies at the exit of the first unit. A membrane or a CMR decreases significantly the propyne concentration, even at very low Γ values (feed value is 20 000 ppm). It is worth noting that as the membrane selectivity increases, the difference in performance between a membrane and a CMR is accentuated.

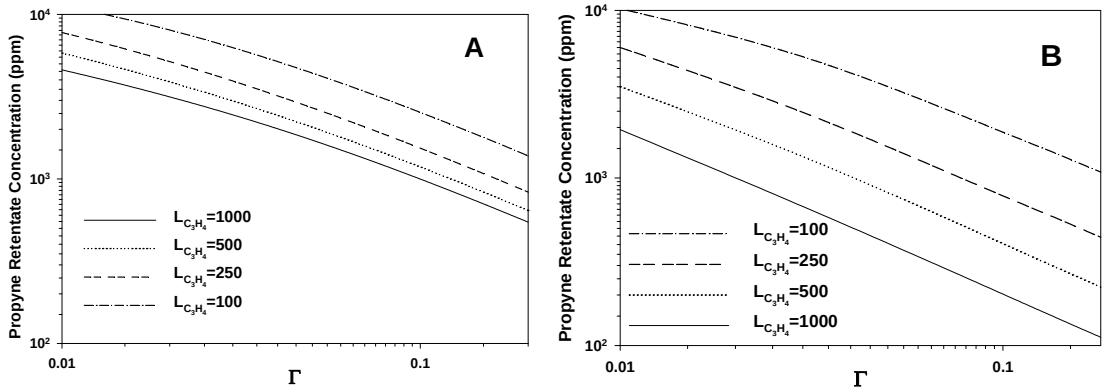

Figure 4 – Propyne retentate concentration at the exit of the first unit as a function of the dimensionless contact time. (A) – membrane; (B) – CMR. CMR results are for optimum Damkhöler values for each pair of Γ and membrane selectivity (*Da* ranges from 1 to 200).

Results at the exit of the second unit for both strategies are summarized in Table 2. In general, two membrane reactors in series generate better results than a membrane followed by a CMR; indeed, while the flow rate at the exit of the second unit is much higher in the case of the CMR/CMR configuration, there is little difference in the Damkhöler number. To obtain high flow rate recoveries ($\geq$ 75 %), membrane selectivity must be at least 500.

Table 2 – Set of conditions that maximize the production retentate flow rate for both strategies. $ProdFR_1$ (%) and $ProdFR_2$ (%) represents the flow rate percentage relative to the initial feed flow rate for units 1 and 2, respectively. Da_1 and Da_2 are the optimum Damkhöler values for units 1 and 2, for each pair of Γ and membrane selectivity.

System	$L^*_{C_3H_4}$	Da_1	$ProdFR_1$ (%)	Da_2	$ProdFR_2$ (%)
Membrane/CMR	500	-	75%	50	58%
CMR/CMR	500	75	85%	15	75%
CMR/CMR	250	100	75%	45	54%

4. Conclusions

Alternative methods to the typical fixed bed reactor were considered for propyne hydrogenation. The use of a low-pressure hydrogen feed on the permeate side of a catalytic membrane reactor (CMR) greatly increases propyne's driving force for transport across the membrane as it is selectively hydrogenated therein. A CMR with

such a design decreases propyne concentration to the desired levels with low Damkhöler number (low catalyst amount, for example), but very high selective membranes towards propyne are required. An alternative two-step approach consisting of a membrane-based separation and a CMR or two CMRs in series was analyzed. In the latter configuration, higher flow rate streams were obtained with low propyne contents, low Damkhöler numbers and with relatively high selective membranes.

Improvement by alkaline treatment of HZSM-5 zeolite performance in DME steam reforming

Jorge Vicente*, Javier Ereña, Alaitz Atutxa, Ana G. Gayubo, Javier Bilbao
Dpto. Ingeniería Química, Universidad País Vasco, Apartado 644, 48080 Bilbao, Spain

Keywords: dimethyl ether, steam reforming, HZSM-5 zeolite, alkaline treatment
Topic: Advancing the chemical and biological engineering fundamentals

Abstract

Dimethyl ether (DME) steam reforming to produce hydrogen has been studied over a bifunctional catalyst prepared by (wet) physical mixture of a metallic function (a commercial $Cu/ZnO/Al_2O_3$ catalyst for methanol steam reforming) and an acidic function of HZSM-5 zeolite modified by alkaline treatment. The alkaline treatment affects the porous structure of the zeolite (leading to an increase in the mesoporous surface and a decrease in microporous volume and BET surface area) and its acidic properties (attenuating both total acidity and acidic strength). The attenuation in acidity lowers the formation of undesired hydrocarbons from oxygenates (methanol + DME) over the acidic function in DME steam reforming. Consequently, a moderate alkaline treatment (with a 0.2M NaH solution for 300 min) improves the kinetic behavior of the bifunctional catalyst as it enables to obtain high selectivity and yield of H_2 at temperatures (< 300 ºC) which are low enough to minimize the formation of byproducts (hydrocarbons) and CO and deactivation by Cu sintering.

1. Introduction

Hydrogen fuel cells are presented as an efficient and environmentally friendly power generator applicable to both mobile and stationary use (Funagnawakj et al., 2007). Although hydrogen has a high fuel density, it is difficult to handle. Therefore it is necessary to use a hydrogen vector like ethanol, gasoline, diesel and methane. However, the reforming of these fuels requires high temperature, which means that carbon deposit formation and catalyst poisoning by sulphur must be borne in mind (Semelsberger et al., 2005).

Over the last few years, there has been significant interest in methanol steam reforming. However, dimethyl ether (DME) steam reforming is a more promising alternative for hydrogen production than methanol steam reforming, given that DME synthesis from syngas is more profitable and, moreover, CO_2 can be added in the feed together with the syngas (Aguayo et al., 2007). Furthermore, DME is relatively inert, non-corrosive, non-carcinogenic and can be stored and handled as LPGs. DME has also attracted increased attention as a clean fuel. An interesting review of the advantages of DME has been published recently (Semelsberger et al., 2006).

Steam reforming of DME consists of two steps in series (Tanaka et al., 2005): DME hydrolysis (Eq. (1)) upon an acid function, and methanol steam reforming (Eq. (2)) upon a metallic function.

$$(CH_3)_2O + H_2O \leftrightarrow 2CH_3OH \quad (1)$$

$$CH_3OH + H_2O \leftrightarrow 3H_2 + CO_2 \quad (2)$$

$$(CH_3)_2O + 3H_2O \leftrightarrow 6H_2 + 2CO_2 \quad (3)$$

Besides DME SR, reverse water gas shift reaction (r-WGSR) (Eq. (4)) generally takes place over metallic catalysts in the reforming process. In addition, methane is also

* Corresponding author. Tel + 34-94-6015361. E-mail: jvicente003@ikasle.ehu.es

generated via DME decomposition (Eq. (5)) when strong acidic catalyst or high reforming temperatures are used (Faungnawakij et al., 2007).

$$CO_2+H_2 \leftrightarrow H_2O + CO \quad (4)$$

$$(CH_3)_2O \rightarrow CH_4 + H_2 + CO \quad (5)$$

Finally, conversion of methanol and dimethyl ether to hydrocarbons (MTG process) (Eq. (6)) can take place at temperatures above 300 ºC over strong acid sites (Semelsberger et al., 2005), and a significant coking may occur on the catalyst surface due to dehydrogenation of the hydrocarbons formed (Eq. (6)) (Kawabata et al., 2006).

$$\text{Oxygenate} \rightarrow \text{hydrocarbons} \rightarrow \text{coke} \quad (6)$$

Consequently, suitable metallic and acid functions are required for attaining high DME conversion and high H_2 selectivity. Cu based catalysts are well known for their high activity for DME steam reforming (Badmaev and Snytnikov, 2008) and a commercial $Cu/Zn/Al_2O_3$ catalyst has been widely used as metallic function. Another important characteristic is the contact mode of the metallic and acid functions. Kawabata et al. (2006) reported that composite materials showed better activity than separate loading and mechanically mixed loading of acid and metallic functions.

The selection of the acid function is essential for the development of catalysts for DME steam reforming, given that hydrolysis is the process limiting step and MTG reactions must be avoided. γ-Al_2O_3 is the more commonly used acid function in the literature for DME steam reforming (Takeishi and Suzuki, 2004), but due to its very low acidity, high temperatures (> 400 ºC) are required for attaining high conversion, and sintering of the metallic function based on Cu may be considerable at these temperatures. As an alternative, the use of zeolites such as ZSM-5 has been proposed (Semelsberger et al., 2006), but due to their excessive acidity, they give way to hydrocarbon formation.

In this paper, a HZSM-5 zeolite has been subjected to an alkaline treatment in order to moderate its acidity (Alonso et al., 2007), with the aim of minimizing the formation of hydrocarbons in DME steam reforming. The severity of the treatment with alkali for maximizing the selectivity and yield of hydrogen has been determined.

2. Experimental

The bifunctional catalysts have been prepared by (wet) physical mixture of equal mass proportions of the metallic function $Cu/ZnO/Al_2O_3$ (a commercial catalyst for methanol steam reforming supplied by Süd-Chemie) and different acid functions; pure HZSM-5 zeolite (SiO_2/Al_2O_3=30 supplied by Zeolyst) and zeolites modified by different alkaline treatments. The homogeneous mixture obtained was dried in air for 12 h, pressed, crashed and sieved to a particle size between 0.15-0.25 mm.

The alkaline treatments have consisted of mixing at 80 ºC the ammonium ZSM-5 zeolite with a NaOH solution of different concentration (0.2 or 0.4 M) for different times (10 or 300 min). The sodium ZSM-5 zeolites obtained have been ion-exchanged with ammonium nitrate solution, and subsequently washed and dried in air for 24h. All the zeolites have been calcined at 575 ºC for 2 h. The parent zeolite has been called Z30 and the treated zeolites A02T10, A02T300 and A04T300, where the number following A refers to the concentration of the NaOH solution and the number following T denotes the duration of the treatment.

The porous structure of the zeolites has been measured by N_2 adsorption using a Micromiretics ASAP 2010 instrument. Before the measurements, samples were degasified under vacuum at 150 ºC for 10h.

Total acidity and the acid strength distribution of the zeolites have been measured by calorimetric measurements of differential adsorption of ammonia and subsequent temperature programmed desorption (TPD) of NH_3, which have been carried out in a Setaram TG-DSC 111 calorimeter connected on-line to a Balzers Omnistar mass

spectrometer. After degasing the zeolite sample (1h in He stream at 500 ºC), it has been cooled to 150 ºC, an ammonia stream (10 μl/min) has been introduced by means of a syringe until saturation of the sample and finally the sample has been swept with He at 150 ºC in order to desorb physisorbed ammonia. The ratio between the continuous signals corresponding to heat flow and to weight change obtained during the ammonia adsorption step provides a measurement of the acid strength distribution, whereas the total amount of chemically retained base corresponds to the total acidity of the sample. Subsequently the TPD of ammonia has been carried out by heating the sample at 5 ºC min^{-1} to 550 ºC and the mass corresponding to desorbed ammonia has been registered in the mass spectrometer.

The nature of the sites (Bronsted or Lewis) has been determined by FTIR spectroscopy (Nicolet 6700 spectrometer provided with a Specac catalytic chamber) of adsorbed pyridine. After subjecting the finely ground sample to high vacuum at 400 ºC for 30 min temperature has been stabilized at 150 ºC and successive pyridine pulses have been injected until saturation of the sample, which has been subsequently subjected to vacuum at 150 ºC for 1 h to eliminate physisorbed pyridine, and the corresponding spectrum has been recorded. Brosnsted/Lewis ratio has been determined by integration of the bands at 1545 and 1450 cm^{-1} and taking into account the molar extinction coefficients of both adsorption bands (Emeis, 1993).

The kinetic runs have been carried out in automated reaction equipment provided with an isothermal fluidized-bed reactor with 22 mm of internal diameter connected on-line to a MicroGC Agilent 3000 for product analysis. The hydrodynamic properties of the bed have been improved by mixing the catalyst (particle size between 150 and 250 μm) with inert alumina (particle size between 60 and 90 μm) in a catalyst/inert ratio of 1/4. The operating conditions were: atmospheric pressure, steam/DME/He ratio= 3/1/0.85, space time up to 0.60 $g_{catalyst}h/g_{DME}$, temperature between 225-325 ºC. Prior to the catalytic runs, the catalyst was reduced using 10% H_2 in He at 300 ºC for 2 h with a total flow rate of 60 ml min^{-1}.

DME conversion and selectivity and yield of H_2 and CO have been calculated as follows:

$$X_{DME} = \frac{F_{DME,0} - F_{DME}}{F_{DME,0}} \quad (7)$$

$$S_i = \frac{F_i \cdot \upsilon_i^{-1}}{F_{DME,0}} \quad (8)$$

$$Y_i = X_{DME} \cdot S_i \quad (9)$$

where F_i is the molar flow of component i, which is evaluated from its molar fraction (calculated from chromatographic results) and the total molar flow (determined by atomic balances of H, C and O), υ is the stechiometric coeficient of the component i produced in DME SR, and the subscript 0 denotes the initial molar flow.

3. Results and discussion

3.1. Characterization of the zeolites

Table 1 shows the BET surface area, total pore volume, micropore volume and mean pore diameter of the acid functions. All the zeolites have high surface area due to their microporosity. However, increasing the severity of the alkaline treatment the surface area and the micropore volume are reduced, whereas the pore volume and the mean pore diameter are increased. Therefore, the alkaline treatment affects the porous structure of the zeolite leading to an increase in the mesoporous surface area.

Table 1 also shows the B/L ratio of the zeolites. As observed, a moderate alkaline treatment increases the B/L ratio, which is evidence that alkali attacks Lewis sites to a greater extent than Bronsted sites. Furthermore, a severe treatment lowers the B/L

ratio, which is a consequence that, under severe conditions, weak Bronsted sites (together with strong sites) are also affected by the alkali.

Table 1. Physic properties of the zeolites and B/L ratio.

	Z30	A02T10	A02T300	A04T300
BET surface area ($m^2\ g_{cat}^{-1}$)	430	387	413	358
Micropore volume ($cm^3\ g_{cat}^{-1}$)	0.134	0.118	0.121	0.093
Pore volume ($cm^3\ g_{cat}^{-1}$)	0.258	0.317	0.412	0.585
Mean pore diameter (nm)	40.8	67.6	71.9	103.6
$B/L^{150ºC}$	1.83	2.23	1.93	1.44

Figure 1 illustrates the effect of the alkaline treatment on the acid strength and total acidity of the zeolites. Graph (a) shows the acid strength distribution and total acidity obtained in the differential adsorption of NH_3 at 150 ºC, whereas graph (b) corresponds to the results of TPD of NH_3. It is observed that the alkaline treatment attenuates both total number of acid sites (which decreases from 0.92 mmol of NH_3/(g of zeolite) for the parent zeolite to 0.68 mmol of NH_3/(g of zeolite) for the catalyst that has been more severely treated with alkali). This treatment also affects the acid strength of the sites (which has a predominant value of 135 kJ/(mol of NH_3) for the untreated zeolite and decreases to 115 kJ/(mol of NH_3) for the more severely treated catalyst). The results of TPD show that the strong acid sites (desorption peak at 420 ºC) are the more affected by a moderate alkaline treatment, whereas a severe treatment affects both strong and weak sites (desorption peak at 250 ºC), with strong sites being affected to a greater extent.

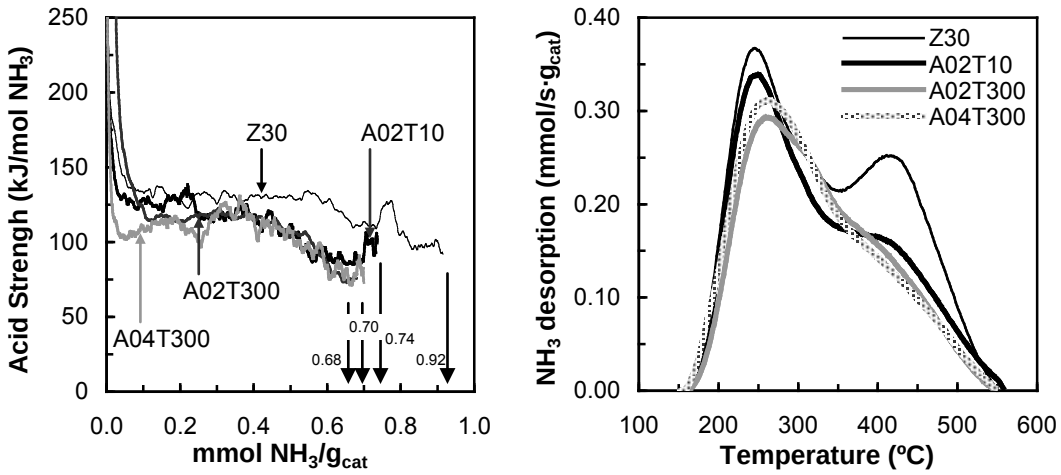

Figure 1. Acidic strength distribution and total acidity (a) and TPD of ammonia (b) for the parent HZSM-5 zeolite and for zeolites subjected to alkaline treatment

3.2. The effect of the acid function in the DME steam reforming

Figure 2 shows the results of initial DME conversion (left) and yields of hydrogen and CO (right) for different operating conditions at zero time-on-stream. The conversion and yield of H_2 with the Z30 zeolite catalyst are slightly higher than with the treated zeolites, as would be expected taking into account its higher acidity. Nevertheless, the yield of CO with this catalyst is significantly higher than with the modified zeolites.

For the catalysts of pure zeolite or zeolite subjected to a moderated alkali treatment (A02T10 or A02T300), the maximum yield of H_2 is obtained at 300 ºC, and the subsequent decrease in H_2 production at 325 ºC is due to the rapid formation of hydrocarbons from methanol and DME (MTG process).

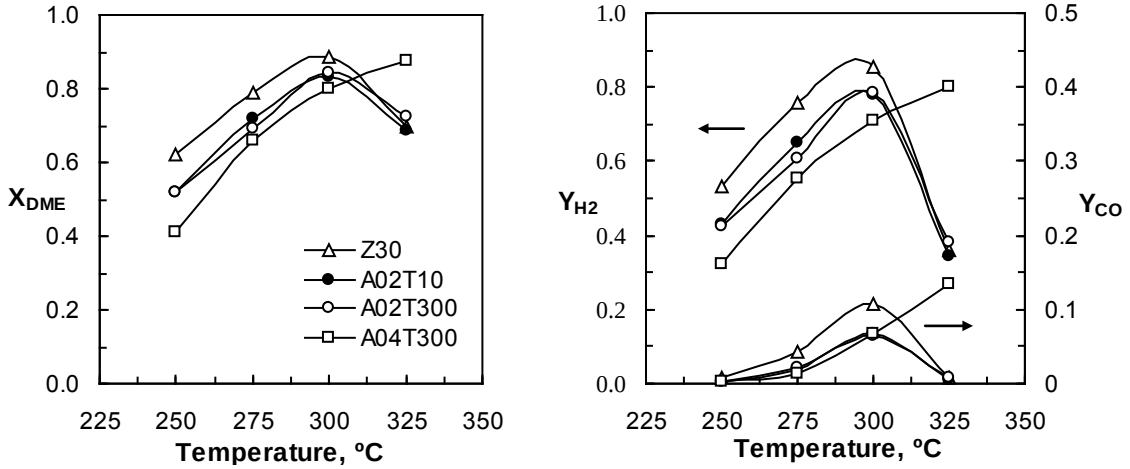

Figure 2. Conversion of DME (left) and yield of H_2 and CO (right) in DME steam reforming for the catalysts prepared with the different acid functions. Space time= 0.60 $g_{catalyst}h/g_{DME}$; steam/DME= 3/1; 1 atm.

In order to explain more clearly the differences in the kinetic behaviour above 300 ºC, Figure 3 shows the evolution with time of the molar fraction of byproducts (hydrocarbons) at different temperatures. None of the catalysts based on zeolites favours the MTG reactions under 300ºC. At 300 ºC this reaction only takes place with the catalyst based on Z30, although an induction period is needed (Aguayo et al., 2005). At 325 ºC the formation of hydrocarbons is fast for the catalyst based on Z30, but requieres an induction period for the catalysts based on treated zeolites, whose duration significantly increases with alkaline treatment severity (consistent with the decrease in acidity). The catalyst based on A04T300 zeolite (severe alkaline treatment), avoids hydrocarbons formation in the whole range of temperature studied. Nevertheless, the higher temperature required for attaining high DME conversion using A04T300 catalyst favours a higher formation of CO by reverse water-gas shift reaction.

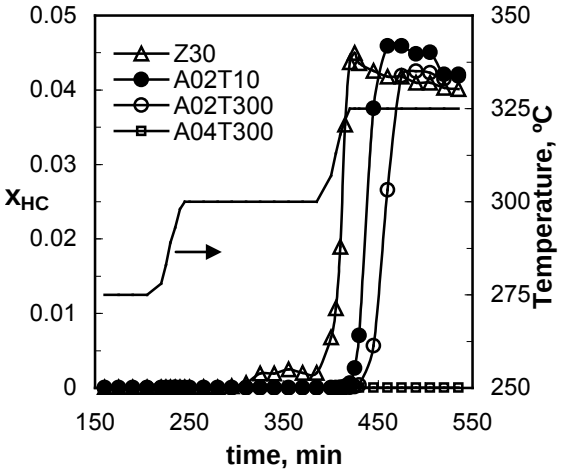

Figure 3: Evolution with time and temperature of the molar fractions of the hydrocarbons produced from oxygenates in DME SR.

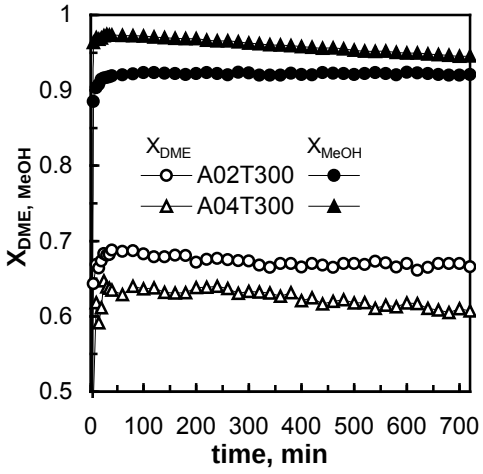

Figure 4. Evolution with time of DME and methanol conversion during DME steam reforming over catalysts A02T300 at 300 ºC and A04T300 at 325 ºC.

Moreover, catalyst deactivation by Cu sintering will also be higher due to the higher temperature required for obtaining high DME conversion with A04T300 catalyst. Thus, in a long duration run (Figure 4) carried out with a space time of 0.30 $g_{catalyst}h/g_{DME}$ at

300 ºC with A02T300 catalyst, DME conversion decreased from 0.687 to 0.666 subsequent to 12 h, whereas the conversion of DME decreased from 0.643 to 0.608 in the same period of time when the run was carried out with the same value of space time at 325 ºC and using A04T300 catalyst.

4. Conclusions

A moderate alkaline treatment (with a 0.2 M NaOH solution during 300 min) is suitable for modifying the HZSM-5 zeolite in order to use as an acid function for DME steam reforming. This moderate alkaline treatment slightly moderates the acidity of the zeolite, which allows for obtaining high H_2 selectivity and yield at temperatures that are low enough to minimize the formation of byproducts (hydrocarbons) and CO and deactivation by Cu sintering.

Keywords: Biodiesel, Group contribution method, CPA EoS, Water solubility
Topic: Systematic methods and tools for managing the complexity.

Abstract

Due to the continuous increase in crude oil prices, limited resources of fossil energies and environmental concerns, biodiesel (a blend of fatty acid esters) is being considered as a good alternative to conventional diesel for road transportation.

During biodiesel production several aspects need to be considered to insure fuel quality. One of the most important is the water content. Up to now, little information was available about the water solubility in esters and commercial biodiesels. To overcome this lack of data, solubility measurements were carried out for 11 esters and 6 biodiesels. Simultaneously, mutual solubility measurements were made for 6 fatty acid (C_5-C_{10}) + water systems. This new experimental data was used to support the development of a group contribution version of the Cubic plus Association (CPA) equation of state, that can adequately predict water solubility in fatty acids, esters and biodiesel mixtures, required for a correct design of the biodiesel washing and purification processes.

1 Introduction

The most commonly used method to produce biodiesel is the transesterification of vegetable oils and animals fats with monohydric alcohols, using a homogeneous basic catalyst such as NaOH. As, chemically, biodiesel is different from conventional diesel, the European Committee for Standardization (CEN) developed quality standards specifying minimum requirements and test methods for biodiesel to be used in diesel engines and for heating purposes, in order to increase the biodiesel quality and its acceptance. One of these quality values is the water content, that the DIN EN 14214:2003 limits below 0.05% (w/w).

Water is introduced into biodiesel during production and may remain in it if the drying procedure is not efficient. It can also be absorbed during storage, since fatty acid esters are hygroscopic, making biodiesel much more hydrophilic than regular diesel. Water in biodiesel affects its calorific value and, above all, the shelf life of the fuel (lower oxidation stability).

During biodiesel production the fatty esters rich current leaving the reactor is saturated with glycerol, alcohol, catalyst and unreacted soaps. This current is washed in a liquid-liquid extractor in counter current with acidified water to neutralize the catalyst and to convert soaps to free fatty acids. The raffinate current is composed of water saturated biodiesel while the extract is a low pH aqueous solution containing the polar compounds. The design and optimization of the purification of biodiesel with water thus requires a model that can describe this phase equilibria.

To overcome the inability to apply equations of state in the absence of pure component data

and to reduce the amount of experimental work and related costs, it is useful to develop predictive thermodynamic models based on group contributions.

When water is involved, association equations of state are needed, since the general cubic equations of state such as SRK and PR EoS are not able to take into account the association between molecules of water and alcohol or the solvation between esters and water. Among these associating equations there is the Cubic plus Association equation of state (CPA EoS) that combines the SRK cubic contribution for describing the physical interactions with the association contribution proposed by Wertheim. CPA has previously shown to be able to provide an accurate description of the phase equilibria of aqueous mixtures with n-alkanes, aromatics, fluorocarbons, alcohols and glycols.

One of the goals of this work is to create a new group contribution model for the Cubic plus Association equation of state (CPA EoS), combining the good description of this equation to represent associating systems with the predictive character of a group contribution method.

2 Experimental Section

Water solubility measurements were carried out at 288.15 - 323.15 K and atmospheric pressure. The organic and water phases were agitated and allowed to reach equilibrium by the separation of both phases in 20 mL glass vials for at least 48 h. This period proved to be the minimum to guarantee a complete separation and no further variations in solubilities.

Temperature was maintained by keeping the vials inside an aluminium block, placed in an isolated air bath (± 0.01 K). Temperature control was achieved with a PID controller driven by a calibrated Pt100 sensor. To reach temperatures below room temperature, a Julabo circulator, model F25-HD, was coupled to the overall oven system.

Water solubilities in the ester or acid rich phases were determined using a Metrohm 831 Karl Fischer (KF) coulometer.

The organic phase was sampled at each temperature from the equilibrium vials using glass syringes maintained dry and at the same temperature of the measurement. Samples of 0.1 to 0.2 g were taken and injected directly into the KF coulometric titrator.

For pentanoic and hexanoic acids, measurements of the phase envelope for the two phase region were made by turbidimetry. Several samples covering the entire concentration range were prepared. The mixture was heated inside a closed glass tube in a thermostatic bath up to the one phase region. On slowly cooling, the phase separation temperature was registered. The temperature assigned to the phase envelope is an average of five measurements.

3 Model

The CPA equation of state, in terms of the compressibility factor, is given by:

$$Z = Z^{phys.} + Z^{assoc.} = \frac{1}{1-b\rho} - \frac{a\rho}{RT(1+b\rho)} - \frac{1}{2}\left(1+\rho\frac{\partial \ln g}{\partial \rho}\right)\sum_i x_i \sum_{A_i}(1-X_{Ai}) \quad (1)$$

where a is the energy parameter, b the co-volume parameter, ρ is the density, g a simplified hard-sphere radial distribution function, X_{Ai} the mole fraction of pure component i not bonded at site A and x_i is the mole fraction of component i.

X_{Ai} is related to the association strength Δ^{AiBj} between sites belonging to two different

molecules and is calculated by solving the following set of equations (2):

$$X_{Ai} = \frac{1}{1+\rho\sum_j x_j \sum_{B_j} X_{Bj}\Delta^{A_iB_j}} \quad (2) \qquad \Delta^{A_iB_j} = g(\rho)\left[\exp\left(\frac{\varepsilon^{A_iB_j}}{RT}\right)-1\right]b_{ij}\beta^{A_iB_j} \quad (3)$$

where ε^{AiBj} and β^{AiBj} are the association energy and the association volume, respectively.

For non-associating components, such as n-esters, CPA has three pure component parameters (a_0, c_1 and b) while for associating components like water and organic acids it has five (a_0, c_1, b, ε, β). These parameters are estimated by a simultaneous regression of vapour pressure and liquid density data. To overcome the inability to apply this approach in the absence of density and vapour pressure data, a group contribution method was developed (Oliveira et al. (2008)). This method may be applied as a predictive tool for the following families: n-alkanes, n-alcohols, saturated and unsaturated fatty acid esters and fatty acids.

The development of the group contribution scheme started with the definition of the groups. The chemical groups adopted as suitable for the description of these compounds were: (CH_3), (CH_2), (OH), (COO), (HCOO), (COOH), and (CH=).

The CPA pure component parameters are thus calculated from the following relations:

$$a_0 = k_1 \times \left(\ln\left(k_2 + \sum_{i=1}^{n_{groups}} n_i a_{0i}\right)\right)^{k_3} \quad (4) \qquad c_1 = k_1 \times \left(\ln\left(k_2 + \sum_{i=1}^{n_{groups}} n_i c_{1i}\right)\right)^{k_3} \quad (5)$$

$$b = \sum_{i=1}^{n_{groups}} n_i b_i \quad (6) \qquad \beta = k_1 + k_2 \exp(-k_3 \sum_{i=1}^{n_{groups}} n_i \beta_i) \quad (7) \qquad \varepsilon = \sum_{i=1}^{n_{groups}} n_i \varepsilon_i \quad (8)$$

In these equations, subscript i refers to a specific structural group, n_i is the number of structural groups of type i, and n_{groups} is the total number of structural groups in the molecule. The parameters a_{0i}, c_{1i}, b_i , ε_i, and β_i are the values of the parameter related to each group i. These values, along with the constants for each equation, are reported in **Table 1**.

Table 1. Group contribution parameters for the CPA EoS and constant values for equations 4, 5 and 7.

	Group Parameters									
Parameter	**CH_3**	**CH_2**	**OH**	**HCOO**	**COO**	**C=**	**COOH**	**k_1**	**k_2**	**k_3**
a_o	13.787	6.884	13.218	16.8781	11.025	8.443875	27.124	1.69E-04	-3.349	6.953

∗For the unsaturated methyl esters with more than one double bound, a correction factor should be added when calculating c_1:

$$k_1 \times \left(\ln\left(k_2 + \sum_{i=1}^{n_{groups}} n_i c_{1i} + 1.269\right)\right)^{k_3}$$

4 Results and discussion

In order to compare the performance of the proposed group contribution approach, CPA parameters were initially regressed for compounds for which there were vapor pressure and liquid density data. This will be hereafter callled the “usual approach”.

While using the “usual approach” for obtaining the pure component parameters, an excellent description of vapour pressure and liquid densities was achieved for 42 esters and 20 organic acids, covering the range of reduced temperatures from 0.45-0.85, with global average deviations of about 2% for both properties. Although the GC parameters were very similar to the “usual approach” ones, generally, the quality of the pure component vapour pressure estimates was significantly decreased, while in terms of liquid densities, a minor decrease in the description quality was observed.

Having the pure compound parameters, it was possible to model binary mixtures of water with several methyl, ethyl and propyl esters, and fatty acids. Solubility calculations were performed using both set of parameters: from the “usual approach” and from the group contribution model.

The cross-association (solvation) between the ester group and water was taken into account as previously done for aromatic hydrocarbons. Using this approach, both the binary interaction k_{ij} and the cross-association volume (β_{ij}) parameters are fitted to solubility data. As cross-association between water and esters will always occur between water and the ester group, the β_{ij} value was fixed to 0.20 for all ester + water systems, and the binary interaction parameters were then regressed using this value.

To obtain a good description of the mutual solubilities of water + fatty acids, the fitting of the k_{ij} parameter was also required. Calculations for fatty acids were performed initially using two different combining rules (CR-2 and CR-4), but it was found that for long chain esters the CR-4 combining rule gave the best results, as can be seen from **Table 2**.

A generalized linear correlation for the k_{ij} parameter was found with the chain length of the ester and the acid, C_n, when using the “usual approach” and the group contribution parameters, described, respectively by equations 9-12.

Usual approach Acids (CR-4)	$k_{ij} = -0.0142 \times C_n + 0.0020$	(9)
Usual approach Esters	$k_{ij} = 0.0136 \times C_n - 0.3322$	(10)
GC approach Acids (CR-4)	$k_{ij} = -0.0106 \times C_n - 0.040$	(11)
GC approach Esters	$k_{ij} = 0.0154 \times C_n - 0.3458$	(12)

With this single value of k_{ij} for each system, it was possible to describe the water solubility in fatty acid esters with a global average deviation of 7.0 % for both the “usual approach” and the group contribution approach parameters. For fatty acid + water systems, global average deviations lower than 30 % were obtained for the water solubility and lower than 6% for the acid solubility, with both approaches.

Values for the binary interaction parameters and average deviations are presented in **Tables 2** and **3**. Water solubility in two fatty acid esters and mutual solubilities for three fatty acid + water systems are presented, as examples, in **Figures 1** and **2**.

The proposed GC approach, while producing worst estimates for pure component vapour pressure, is as accurate as the approach with fitted parameters for the estimation of water solubilities in ester systems, and mutual solubilities of acid + water systems, and may even present lower global average deviations.

Using the group contribution approach and the linear correlation for the binary interaction parameters, the proposed model can be used as a predictive tool for more complex mixtures

such as biodiesels. Good results were obtained for the water solublity in biodiesels with both approaches with global average deviations of 15.5 % and 14.9 %, respectively, for the usual and the GC approach. Water solubility in one of the studied commercial biodiesels is depicted in **Figure 2**.

5 Conclusions

Using an equation of state for phase equilibria requires parameters that in the absence of pure component data are not possible to determine. In this work, a new group contribution method for the estimation of the pure compound parameters of the CPA EoS was developed. This new method was used to describe the water solubility in ester systems and the mutual solubilities of fatty acid + water systems and compared with the "usual approach" where these parameters are regressed from vapour pressure and liquid density data.

For both approaches a single, small, and temperature-independent k_{ij} was sufficient. The binary interaction parameters are chain length dependent making the model predictive.

It was possible to conclude that the proposed GC approach may lead to poorer vapour pressure estimates, but is as accurate as the "usual approach" for the estimation of water solubilities in ester systems, and mutual solubilities of fatty acids and water systems. For the majority of the binary mixtures, the results provided by GC parameters are even better than those with the parameters adjusted from vapour pressure and density data. Therefore, it is possible to conclude that the group contribution parameters take more information into account than the adjusted parameters, leading to improved liquid-liquid equilibria results.

The proposed model thus seems to be a promising tool for the biodiesel industry and future work will focus in extending this approach to other phase equilibria and systems of interest for biodiesel production and purification.

Suitable Topics: Process Systems Engineering, Wastewater Modeling and Simulation, Environmental Engineering.

Abstract

A single Plug Flow Reactor Network (PFRN) approach to modeling continuous wastewater treatment plants based on Sequential Batch Reactors (SBR) was developed. The simplified structure of PFRN makes this representation more suitable for stationary analysis and design purposes. New insights were obtained through the comparison of transient responses to typical industrial disturbances from both models (SBR and PFRN). Despite the different nature of SBR (lumped) and PFRN (distributed) models, they presented quite similar qualitative dynamic evolutions, and even their quantitative values were not so different. The similarities of the transient responses encourage the use of PFRN models to describe confidently the stationary as well as the dynamic behavior of real SBR plants, since the PFRN structure is considerably easier.

Introduction

The Sequential Batch Reactor (SBR) technology is widely used for biological wastewater (WW) treatments with carbon and nutrients removal purposes. This kind of technology can be applied to aerobic, anoxic, as well as to anaerobic processes (Artan and Orhon, 2005; Benitez et al., 2006). Figure 1 shows an example of a classic SBR process.

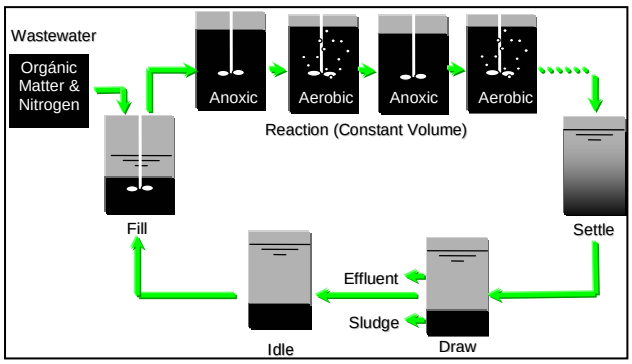

Figure 1: Typical SBR Configuration for Carbon and Nitrogen Removal

This process can be partitioned by two main role patterns: a Batch Reactor Network ("sequencing"), and a Feeding Pattern ("wastewater management"), as presented in Figure 2(a). Under steady state conditions, SBR compositions at the beginning and at the final of cycled operations are equal, and wastewater composition and flow rate are both maintained constant.

The main purpose of this contribution is to compare two models of a real multiple parallel SBR plant (applied to a continuous WW treatment): (i) Batch Reactor Network/Feeding

Pattern; (ii) Plug Flow Reactor Network (PFRN) (Artan and Orhon, 2005). Diagrams of the structures of both models are presented in Figure 2.

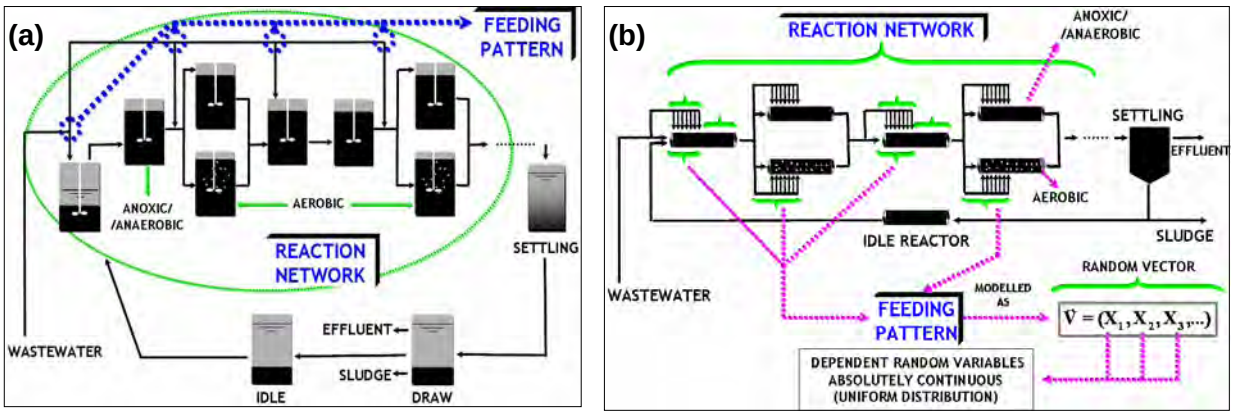

Figure 2: SBR representations: Batch Reactor Network/Feeding Pattern (a) and PFRN (b)

The simplified structure of the PFRN, in comparison with the multiple parallel SBR representation, makes this model more adequate for design purposes and stationary analysis. New insights of both approaches can be obtained comparing their dynamic simulations. Very few papers related with the dynamic behavior of this kind of equipment can be found in the open literature.

A comparison of dynamic responses of SBR and PFRN structures, when submitted to step changes in feed wastewater flowrate and composition, is presented in this paper. This kind of perturbation occurs typically in real industrial processes.

Mathematical Modeling and Applied Numerical Methods

SBR Model

The dimensionless transient component *i* mass balance (incompressible fluid) applied to the multiple parallel SBR representation is presented below:

$$\frac{dc_i(t)}{dt} = Fe_{SBR} \cdot \frac{q(t)}{v(t)} \cdot \left[c_{f,i}(t) - c_i(t) \right] - Da_i \cdot r_i \left[\mathbf{c}(t) \right]$$

Where:

- c_i: Dimensionless component *i* concentration;
- $c_{f,i}$: Dimensionless component *i* feed concentration;
- t : Dimensionless time variable;
- q: Dimensionless wastewater flow rate;
- v: Dimensionless reactor volume;
- r_i: Dimensionless component *i* consumption rate;
- Da_i : Damköhler number (dimensionless) for component *i*;
- Fe_{SBR} : Dimensionless feeding number;
- $\mathbf{c}$: Column vector of the dimensionless concentration of all components.

The lumped nature of SBR process model is characterized by the ordinary form of the differential equation system above.

PFRN Model

The dimensionless transient component *i* mass balance (incompressible fluid) applied to the plug flow reactor network (PFRN) is presented below:

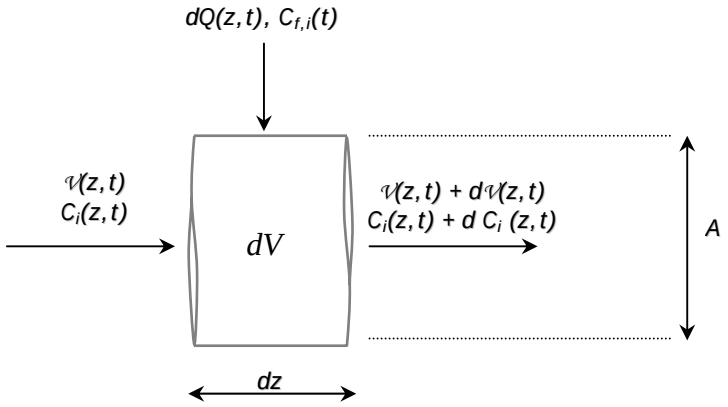

Figure 3: PFRN Control Volume

$$\frac{\partial c_i(z,t)}{\partial t} + v(z,t)\frac{\partial c_i(z,t)}{\partial z} = Fe_{PFRN} \cdot q(z,t) \cdot \left[c_{f,i}(t) - c_i(z,t)\right] - Da_i \cdot r_i\left[\boldsymbol{c}(z,t)\right]$$

Where:

- c_i: Dimensionless component *i* concentration;
- $c_{f,i}$: Dimensionless component *i* feed concentration;
- z : Dimensionless axial space variable;
- t : Dimensionless time variable;
- q: Dimensionless wastewater flow rate;
- v : Dimensionless interstitial flow rate;
- r_i: Dimensionless component *i* consumption rate;
- Da_i : Damköhler number (dimensionless) for component *i*;
- Fe_{PFRN} : Dimensionless feeding number;
- $\boldsymbol{c}$: Column vector of the dimensionless concentration of all components.

The distributed nature of PFRN process model is characterized by the partial form of the differential equation system above. This equation was spatially discretized by an implicit finite difference method resulting in the system of *N* ordinary differential equations:

$$\frac{dc_i^{(j)}(t)}{dt} + \upsilon^{(j)}(t)\frac{c_i^{(j)}(t) - c_i^{(j-1)}(t)}{\Delta z} = Fe_{PFRN}.q^{(j)}(t).\left[c_{f,i}(t) - c_i^{(j)}(t)\right] - Da_i.r_i\left[c^{(j)}(t)\right]$$

Where:

- $c_i^{(j)}(t) = c_i(z_j, t)$: Dimensionless component *i* concentration at z_j;
- $c^{(j)}(t) = c(z_j, t)$: Column vector of the dimensionless concentration of all components at z_j;
- z_j : Dimensionless value of the axial space variable at node *j* (*j* = 1, 2,…*N*).

Numerical Methods

The ordinary differential equations of both mathematical models were solved using an adaptive 4th order Runge-Kutta method.

Operational Conditions and Simulation Parameters

The Table 1 summarizes the plant conditions adopted in our simulations. These conditions were obtained from a typical real dairy SBR plant (milk powder plant).

Table 1: Operational data and simulation parameters for the dairy SBR plant

WW Steady State Composition & Flow Rate	3000 mgChemical Oxygen Demand(COD_{Total})/L - 100mgTotal Kjeldhal Nitrogen(TKN)/L - 100mgN-NO_3^-/L & 1500 m^3/d (Buitron et al., 2008)		
Effluent Steady State Composition	2.5 mg$COD_{Soluble}$/L – 0 mgTKN/L – 0.9 mgN-NO_3^-/L		
SBR's in Parallel // Cycle Period // Total Cycles by Day	2 // 24 hs. // 2		
SBR Sequencing (each cycle) (Idle Time ~ 0)	Stage 1: Anoxic Fill 5.5hs	Stage 2: Aerobic Fill 2hs	Stage 3: Anoxic Fill 4.5hs
	Stage 4: Aerobic 1.7hs	Stage 5: Settling 9.3 hs	Stage 6: Draw (effluent & sludge) 1 h
Initial // Maximum Volume (each SBR)	4000 m^3 // 4750 m^3		
Initial Biomass Content // Biomass Residence Time	3000 mgVolatile Suspended Solids (VSS)/L // 18 days		
Dissolved Oxygen (DO) Content	Not limiting (DO > 3 mgO_2/L)		
Kinetic Modelling	Based on ASM1 Model [Aerobic Carbon Removal & Denitrification Processes] (Orhon and Artan, 1994; Buitron et al., 2008)		
Dynamic Test 1: WW Composition Step Change to:	6000mgCOD_{Total}/L - 200mgTKN/L - 200mgN-NO_3^-/L		
Dynamic Test 2: WW Flow Rate Step Change to:	3000 m^3/d		

The kinetic modelling description considered in the simulations is summarized in Appendix 1. Autotrophic processes extent in the system (nitrification) is neglected due to the high wastewater COD_T/TKN ratio.

The effluent steady state composition, the initial reactor volume (analogy with the interstitial flow rate in PFRN) and the initial biomass content showed in Table 1 represent the initial (SBR) and boundary (PFRN) conditions employed for the steady state simulations.

Results and Discussion

Dimensionless Numbers

The Feeding and Damköhler number calculations for both developed structures are shown in Table 2.

Table 2. Dimensionless Number Values

Parameter	Name	Value
Fe	Feeding	0.312
Da_{Sc}	Damköhler for Organic Matter	1.67
Da_{SNO}	Damköhler for Nitrate	4.04
Da_{XH}	Damköhler for Biomass	0.65

It must be pointed out that same values of dimensionless parameters were considered in SBR and PFRN models. This has been done to reinforce the existing analogy between the models.

Steady State Simulations

Figure 4 shows the stationary composition profiles obtained for SBR and PFRN structures considering the values listed in Table 1. The results presented show that the stationary composition profiles of both models are quite similar. However, comparing SBR and PFRN responses, larger profile difference occurs for nitrate profile, during the initial stage of the process (low time/position values). As can be verified in Table 2, nitrate Damköhler number is larger than organic matter and biomass Damköhler numbers. This fact is a possible explanation to the nitrate profiles difference. Regardless of this, it must be pointed out that these differences are unimportant from an industrial point of view. Besides, the final effluent composition results at draw stage (the most important quality parameter of the system) in both models are practically the same.

The results obtained confirm the analogy between SBR and PFRN models during steady state conditions.

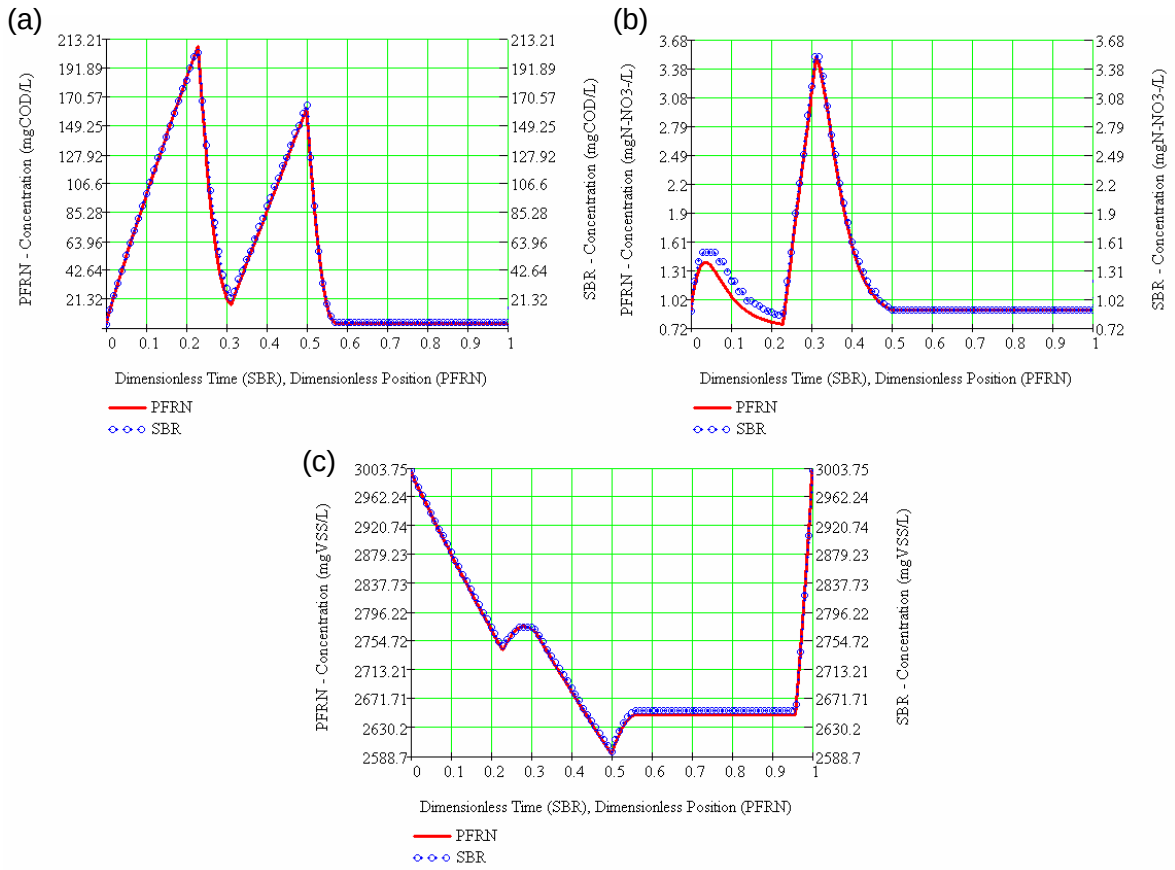

Figure 4: SBR and PFRN Steady State Results: Organic Matter (a), Nitrate (b) and Biomass (c) profiles

Dynamic Simulations

The dynamic response profiles for effluent composition for both models (Table 1) are shown in Figure 5 and Figure 6. All the simulations were made during a real total transient time of eight days. This value was adopted considering a realistic time scale of industry processes. Further details related with the dynamic simulations are presented in Appendix 2.

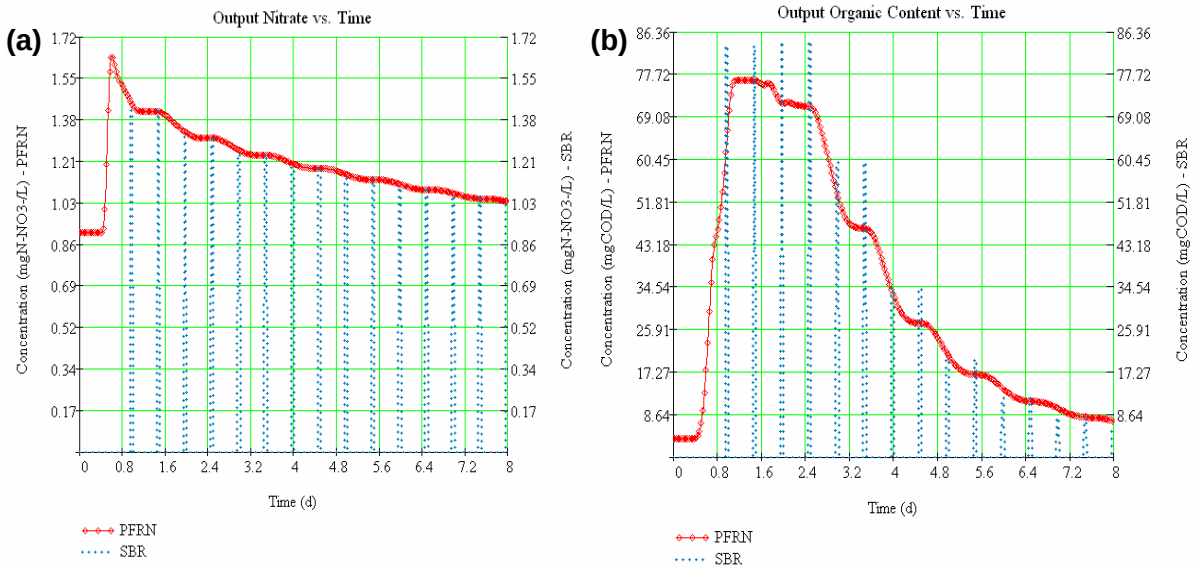

Figure 5: Simulation results for effluent composition during Test 1: Nitrate (a) and Organic Content (b) evolution

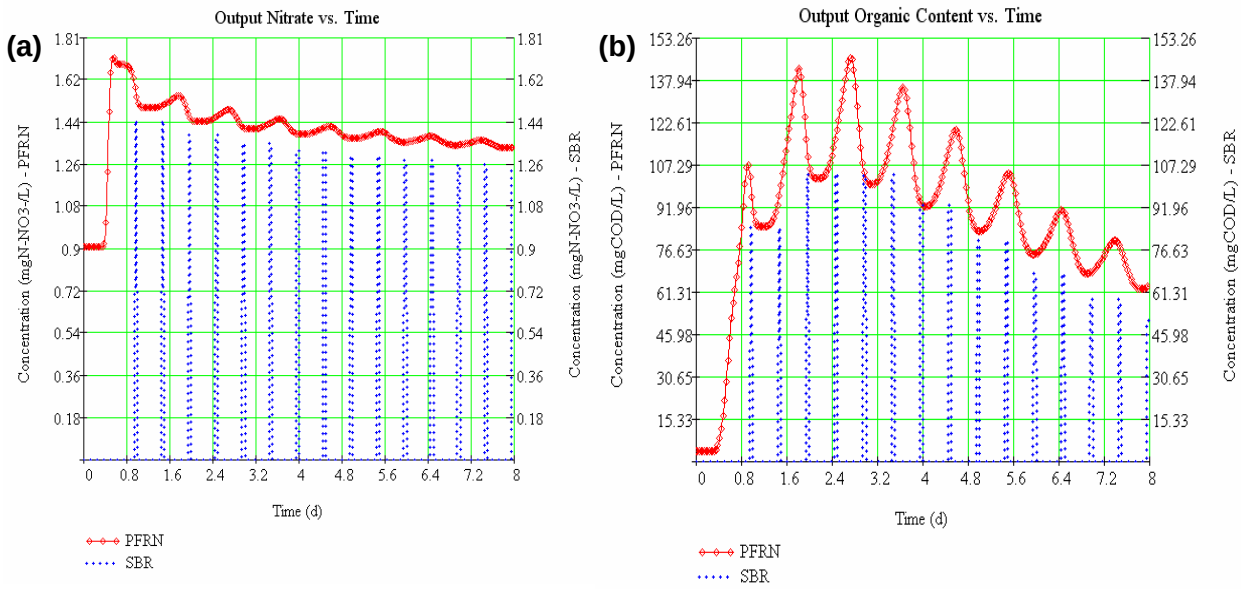

Figure 6: Simulation results for effluent composition during Test 2: Nitrate (a) and Organic Content (b) evolution

These results show that, despite the different nature of SBR (lumped) and PFRN (distributed) dynamic models, the qualitative dynamic evolutions are quite similar, and even their quantitative values are not so different if they compare with the corresponding WW composition (Table 1).

These observations can be very useful for industrial purposes, because, despite PFRN represents an easier handling model than SBR (multiple parallel plants), in real WW treatment processes high accuracy is not normally of special interest.

Conclusions

The well known analogy of the SBR and PFRN stationary models were also verified in this contribution. New insights were obtained through the comparison of transient responses to typical industrial perturbations of both models. Qualitative and quantitative aspects of both dynamic responses were analysed. The similitudes of the dynamic responses encourage the use of PFRN models to describe confidently the stationary and dynamic behavior of real SBR plants (industrial scale). Dynamic optimization of real SBR plants using the PFRN approach is a work in progress by the authors.

Systematic Modelling Framework in Product-Process Design and Development

Ricardo Morales-Rodríguez[1], Rafiqul Gani[1*]
[1] CAPEC-Department of Chemical and Biochemical Engineering, Technical University of Denmark, DK-2800 Lyngby, Denmark.

Keywords: Product Design, process design, work-flow, multi-scale modelling.
Topic: Systematic methods and tools for managing the complexity — see Process synthesis & design.

Abstract

One way to achieve success in product-process design/development is first to identify the end-use properties of a product and then to match product quality by controlling the structure, shape, odor, color, etc, of the chemical species. Usually, many repetitions of experiments need to be performed with asociated high expenses of time and material resources to find an acceptable design. A computer-aided modelling framework for product-process design is proposed as an alternative, where some of the tasks related to product-process design can be performed efficiently and systematically through an integrated set of computational tools. The application of a model-based framework specially developed for product-process design is illustrated through a case study involving the design and evaluation of a microcapsule for controlled release of active ingredients.

1 Introduction

The design, development and manufacture of a product and its process need to be consistent with the end-use characteristics of the desired product. One of the common ways to achieve the desired characteristics of the product-process is through trial and error based experiments. Although it is the most commonly used practice, it can be expensive and time consuming. An alternative approach is the introduction of a systematic model-based framework consisting of established work-flows in product-process design. In this way, some of the time consuming and/or repetitive experimental steps can be replaced with the use of reliable computational tools.

The appropriate set of models and the model-based framework for product-process design need to have multi-scale modelling features as the properties defining the chemical structure and end-use characteristics of the product are dependent on parameters of different size and time scale. The advantages of the use of multi-scale modelling approach is that the design, development and/or manufacturing of a product-process can be described at different scales of length and time, providing thereby the knowledge of the applied phenomena at diverse degrees of abstractions and details. Charpentier (2002), Gani (2004), Klatt and Marquardt (2007) and Charpentier (2007) have highlighted the importance of the multi-scale and multidiciplinary approach in product-process design and identified design issues related to different scales of size, time and complexity.

In this paper, the development and use of a model-based a framework for systematic product-process design using established work-flows is proposed. This framework will allow the design of the product-process through a set of computer-aided modelling tools by guiding

* Corresponding author. Tel + 45-4525-2882. E-mail: Rag@kt.dtu.dk

the user through the calculation steps to determine the desired product-process. Although the method and tools are generic, their application is highlighted in this paper to a class of formulated chemical products. The performance of the model-based framework, the associated models and the work-flow for a specific product-process design is illustrated through a case study involving the modelling and design of the release of a formulated pesticide product through a polymeric microcapsule. Product design, in this case, involves the design of the microcapsule and its contents (the active compound, the membrane used for the microcapsule, solvents, additives, release medium, etc.). Process design and modelling, in this case, involves the the simulation of the release of the active ingredient through the microcapsule, that is, evaluation of the product performance.

2 Development of Framework for product-process design

The framework for chemical product-process design is shown in figure 1 where chemical product-process design pathway has four main section embedded within the model-based framework:

i) Problem Definition
ii) Product Design
iii) Product-Process Modelling
iv) Product-Process Evaluation

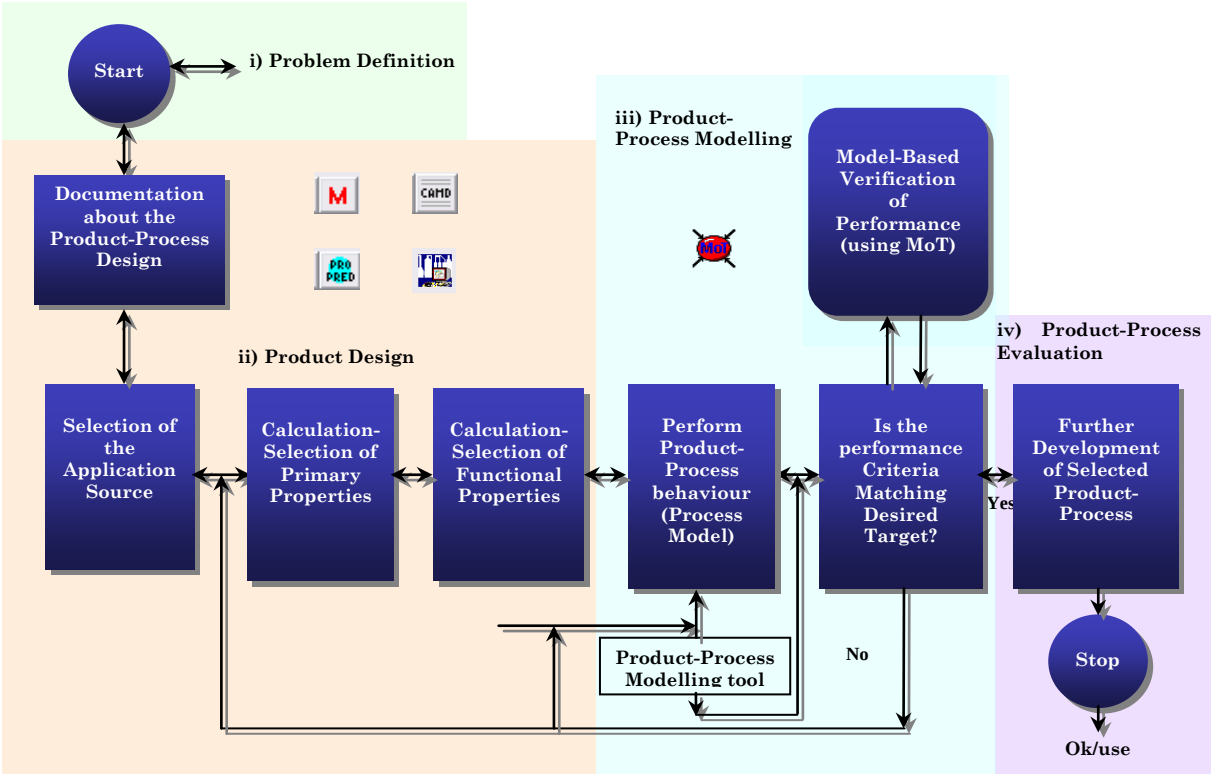

Figure 1. Systematic modelling Framework for chemical product-process design

For any chemical product-process design problem, the model-based framework guides the user though a conceptual problem definition steps, which concerns the definitions of desired characteristics of the products, its properties, its needs, and its qualities. This is true for a new product or an existing product that needs an improvement.

The product design step consists of sub-steps for design and/or selection of product alternatives; a sub-step to generate data/knowledge related to the modelling needs for product-process behaviour and evaluation; and a sub-step for product design problem definition in terms of property targets.

In the next product-process modelling step, prediction/verification of the product behaviour is performed through the use of different computer-aided tools whitin the model-based framework. Also, a comparison of the results from the current process analysis and desired target is carried out to validate the quality of the designed product.

Further developments of the product-process is evaluated in the last step of the model-based framework for chemical product-process design before the production/manufacture of the designed product.

The model-based framework to be useful for chemical product-process design, different computer-aided modelling tools are necessary. For instance; modelling tools (ICAS-MoT), model-based libraries, databases (database manager), property prediction package (ProPred), solvent selections and molecular design software (CAMD), etc. where, the use of the methods and tools are related in accordance with the different products and phenomenon behaviour. All these software suites are available in the Integrated Computer Aided Software (ICAS) developed by Computer Aided Process Engineering Center (CAPEC) at Technical University of Denmark (DTU).

Work-flows, their corresponding data-flows as well as methods/tools needed for the different calculaion steps are usually associated with the product to be designed. That is, the amount of “knowledge” (data-flows) and the needed sequence of steps (work-flow) are related to the kind of product that is to be created. For example, after the problem definition and the generation of relevant documentation, the next step is to select-calculate the design properties (such as, application source, active ingredients, additives, solvents, etc. are the main steps in product design). Here, documentation, databases and search engines (for data retrieval) play an important role in the model-based framework as these tools are useful to verify some properties and available information during the creation and development of the product. Therefore, product design consists in the selection of the material of the product, the main ingredient, solvent/additives in the product, etc., as well as the calculation of the necessary product properties. In the analysis of the behaviour of the product as, thermodynamic properties, physical properties, etc.; frequently, the lack of information to perform the behaviour of the product is found; so as to overcome those gaps of information, computer-aided methods and tools can be applied to address this issue. The properties calculated in this part of the product-process design framework, for instance, diffusion coefficients, partition coefficients, viscosities of compounds and/or mixture, mass and heat transfer coefficients and so on, are transferred (data-flow) to the product-process modeling tools to carried out the calculation of the product-process behaviour.

Once, the complete information and characteristics about the product have been chosen; product behaviour and performance can be carried out. Here, modelling tools can assist in the simulation, generation of alternatives and verification of the formulation properties through the use of ICAS-MoT, that basically is a modelling tool able to perform the generation/analysis/simulation of mathematical models without extra programming effort; at this point, the values of target variables are calculated based in the information obtained from

property model section.

Subsequently, simulation results of product behaviour is compared with the desired targets established at the beginning and decide if the targets have been matched? If, “No”, new design of the product is started, or, an adjustement or analysis of the mathematical model is made to repeat the subsequent steps; if, “Yes”, before starting the production of the product; product-process performance verification is performed through the use of the modelling tools (for instances, ICAS-MoT). Furthermore, a sustainability analysis may also be carried out in order to evaluate the environmental impact of the production and performance of the product.

The work-flow for any specific product-process design is different and therefore, the corresponding data (knowledge), models, methods and tools needed for the various calculation steps in the work-flow need to be identified, However, in general terms, the following main steps are followed in many formulated chemical product design:

- Define product-needs in terms of target (design) properties
- Generate product (molecule, mixture, formulation, etc.) alternatives
- Determine if process considerations are important
- If yes, define the process design problem and solve/create it
- If no, go directly to the product evaluation (analysis) step
- Analyse the product-process in terms of a defined set of performance criteria

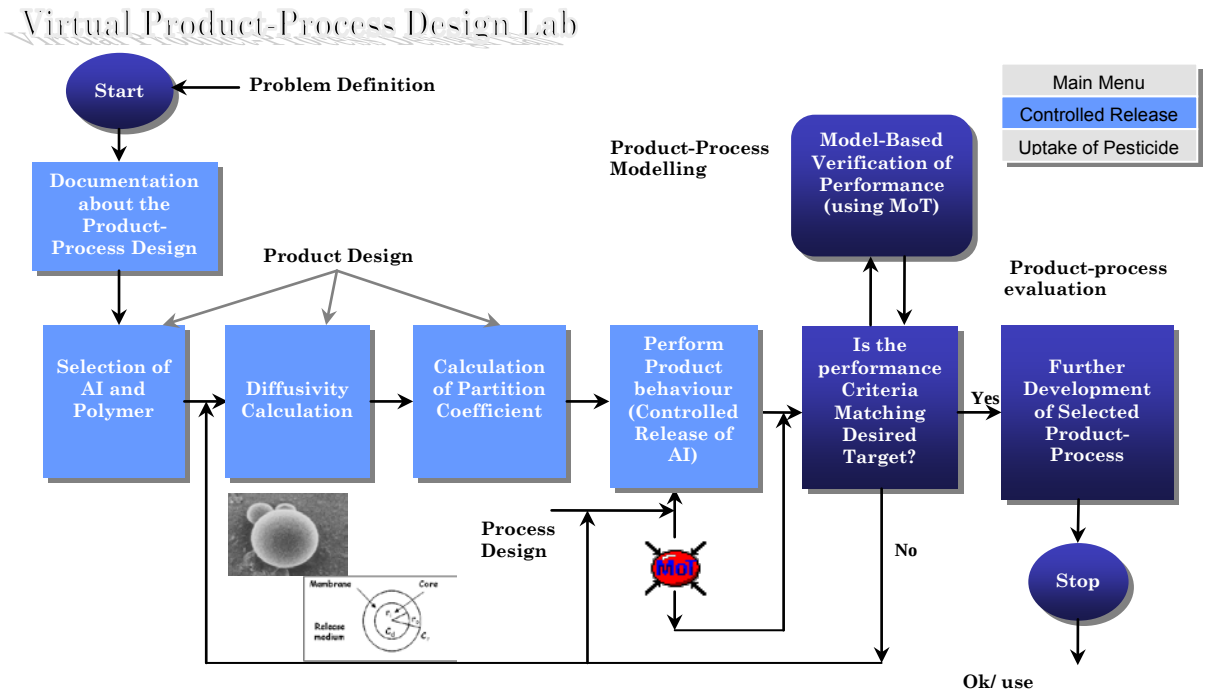

Figure 2. Virtual product-process design lab

A framework (see fig. 1) is neccesary to allow the work-flow to function by producing the different needs for each calculation step. From an analysis of the model and data used through this framework for any specific work-flow, it is easy to observe that product-process design problems are by nature, multidisciplinary and multi-scale and the gaps among the different disciplines/scales need to be bridged for efficient methods of solution. Also, this

model-based framework requires the interaction between human and computer, where human is handling and controlling the work-flow while the computer is carrying out the calculations in the work-flow and most of the tasks in the data-flow. It is important to highlight that the performance of this computer-aided system will depend on the availability of appropriate models and the ability to quickly generate them.

3 Design of a controlled release for microcapsule through the use of the systematic modelling framework for Product-Process Design.

A software called the "Virtual Product-Process Design Lab" has been developed by implementing the model–based framework for chemical product-process design. Currently, the software contains model-based libraries for design/analysis of controlled release and pesticide uptake. Figure 2 illustrates the work-flow related to design for controlled release though microcapsules.

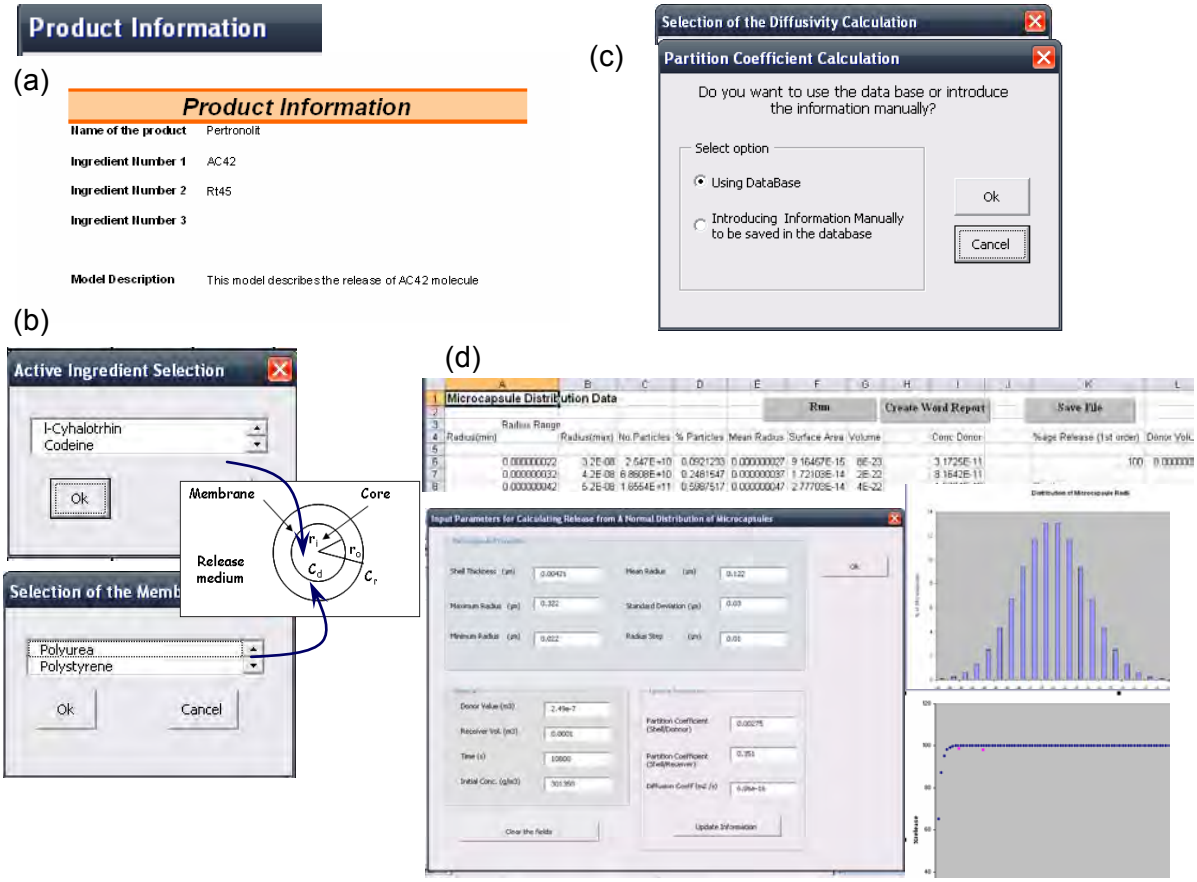

Figure 3. Design of the microcapsule controlled release

Figures 3a-3d illustrate the different steps of the work-flow for design/analysis of controlled release through microcapsules. Figure 3a shows the first step involving the generation of the documentation for the new product, where information related to model assumptions, ingredients of the product, etc., are given and saved in a documentation file. Figure 3b highlights the selection of the active ingredient and the polymer to be used for the microcapsule. Figure 3c highlights the calculation of the diffusivity and partition coefficients using the mathematical models proposed by Muro-Sune (2005), which are necessary for the microcapsule design calculations. Figure 3d highlights the performance simulation step. That is, once, all the information about the ingredients and polymers (specifically diffusion partition

coefficients) have been generated/obtained; an excel interface using the model for controlled release through a microcapsule is used in order to predict the product behaviour. Here, plots of the distribution of microcapsules according to size and number and the percent release of the active ingredient as a function of time are highlighted. At this point, it is possible to ask whether the performance criteria have matched the desired target, if “Yes” a new product alternative has been found. Otherwise, it is possible to return to the product design steps and try with other options until the target criteria are reached.

4 Conclusions

A model-based framework for systematic product-process design has been developed and its application illustrated through the design/analysis of controlled release of a pesticide active ingredient through a microcapsule. This important aspect has been demonstrated for virtual design of new products with the desired end-used characteristics without the use of a trial and error experimental-based approach but recommending the use of experiments only to verify the final product selection.

Finally, for the virtual product-process design lab to succeed, reliable models must be available in a model-library and used through an appropriate model-based framework, that can also help to generate models, when they are not available.

The framework provides the architecture needed for a software to implement specific work-flows of product-process design and defines the integration issues related to multi-scale models, methods, tools and data from various sources.

Combining Predictions at Multiple Scales for Process Modelling

Marco S. Reis *
Department of Chemical Engineering, University of Coimbra
Rua Sílvio Lima, 3030-790, Coimbra, Portugal

Keywords: Multiscale modelling, Wavelets, Data-driven modelling, Time series
Topic: Multiscale modelling

Abstract

An inductive data-driven multiscale framework for empirical process modelling is presented. This approach essentially consists of combining independently estimated models for the different scales of data representation obtained with the wavelet decomposition. Such transformation is performed over a receding horizon moving window of data, with dyadic length, that always includes the last observation, in order to enable the on-line application of the proposed procedure. The scales, whose models will be combined, are selected on the basis of their prediction accuracy, and those not showing good prediction performance during the preliminary assessment, that essentially consist of unstructured variation, are discarded from the analysis. An illustrative example, consisting of a non-isothermal dynamic CSTR under feedback control shows the method's potentialities when compared to their single-scale counterparts, in particular when addressing prediction problems when the output variable has most of its energy concentrated in intermediate or higher (coarser) time-scales, i.e., when the focus of prediction is not strictly at the finest scale.

1 Introduction

Process modelling plays a central role in Chemical Engineering, as virtually any activity in this field requires a simplified description of reality, i.e., a model. Multiscale modelling, is a class of modelling approaches that has recently gained momentum with new and relevant applications emerging in engineering, where the phenomena to be simultaneously addressed appear spread through different scales of length and operating at different scales of time. In fact, this is not a new problem for chemical engineers. For instance, the dynamic analysis of fixed bed catalytic reactors does require the simultaneous modelling of phenomena going on in the catalytic particle and in the bulk phases of the reactor. However, such traditional analysis usually led, after some simplifications, to modelling at a single scale, with appropriate boundary conditions linking phenomena at different scales. Current applications are however more demanding in the way the vertical integration of all relevant scales for the problem at hand is accomplished. For instance, as we move down to the micro- and nano-scales, in order to analyze, design, control and monitor systems and operations at such fine scales, the whole hierarchy of phenomena occurring at the different, intermediate scales of length and time must be necessarily addressed and properly combined. It is also becoming increasingly evident that some class of systems do exhibit very well defined scale dependent associations and dynamics, notably biologic complex systems (Butts et al., 2007; de la Rocha et al., 2007; Henzler-Wildman et al., 2007).

Significant advances have been achieved in modelling multiscale systems, using first principles approaches (Braatz et al., 2004; Charpentier and McKenna, 2004; Li and Kwauk, 2003; Li and Christofides, 2005). However, another paradigm of multiscale modelling should also be developed, in order to properly address those situations where large amounts of data are available, that are generated from phenomena occurring at different scales, but where fundamental knowledge of the underlying mechanisms is incomplete or even inexistent. Such data-driven multiscale modelling of systems, is therefore an area demanding for new

* Corresponding author. Tel + 351-239-798700. E-mail:marco@eq.uc.pt

developments, to keep the pace of the challenges raised by modern science, namely by the large amounts of information currently being made available with the recently developed measurement techniques, that now require proper processing and integration in order to generate useful information about the systems.

In this communication, we present an approach for data-driven modelling, where predictions computed from models estimated at different scales are properly combined, after a preliminary stage of scale selection. Such an approach is focused on prediction ability and is implemented according to a well defined and coherent sequence of steps, which can be performed quite efficiently, leading to potential improvements in the time and efforts spent in complex system identification tasks.

2 Methods

The multiscale data-driven modelling approach essentially consists on independently estimating models at different scales, using the wavelet transform coefficients of a receding horizon sliding window that always includes the last measured values, in order to make the resulting model adequate for on-line use (Figure 1).

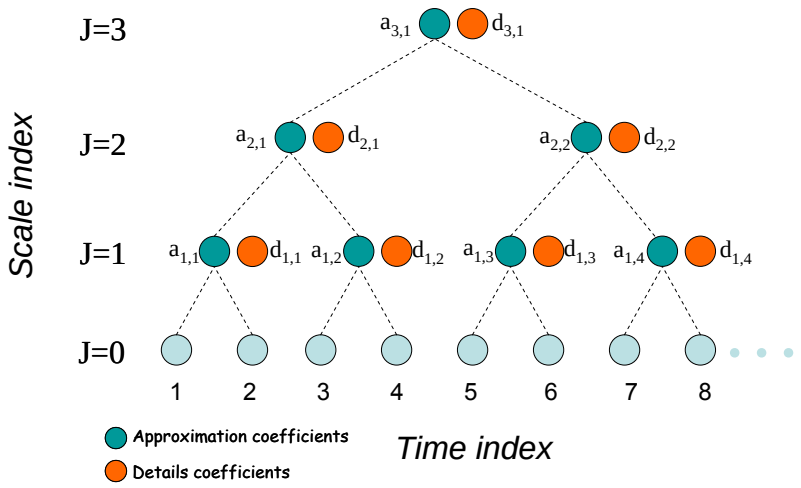

Figure 1. Scheme illustrating the computation of wavelet coefficients, starting from the finest scale representation of data, at scale $j = 0$, and recursively proceeding to coarser scales. In this case, the decomposition depth used was three ($J_{dec} = 3$), and the recursive relationship linking coefficients at different scales is the one for the Haar wavelet transform. In the proposed framework, this window of data is successively shifted in order to always include the last measured value.

The procedure is essentially based on a well defined sequence of steps (Figure 2). Simple models are first estimated at each scale in order to infer their prediction ability. The use of simple models in this task is a direct consequence of the decorrelation ability of the wavelet transform, that approximately diagonalise the variables' autocorrelation matrix, meaning, in practice, that simpler model structures are enough for capturing the dynamic behaviour at each scale (Dijkerman and Mazumdar, 1994; Golden, 1991). Analyzing these results, the relevant scales to include in such a multiscale modelling can be selected (those with predictive information power), after which the final model structure is again re-estimated and fine tuned.

The final model will consist of a set of models at different scales, that provide independent estimates for any value to be estimated. Such estimates, arising from different scales, are

then combined upon application of the inverse wavelet transform (using only the selected scales) in order to get the desired estimated value at the finest scale.

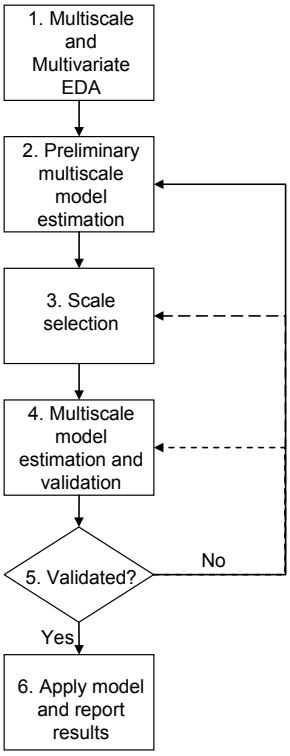

Figure 2. Basic sequence of steps for conducting the proposed multiscale data-driven system identification methodology.

3 Illustrative Example

In this section we illustrate the application of the proposed procedure for multiscale combination of predictions. In order to have the complete knowledge about the true values of the output variables, necessary for properly assessing and comparing our methodology with its single-scale counterparts, it was applied to a system which is complex enough to exhibit most of the features of complex processes, namely multiscale dynamics, but whose true values are known, for the sake of computing accurate prediction performance metrics. The system consists of a simulated industrial non-isothermal CSTR operating under feedback control, where an irreversible and exothermic first order reaction (A→B) takes place (Luyben, 1990; Reis and Saraiva, 2006). There are 10 variables involved in this process, collected every 10s, and the main purpose is to identify and estimate a proper model for predicting the composition of reactant A (CA) in the outlet stream, using all variables available (i.e., the goal is essentially to develop a soft sensor for CA). The data set used for the estimation tasks is composed by 10000 observations (~28h of continuous operation), while a second group of data, also with 10000 observations, constitutes a test set, based on which the prediction performance relative to each model structure is computed.

Following the procedure presented in Figure 1, after a preliminary stage of exploratory data analysis, simple models were estimated at each scale. The predictions thus obtained as a function of the respective measured values, are presented in Figure 3, where it is possible to see that some scales do present good prediction ability regarding CA for the phenomena contained in their frequency range (those relative to the three plots in the lower row of

graphics), whereas others do not (see plots in the upper row) and therefore should be removed from the analysis.

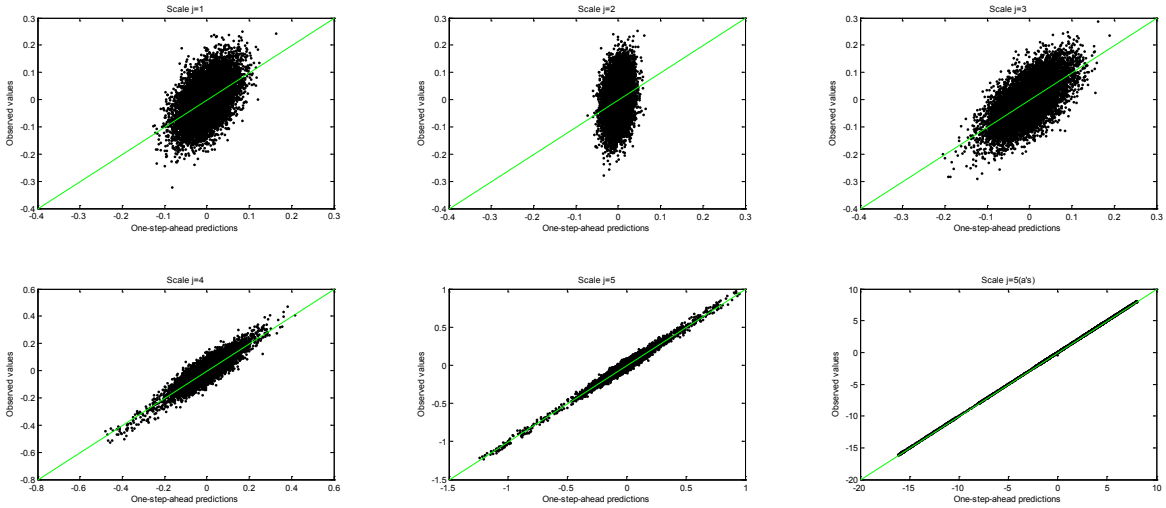

Figure 3. Plots of predicted versus observed values for CA at each scale, using independent ARX(1,1) model structures (Box et al., 1994).

Selecting the relevant scales in this way (namely, j=4, 5 and the approximation coefficients for scale j=5), and apply the estimated multiscale model to perform one-step-ahead predictions over the test set, the results presented in Table 1 were obtained, where RMSEP stands for the root mean square error of prediction, computed using both the real values of CA as a reference (since we are using a simulates system) and the observed values as reference (the true values plus additive noise). Such results do show the superiority of the proposed approach regarding the single-scale counterparts.

Table 1. Prediction results obtained (RMSEP).

RMSEP	***MS-ARX(1,1)***	***ARX(1,1)***	**ARX(2,2)**
Observed	0.0820	0.1065	0.0900
Real	0.0422	0.0806	0.0570

Figure 4 provides a graphical picture of the performance achieved with the multiscale method, where it can be seen that this method has an inherent ability to simultaneously perform prediction and filtering activities, being quite insensible to noise present in data. This observation arises from the preliminary elimination of scales containing mostly unstructured variation, focusing the modeling and predictions efforts only on those scales that really carry information about the output variable.

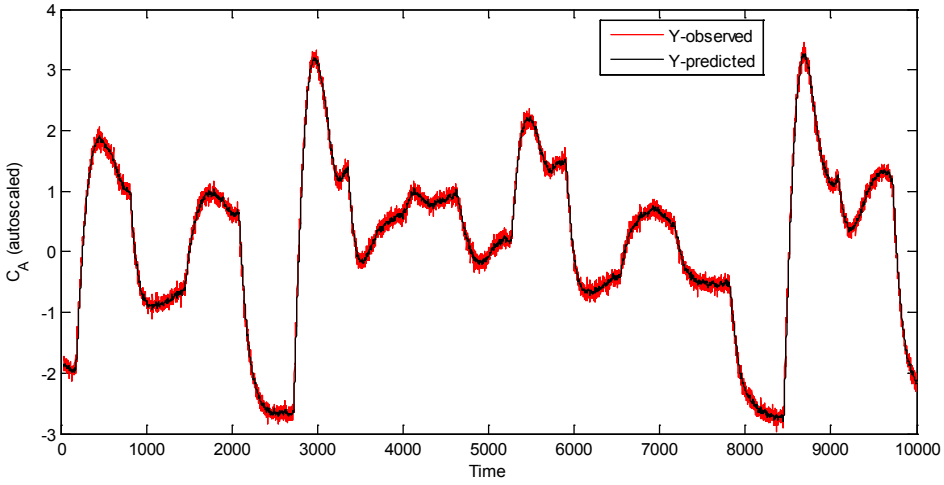

Figure 4. One-step-ahead predictions for CA (at the original scale), using the multiscale model structure with independent ARX(1,1) models at scales 4 and 5.

4 Conclusions

A model structure consisting of assemblies of black-box models describing system evolution at different scales of time (or frequency bands) is proposed, the result of which, once combined by the inverse wavelet transform, give rise to the predicted response at the finest scale. In the illustrative example presented, better predictive results were obtained when comparing to the classical single-scale approaches. The proposed systematic methodology also allows for an effective reduction in the analysis time of complex data sets, as well as brings important concepts to the core of the analysis, such as those leading to the selection of scales with predictive power, something that is absent from other current approaches. Such a multiscale approach can bring new added value to the analysis of problems where the output variable has most of its energy concentrated in intermediate or higher (coarser) time-scales, i.e., when the focus of prediction is not strictly at the finest scale.

Abstract

The effect of the feed streams pulsation on the flow dynamics in a Confined Impinging Jets (CIJ) reactor was studied in this work. Different frequencies and amplitudes are studied. The out phase pulsation of the opposed jets with frequency close to natural oscillation frequencies enhances the order of the system, yielding a well defined vortices street. The results showed that the amplitude of the jets oscillations has a strong effect on the flow dynamics, up to the extreme case where the imposed pulsation completely drives the dynamics of the system.

Introduction

Confined impinging jets (CIJ), where two opposed jet streams impinge each other in a confined mixing chamber have a wide range of applications, mainly for the production of polyurethanes in Reaction Injection Molding, RIM, and in precipitators. The flow regime in the mixing chamber can be oscillatory or self sustainable chaotic. In self sustainable chaotic flow regimes, the jet streams engulf each other in evolving vortices throughout the mixing chamber, see Figure 1 for $Re = 150$. In oscillatory flow regimes both streams flow segregatedly throughout the mixing chamber, see Figure 1 for $Re = 100$. In self sustainable chaotic flow regimes the vortices formation is associated with strong oscillations of the jets' impingement (Teixeira et al., 2005) that present frequencies around typical values, while the oscillatory flow regimes present low amplitude oscillations with very well defined frequency. Erkoç et al.(2007) reported the usage of dynamic measurements of static differential pressure signal between the two impinging jets for the determination of oscillations typical frequencies at both flow regimes.

The flow field structures occurring at self sustainable chaotic flow regimes are the main mixing mechanisms in the RIM process and other CIJ mixers, as shown in Santos et al. (2005). The efficiency of mixing in such kind of processes is critical for the quality of the product as shown from the polymerization works of Kolodziej et al. (1982 and 1986). When fast reactions are present and short mixing times are required it is of outmost importance to operate the CIJ mixers at self sustainable chaotic flow regimes. In case of RIM the process wide spreading has been seriously compromised due to failure of operation at chaotic flow regimes, either self-sustained or imposed.

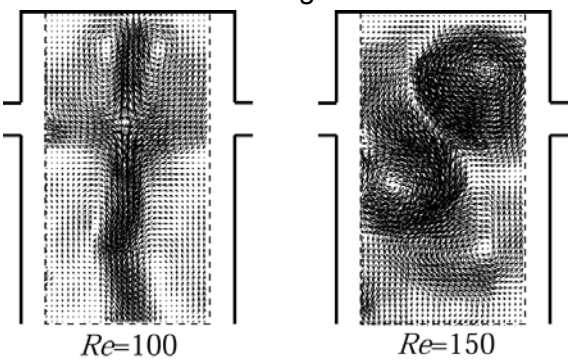

Fig. 1. Vector maps from PIV measurements at Re=100 and 150.

* Corresponding author. Tel + 351-22 -508 16 69. E-mail:lopes@fe.up.pt

From the very early works on RIM of Malguarnera and Suh (1977) it was reported that to establish a self sustainable chaotic flow regime, the Reynolds number has to be above a certain value and the momentum ratio of the jets has to be equal to one. Erkoç et. al. (2007) showed that even if these conditions are satisfied, the continuous operation of RIM at self sustainable chaotic regime is not assured, as for the same conditions, both oscillatory or self sustainable chaotic regime can be observed.

On way to assure mixing is to modulate/pulsate the jets' flowrate. The process of enhancing mixing through modulation/pulsation of the inlet flow streams is called active mixing. Bierdel and Piesche (2001) were the only authors to discuss the pulsation of jets and test the effect of pumps flow pulsation on the beginning of convective mixing in RIM. Active mixing in other CIJ reactors was studied by Deshmukh et al. (2000 and 2001), Zhongliang et al. (2002), Ito et al.(2006), although only its effect on mass transfer was analysed.

In this study, mixing is not engaged from the pulsation, since the flow field in the mixing chamber at the Reynolds number value of 300 here studied has natural advective chaotic pattern. The purpose here is to scrutinise the interaction between the flow natural oscillations and the imposed jets oscillations, namely its effect on the flow dynamics and on the shape and evolution of the natural advective chaotic patterns formed downstream the opposed jets impingement point.

CFD Model

The flow field was simulated with Fluent™ using a 2D model of the mixing chamber introduced and validated previously by Erkoç et al. (2007). Detailed results from the 2D model CFD simulations have been previously presented (Santos 2003,Santos et al.,2002 and Santos et al.,2005). Here the injectors averaged Reynolds number, Re, is defined for the 2D geometry as

$$Re = \frac{\rho \overline{v}_{inj} w}{\mu} \qquad \text{eq1}$$

where w is the injector width, which is 1.5 mm, μ is the viscosity that here is $20\text{mPa}\cdot\text{s}$, ρ is the density that here is 1200kg/m^3 and $\overline{v_{inj}} = 3.333\text{m/s}$ is the time and space average fluid velocity at the injectors. The chamber width is 10mm and the chamber height is 50mm, the injectors are locate at 5mm from the close top of the mixing chamber. The boundary conditions were set as no slip in the walls, and the liquid leaves the chamber from a pressure outlet set at atmospheric conditions. The dynamic simulations were always started from a steady state solution of the flow field for $Re = 300$. The pulsation of the jets is performed according to the following equations:

on the left injector $$v_{inj}(t)_l = \overline{v_{inj}} + A_l \overline{v_{inj}} \sin(2\pi f t) \qquad \text{eq2}$$

on the right injector $$v_{inj}(t)_r = \overline{v_{inj}} + A_r \overline{v_{inj}} \sin(2\pi f t + \varphi) \qquad \text{eq3}$$

where A_l and A_r are the left and right pulsation amplitudes, respectively, f the pulsation frequency and φ the phase displacement between the right and left injector pulsation.

Results

The previous studies of Erkoç et al. (2007) reported that in CIJ the jets impingement point oscillates with a natural oscillation frequency, ϕ. The jets impingement point oscillation frequency is around $\phi = 200\text{Hz}$ for a fluid with $\mu = 20\text{mPa}\cdot\text{s}$ in the defined 2D geometry at $Re = 300$. The tested jets flow rate oscillation frequencies are $f = \phi/2 = 100\text{Hz}$, $f = \phi = 200\text{Hz}$, and $f = 2\phi = 400\text{Hz}$ z. The simulated cases are all at $Re = 300$ and summarized in Table 1. All simulations were performed dynamically using a fixed time step of

10^{-4} s. The x component velocity, v_x, was recorded in the axis of the chamber at a distance of $z = 5$mm from the top (at the jets impingement point: P1).

Table 1 Summary of simulated active mixing strategies

Case Number	Pulsation Strategy	Amplitude and Frequency
1	No Pulsation	$A = 0$
2	Only one jet is pulsed	$A_l = 0.50, f = \phi$
3	On-Phase	$A_l = A_r = 0.50, f = \phi, \varphi = 0$
4	Out-of-Phase	$A_l = A_r = 0.25, f = \phi, \varphi = \pi$
5	Out-of-Phase	$A_l = A_r = 0.50, f = \phi, \varphi = \pi$
6	Out-of-Phase	$A_l = A_r = 1.00, f = \phi, \varphi = \pi$
7	Out-of-Phase	$A_l = A_r = 0.50, f = 2\phi, \varphi = \pi$
8	Out-of-Phase	$A_l = A_r = 0.50, f = \phi/2, \varphi = \pi$

Figure 2 shows the streamlines, at some selected time instants, of the dynamic simulations of the eight defined cases. The same flow behaviour previously reported in Santos *et al*.of the formation of a vortex street downstream the jets impingement point is observed for the eight cases. Some differences are yet observable between the flow fields:

- The vortices in Cases 2 and 3, corresponding to one side oscillation and on-phase oscillation, are more distorted, less rounded, than the case of no pulsation.
- The cases with out-of-phase pulsation present greater regularity of the vortex street, namely Cases 4, 5, 6 and 8 except for Case 7, where pulsation frequency is 2ϕ.

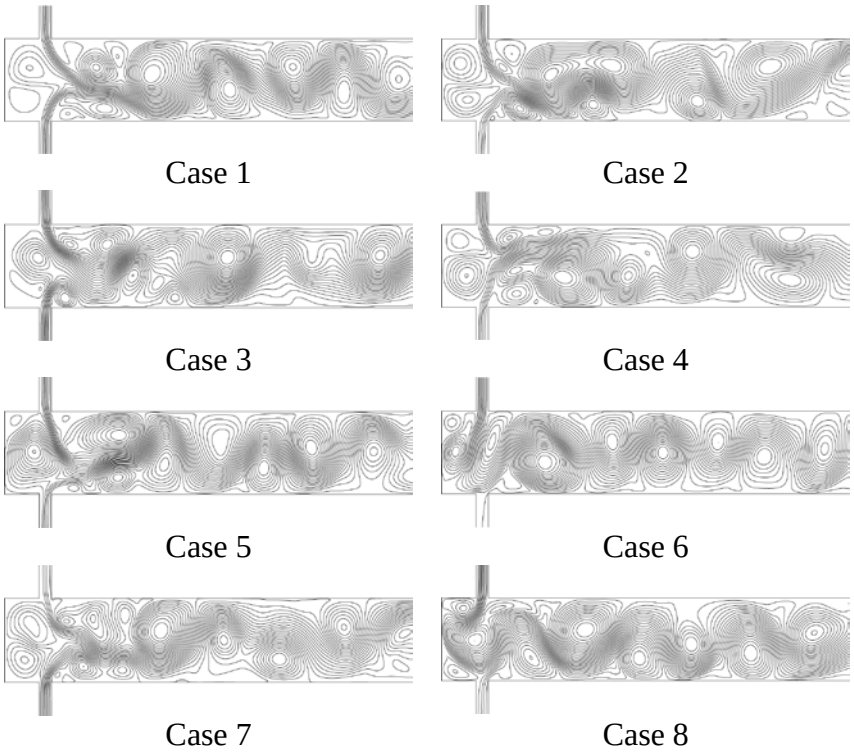

Fig. 2. Streamlines of flow field in the mixing chamber from the dynamic simulations at average *Re*=300, using different pulsation strategies.

For a clear image of the pulsation effect on flow dynamics, in Figure 3 it is presented the power spectra of the velocity time histories at the impingement point, P1, for the simulated

cases. The highest spectral energy values obtained from the spectra are listed in Table 2.

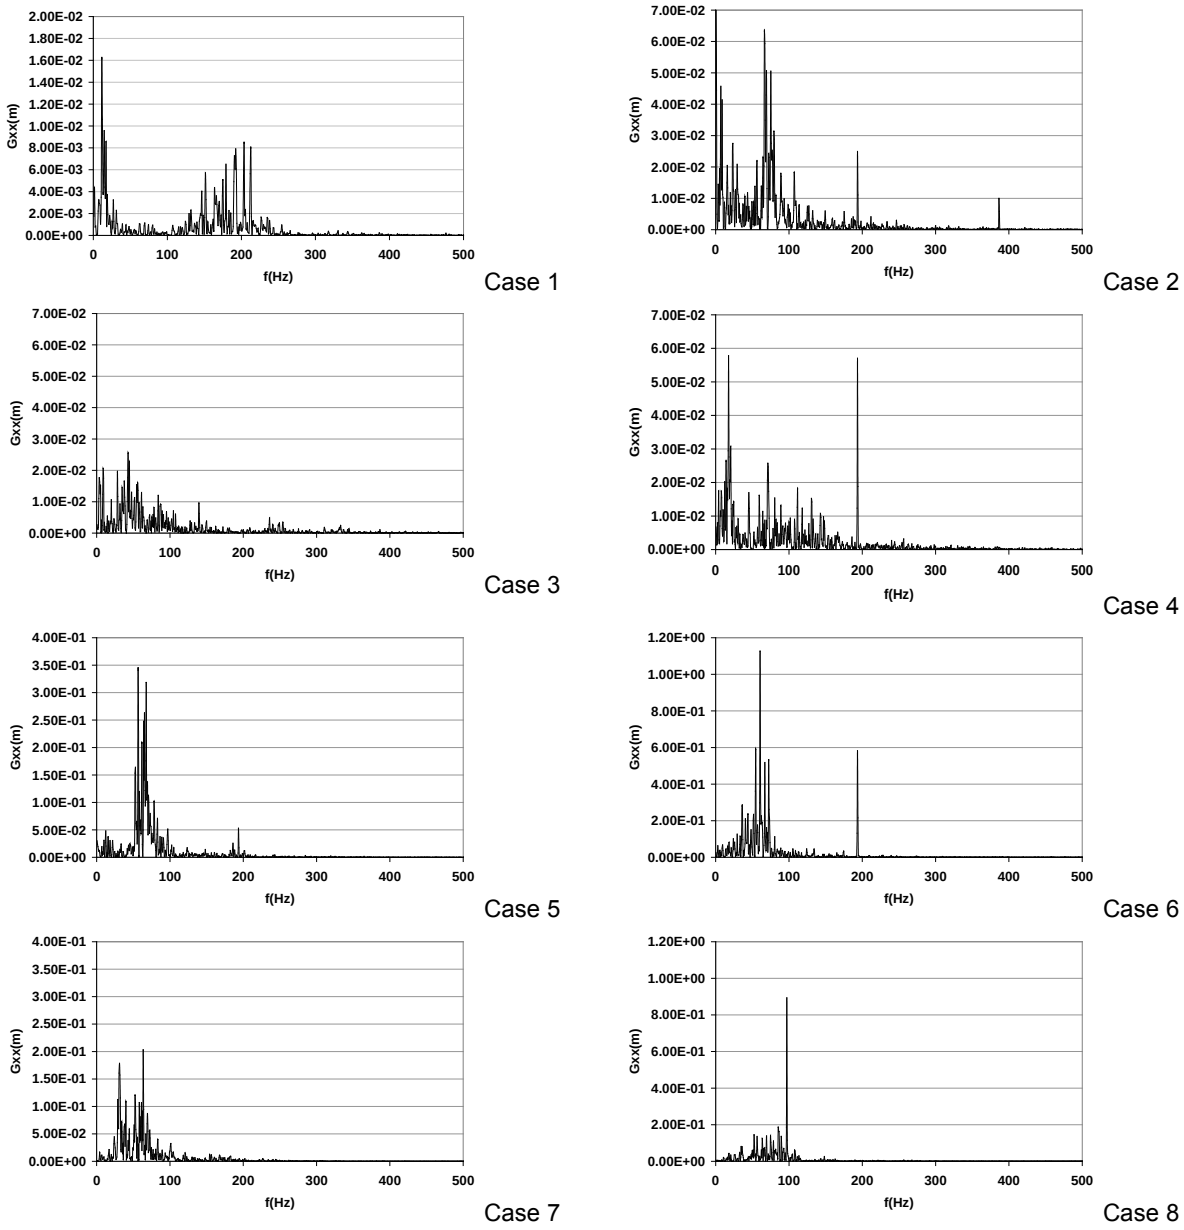

Fig. 3. Power spectra at the impingement point from the dynamic simulations at average Re=300 using different pulsation strategies.

For Case 1, where there is no pulsation applied to the system, typical frequency of the jets oscillations is $\phi = 200\text{Hz}$. The energy of the jets oscillation is much smaller than for the cases with forced pulsation as seen from Table 2, where the maximum energy value is seen to be almost one order of magnitude less than from the out-of-phase pulsation cases with $f = \phi$.

When only one of the jets is pulsed, the appearance of a lower frequency peak, between 50 and 100Hz, is observed, as can be seen in Figure 3 for Case 2. The on-phase pulsation, Case 3, presents the lowest energy peaks, since both jets are pulsated simultaneously, their strengths keep balanced and there is no significant disturbance of the jets oscillation. When a jet loses its strength, it is not compensated by the opposed jet, which is also retracted, and on the other hand when a jet increases its strength it is matched-up by the opposed jet.

Table 2 Maximum energy levels from the power spectra of v_x around f=200Hz, at the impingement point.

Case Number	Max Energy, m
1	0.00843
2	0.0247
3	0.00168
4	0.0571
5	0.0530
6	0.583
7	0.000921
8	0.894 *

The cases promoting the highest dynamics of the jets oscillations are the ones with out-of-phase perturbations, mostly the ones with the highest amplitudes. At $A_l = A_r = 1.00$, the jets oscillations are mainly determined from the imposed pulsation.

On the other cases, $A_l = A_r = 0.50$ there is a strong interaction between the flow field natural oscillations and imposed oscillations by pulsation. The resulting power spectrum, see Figure 3, shows both the influence of the natural flow oscillation, Case 1, and of the imposed jets oscillation. This result suggest that the flow field somehow preserves its own dynamics up to pulsation values of 50% of the inlet flow rate.

For Cases 4 to 6, streamline maps of Figure 2 show the earlier appearance of fully developed vortices, and when $A_l = A_r = 1.00$ the vortices are generated at the jets inlet region, which is the reason for the increase of the energy peaks in the range of 50 to 100Hz. For the double frequency oscillations, where $f = 2\phi$, Case 7, the natural flow oscillations and the imposed oscillations interact in a complex fashion cancelling the high energy peaks above 100 Hz.

The highest energy peak is obtained with a pulsation frequency of $\phi/2$, which is close to the flow oscillation frequency at the vortex street region. The pulsation frequencies probably set the whole system into resonance. From the streamlines in Figure 2, the earlier formation of the fully developed vortices at the impingement point occupying the entire mixing chamber width and evolving in perfect order to the outlet is clearly observed for Case 8.

Conclusion

In summary we studied the effect of opposed jets pulsation on the mixing dynamics and vortex formation on flow field dynamics inside the CIJ reactor. The flow dynamics had a strong effect from the pulsation frequency:

- With values close to the natural jets oscillation frequencies, ϕ, pulsation enhances the regularity of the system which results in a clear oscillatory behaviour of the jets at the impingement point.
- With values close to the natural frequency of the fully developed vortices, $\phi/2$, pulsation can force the frequency of the fully developed vortices passage and make it more orderly.

It was observed that the amplitude of the pulsation also has a strong effect on the flow field:

- Lower amplitudes can not impose to the system dynamics.
- Higher amplitudes, close to 100% of the flow rate, can completely dominate the dynamics of the flow field.

The other studied parameter was the impact of the pulsation strategy, which has shown that the strategies consisting of out-of-phase jets pulsation impose more clearly its dynamics to the system, since the displacement of the jets impingement point is completely determined

from the pulsation. One side oscillation and on-phase oscillation were not able to impose a clear influence on the flow field.

Keywords: Activated Sludge, CFD, Oxidation Ditch
Topic: Integration of life sciences & engineering

Abstract

An oxidation ditch is a modified activated sludge biological process for wastewater treatment. The oxidation ditch process, although being widespread, was rarely studied. In this work Computational Fluid Dynamics (CFD) simulations are used to make a detailed analysis of the overall transport mechanisms in the oxidation ditch: macromixing. The impact of the chosen turbulence model for the CFD simulations is also assessed. The Residence Time Distributions, i.e. macromixing, are computed for the different turbulence models. It is shown that for mixing studies the flow dynamics should always be simulated, if computationally possible. The effect of macromixing in the yield of an Activated Sludge process is computed from an ideal reactor model: Plug Flow Reactor with Recirculation. The macromixing is shown to have a determinant role in the reactor efficiency.

1 Introduction

The oxidation ditch technology was developed in Netherlands by A. Pasveer in 1950s (Pasveer, 1962) and the first full scale plant was set working in Voorschooten at Holland, in 1954 (EPA, 2000). Nowadays, oxidation ditches found application in USA in over 9200 wastewater treatment plants (EPA, 2000). The process is also commonly used in Portugal (Vila Nova de Gaia - Febros, Viana do Castelo – Areosa, Golegã...). A survey of 14 activated sludge (AS) processes in USA showed that oxidation ditches have more robust and reliable operation than other AS processes (Benefield et al., 1980), particularly in enduring unfavorable temperature conditions and with regard to nutrient removal. An oxidation ditch is a modified activated sludge biological treatment process used in Wastewater Treatment Plants having a ditch system with a single or multi-channel configuration, within a ring-, oval- or horseshoe-shaped basin, equipped with aeration and mixing devices, generally surface brush aerators. The process runs with long cell residence times resulting in high Biological Oxygen Demand (BOD) removal efficiency, average 75% – 95% up to 99% (Benefield et al., 1980; EPA, 2000). The oxidation ditches, besides BOD removal, can also perform denitrification, due to presence of zones with high and low dissolved oxygen concentration. The oxidation ditches are usually regarded as complete mix systems (EPA, 2000), although this process is still scarcely studied mainly in what regards to the flow regime.

Simulation for AS has been mostly based on ideal reactor models: Continuous Stirred Tank Reactor (CSTR) or in a cascade of CSTRs. This approach is not based in any hydrodynamics studies, but on the assumption that the reactor yield is not determined from the flow regime (mixing) because the reactions are typically slow. Most of the effort in AS simulations has then been focused on modeling the microbiology of the process (Gernay et al., 2004). One of the aims of this study is to determine the mixing behaviour in oxidation ditches from the computation of the Residence Time Distribution (RTD). The RTD is computed from Computational Fluid Dynamics (CFD) simulations of the oxidation ditch. The effect of the hydrodynamic models used in the CFD simulations will also be assessed.

2 CFD Model and Boundary Conditions

Geometry and boundary conditions

The CFD studies of the oxidation ditch, were conducted using Fluent™ commercial software, considering a 3D model of a scaled, oval-shaped tank with the design shown in Figure 1. The tank volume is around 30m^3. Several simulations were made to determine the grid density that would render the simulation results independent of it. The oxidation ditch system consists of an oval tank and a jet aeration device (hydrojets) that simultaneously forces the fluid circulation throughout the ditch and injects a stream saturated with oxygen. Here, the hydrojets are two slot inlets with 0.1m height extending from one side to the other and positioned at middle height of the tank. The surfaces of the inlet and outlet (0.25mx1.38m) of the ditch are placed in the top of the tank – where usually the piping system is placed. Hydrojets, inlet and outlet are opposite-sided and distant from each other for half of the length of the ditch.

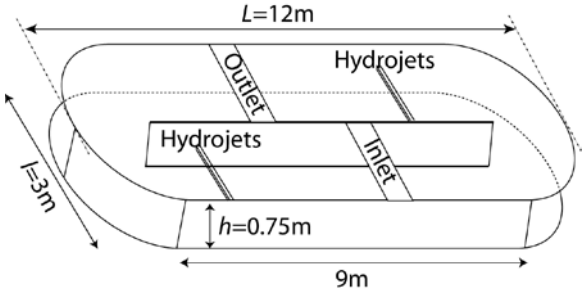

Figure 1 Drawing of the simulated geometry and boudary conditions.

Water was defined as the working fluid. Inlet of the oxidation ditch has a velocity magnitude of 0.006m/s. The hydrojets were set as momentum sources guarantying a fluid velocity of 0.3m/s, typical of oxidation ditches aerated by conventional devices, such as surface brush-type aerators.

Turbulence models

The fluid flow inside the oxidation ditch is simulated using the Reynolds Averaged Navier-Stokes (RANS), and Unsteady Reynolds Averaged Navier-Stokes (URANS) with the $k-\varepsilon$ turbulence model, and using the Large Eddy Simulation (LES) with the Smagorinsky's subgrid scale model.

RTD computing

The RTD was computed from the residence times of particles injected through the inlet in a very short period, 10^{-3}s. The particles trajectories were integrated over the flow field with Fluent™, and the flux of particles out of the tank through the outlet recorded. The physical characteristics of the particles were chosen in order to make them adjust to the flow as much as possible (Le Moullec et al., 2008). Their density is identical to the density of the water (998kg/m^3) and they are spherical having a diameter of 10^{-6}m.

3 Results and discussion

CFD results

The velocity vectors in a vertical plane of the oxidation ditch are presented in Figure 1. The same overall distribution of velocity vectors were observed within the tank for RANS and URANS simulations. The velocity vectors obtained from LES simulation distinctly differs from the others, by the appearance of vortices and of a sinuous path of the jets.

From the vector maps it is clearly seen that the hydrojets create an average flow with great stratification inside the oxidation ditch, with very few vertical transport. However from LES results it is seen that there are transient patterns that mix flow from top to bottom layers.

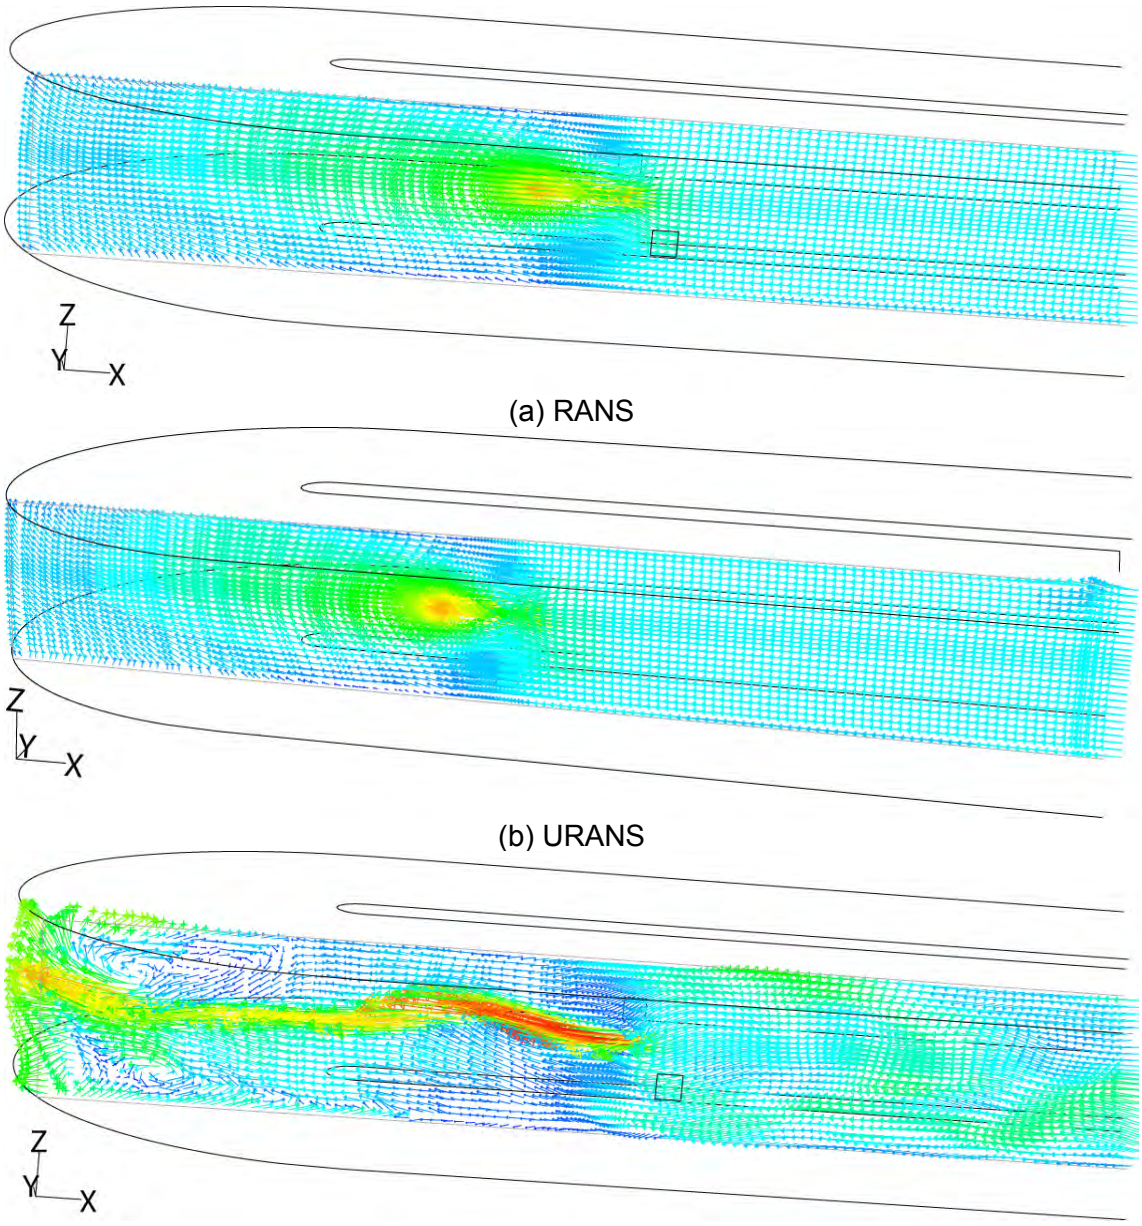

Figure 2 Maps of vectors of velocity magnitude from CFD simulations of the oxidation ditch with (a) RANS, (b) URANS, and (c) LES.

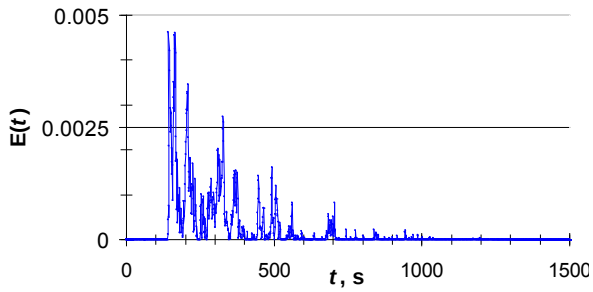
In Figure 3 are shown the RTD functions, $E(t)$, where t is time, for the simulations using the three different turbulence models: RANS, URANS and LES. Although the mean residence time of fluid in the tank is 4h=14400s, in Figure 3 plots only the first 1500s are shown, and LES was only made until 800s, due to the high computational times involved. Since the mean travel time of the flow across the entire ditch is approximately 200s, the average number of turns of fluid particles within the ditch before exiting is around 70.

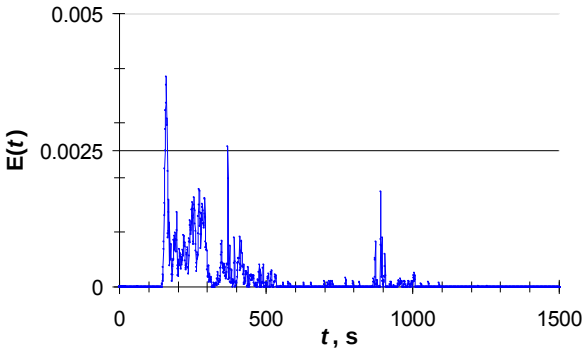
For RANS and URANS there is a considerable amount of particles exiting in the first two turns, as can be seen from the peaks of the RTD around 150s and 350s. This is due to the high stratification of the flow obtained in RANS and URANS, as can be seen in Figure 2. Since particles are not being transported to lower regions of the ditch in the first turns, only a small percentage of the volume is used. The particles that go to the lower part of the ditch will be trapped there for long time, yielding a long tail in the RTD.

The results with RANS and URANS suggest that the hydrojets caused an intense vertical segregation of the flow, rendering only a part of the ditch for the actual wastewater treatment.

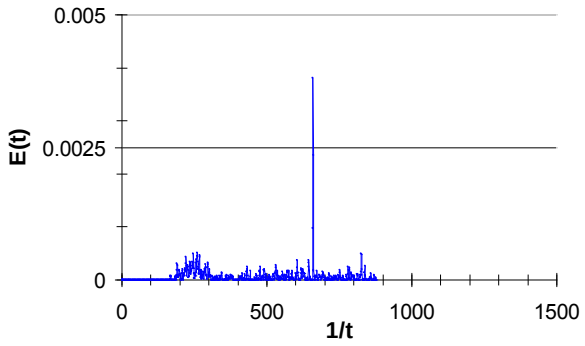
Although, as seen from the LES results in Figure 2, the vertical mixing mechanisms can be accounted if models that simulate the flow dynamics are used.



(a) RANS



(b) URANS



(c) LES

Figure 3 RTD from CFD simulations with (a) RANS, (b) URANS, and (c) LES.

The RTD obtained with LES does not show the peaks related with huge amounts of particles exiting in the first turns. This is due to the convective patterns observed in LES, see Figure 2, that promote transport to the lower regions of the ditch, and thus a greater fraction of the ditch volume is used.

The comparison of results from the different turbulence models is clear when the percentage of total injected particles exiting during the first 800s is considered:

- 30% for RANS;
- 20% for URANS;
- 5% for LES.

As seen from these figures the turbulence model used has a strong impact in the advection patterns took by the particles in the oxidation ditch.

Although from the RANS and URANS simulations the reactor seems to present a high percentage of dead volumes, or strong channeling from inlet to outlet, this is only due to the fact that with these models an average flow is simulated. The computation of macromixing (RTD) based on the average flow field may lead to errors. The flow dynamics underlies mixing at all its scales, both macro and micro, and thus it must always be accounted.

The differences between the turbulence models are clear from the dynamic presentation of the particles advection in the ditch, which is not possible to make on paper. The dynamic visualization of the results will be shown in the oral session at the conference.

ASM1 results

The effect of macromixing on the reactor efficiency/yield is here assessed from the Activated Sludge Model Nº 1 - ASM1, (Henze et al., 1987). The ASM1 was implemented in an ideal reactor closely approaching an oxidation ditch, a Plug Flow Reactor with Recirculation - PFRR (Pereira et al., 2008). The macromixing was changed by varying the internal circulation in the ditch. For a PFRR the RTD is given by

$$E(t) = \sum_{i=1}^{n} \delta\left(t = i \times \frac{s}{\upsilon}\right) \frac{1}{\beta + (i-1)(1+\alpha)} \qquad \text{eq. 1}$$

where δ is the Dirac function, t is the time, υ is the space velocity at the ditch cross section, s is the is the oxidation ditch length, α is the recirculation ratio from the secondary settler to the ditch, and β is the internal recirculation ratio in the ditch. The PFRR RTD is a Dirac comb with peaks spaced by s/υ having coefficients that decay at a ratio of $1+\alpha$ per fluid internal circulation. The macromixing in the PFRR is thus easily changed from the ditch length, s, and the internal circulation ratio, β.

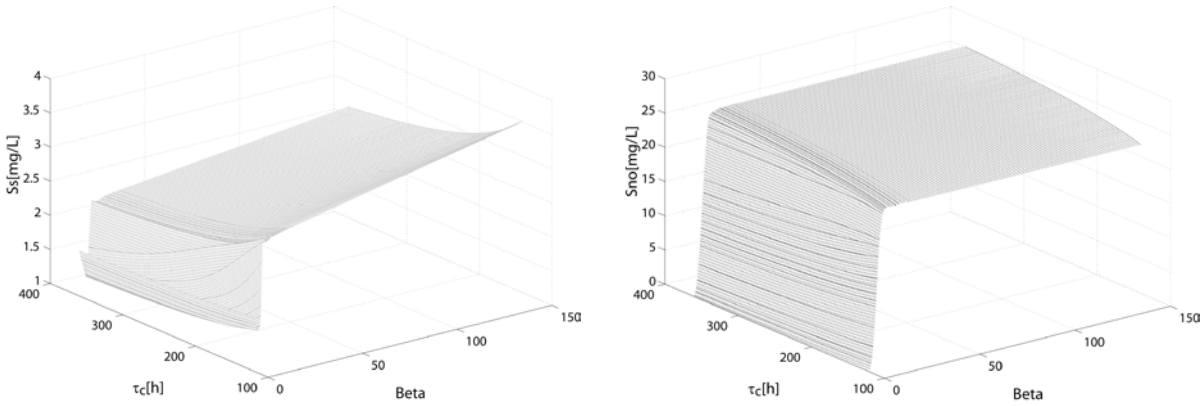
Figure 4 shows the effect of the internal circulation parameter, β, and the cells residence time on the reactor yield in terms of substrate (BOD) and nitrate. The cells residence time is defined as

$$\tau_c(t) = \frac{1}{QX_W}\int_0^V X\, dV \qquad \text{eq. 2}$$

where QX_W is the mass flux of cells wasted from the system, X is the cells concentration and V is the reactor volume.

The ASM1 simulations were made considering the same mean residence time has in the CFD study, 4h, and using the bio-kinetics parameters of Henze et al. (1987). Complete description of the model is made in Pereira et al. (2008).

The macromixing, i.e. β, has a strong effect in the reactor yield, namely for lower values of β. For higher values of β the system tends to the case of a perfectly mixed reactor. Although the reactions in ASM1 are slow, since there are several reaction steps involved, mixing plays a relevant role in the final reactor yield. On the effect of both macro and micromixing on an oxidation ditch see Pereira et al. (2008).



(a) (b)

Figure 4. Oxidation ditch outlet concentrations of (a) substrate and (b) nitrate for several internal circulation values (β) and cells residence time (τ_c).

4. Conclusions and future studies

In North America models such as the ASM1 are regularly used in AS processes design, while in Europe those models are more often used to set the operation parameters of running processes. Mixing is playing a key role in the AS process, but in both sides of the Atlantic it is usually regarded as secondary in comparison with bio-kinetic models.

Here it is shown the relevant role of mixing in the reactor yield. Furthermore, it is shown that the turbulence models used in reactor simulations have a strong impact in the mixing results. From the turbulence models that simulate the average flows, RANS and URANS, mixing is underestimated, as expected. The results of these models may lead to decisions such as introducing baffles to eliminate flow vertical segregation, which can reveal being useless, as seen from the results of LES.

Topic: Multi-scale and multi-disciplinary approach to process-product innovation: CFD & Chemical Engineering.

Abstract

A computational fluid dynamic (CFD) model based on Euler-Euler multiphase approach is presented for a trickle-bed reactor (TBR). The hydrodynamic model is developed with the integration of interphase momentum exchange terms between gas, liquid and solid phases. The interphase coupling parameters are assembled in the momentum balance by means of interstitial velocities and phase volume fractions. A case study comprising the catalytic wet air oxidation (CWAO) of a phenolic acid pollutant is considered at different liquid superficial velocities and operating pressures.

Total organic carbon (TOC) conversion profiles are evaluated radially at different bed heights. Poor radial mixing is remarkable mainly for high liquid flow rates whereas operating pressure at the same liquid superficial velocity only has a minor effect in the radial TOC depletion rate. Afterwards, the Eulerian model was used to probe the interaction of hydrodynamic parameters and chemical reaction. Different catalyst wetting levels were detected which reflect the existence of certain gas-liquid flow maldistribution and local temperature variation.

1 Introduction

Multiphase flows are often encountered in environmental reaction engineering and the knowledge of computational transport phenomena models for the practical analysis of such complex chemical processes is far from being complete. In fact, three-phase systems related with CWAO in the treatment of liquid effluents containing a high content of organic matter are emerging as a new application of trickle-bed reactors (Bhargava *et al*., 2006), specifically in the olive oil mill processing industries that generate a large amount of highly contaminated wastewaters in Mediterranean countries (Paraskeva and Diamadopoulos, 2006).

TBR models reported in the literature considered isothermal operation and used either a pseudo-homogeneous approach or a heterogeneous model with plug-flow for gas and liquid phase whereas others accounted for liquid flow non-uniformity and maldistribution by using an axial dispersion model (Dudukovic *et al*., 2002; Al-Dahhan *et al.*, 1997). To improve the capability of multiphase reactor models, one has to solve the complete multidimensional flow equations coupled with chemical species transport, reaction kinetics and mass and heat transport phenomena. Therefore, multicomponent reacting flows in which kinetic models are experimentally determined have to be modeled with additional phase interaction terms. This study aims to assess an Eulerian multiphase CFD model in order to investigate the phases interaction coupled with turbulence models to make use of large-scale CFD computations that can be helpful in pointing out the cause of incomplete catalyst utilization in particle-scale level.

2 Mathematical Model

Taking into account the numerical power available nowadays to address complex chemical process operational and design issues, our case study outlines an alternative CFD modeling method to investigate the oxidation behaviour of a TBR in terms of total organic carbon concentration profiles taking into account the kinetic expressions obtained elsewhere (Lopes *et al.*, 2007a). Transport phenomena such as mass and heat transfer are integrated in an Eulerian *k*-fluid model, resulting from the volume averaging of the continuity and momentum equations and solved for a 3D representation of the bed at unsteady state. In the Euler-Euler mathematical approach, both the continuous and dispersed phases are considered as interpenetrating continuous media (Jiang *et al*., 2002). These models incorporate two-way coupling, which is specially important for high voidage flows. The interfacial momentum transfer between the liquid and the gas includes a number of force contributions, form and viscous drag, mass force as an inertial force caused by relative acceleration, the effect of turbulent fluctuations on the effective momentum transfer, and the lift force which denotes the transverse force caused by rotational strain, velocity gradients, or the presence of walls. The CFD model equations were implemented in commercial software FLUENT (of Fluent Inc., USA) using user defined routines. Only the main conservation equations are presented. The continuity and momentum balances for phase *q* are written in Eqs. (1) and (2), respectively:

$$\frac{\partial}{\partial t}(\alpha_q \rho_q) + \nabla \cdot (\alpha_q \rho_q \vec{v}_q) = \sum_{p=1}^{n} (\dot{m}_{pq} - \dot{m}_{pq}) + S_q \tag{1}$$

$$\frac{\partial}{\partial t}(\alpha_q \rho_q \vec{v}_q) + \nabla \cdot (\alpha_q \rho_q \vec{v}_q \vec{v}_q) = -\alpha_q \nabla p + \nabla \cdot \bar{\bar{\tau}}_q + \alpha_q \rho_q \vec{g} + \sum_{p=1}^{n} (\vec{R}_{pq} + \dot{m}_{pq} \vec{v}_{pq} - \dot{m}_{qp} \vec{v}_{qp}) + (\vec{F}_q + \vec{F}_{lift,q} + \vec{F}_{vm,q}) \tag{2}$$

$\vec{R}_{pq}$ represents the interphase force and depends on the friction, pressure, cohesion, and other effects, and is subject to the conditions that $\vec{R}_{pq} = -\vec{R}_{qp}$ and $\vec{R}_{qq} = 0$. The momentum balance equation is closed with interphase exchange terms assuming individually the form of a simple phase interaction term given by Eq. (3):

$$\sum_{p=1}^{n} \vec{R}_{pq} = \sum_{p=1}^{n} K_{pq} (\vec{v}_p - \vec{v}_q) \tag{3}$$

where $K_{pq} = K_{qp}$ is the interphase momentum exchange coefficient which is expressed based on the model developed by Attou and Ferschneider, 1999. The interphase coupling terms are written in terms of interstitial velocities and phase volume fractions for gas-liquid, gas-solid and liquid-solid momentum exchange forms as expressed in Eqs (4-6):

$$K_{GL} = \varepsilon_G \left(\frac{E_1 \mu_G (1-\varepsilon_G)^2}{\varepsilon_G^2 d_p^2} \left[\frac{\varepsilon_S}{1-\varepsilon_G} \right]^{2/3} + \frac{E_2 \rho_G (u_G - u_L)(1-\varepsilon_G)}{\varepsilon_G d_p} \left[\frac{\varepsilon_S}{1-\varepsilon_G} \right]^{1/3} \right) \tag{4}$$

$$K_{GS} = \varepsilon_G \left(\frac{E_1 \mu_G (1-\varepsilon_G)^2}{\varepsilon_G^2 d_p^2} \left[\frac{\varepsilon_S}{1-\varepsilon_G} \right]^{2/3} + \frac{E_2 \rho_G u_G (1-\varepsilon_G)}{\varepsilon_G d_p} \left[\frac{\varepsilon_S}{1-\varepsilon_G} \right]^{1/3} \right) \tag{5}$$

$$K_{LS} = \varepsilon_L \left(\frac{E_1 \mu_L \varepsilon_S^{\ 2}}{\varepsilon_L^2 d_p^2} + \frac{E_2 \rho_L u_G \varepsilon_S}{\varepsilon_L d_p} \right) \tag{6}$$

The energy conservation balance for multiphase flow is described by a separate enthalpy equation for each phase as shown in Eq. (7):

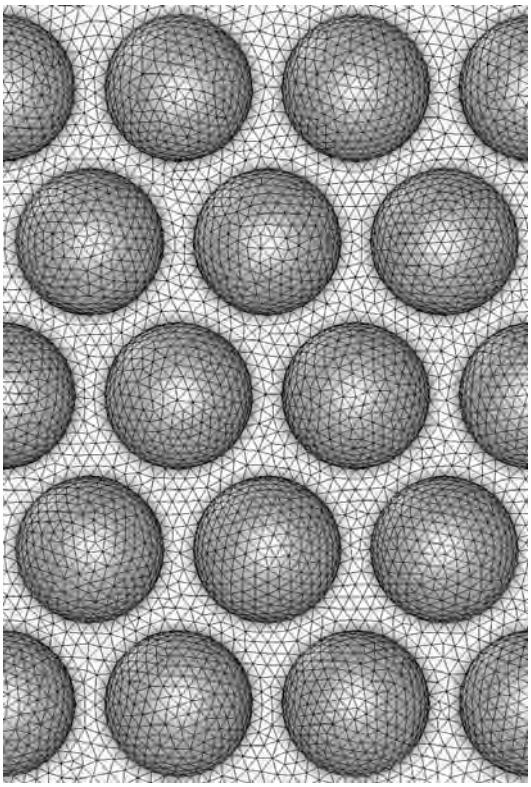
$$\frac{\partial}{\partial t}(\alpha_q \rho_q h_q) + \nabla \cdot (\alpha_q \rho_q \vec{u}_q h_q) =$$
$$-\alpha_q \frac{\partial p_q}{\partial t} + \overline{\overline{\tau}}_q : \nabla \vec{u}_q - \nabla \cdot \vec{q}_q + S_q + \sum_{p=1}^{n} (\vec{Q}_{pq} + \dot{m}_{pq} h_{pq} - \dot{m}_{qp} h_{qp}) \tag{7}$$

Turbulent flows are characterized by fluctuating velocity fields mixing transported quantities such as momentum, energy and species concentration, and cause the transported quantities to fluctuate as well. It was used the *k*-**ε** mixture model which is a semi-empirical model based on model transport equations for the turbulence kinetic energy (*k*) and its dissipation rate (ε) as described for the liquid phase in Eqs. (8-9), respectively.

$$\frac{\partial}{\partial t}(\rho_L \alpha_L k_L) + \nabla \cdot (\rho_L \alpha_L \vec{u}_L k_L) = \nabla \cdot \left(\alpha_L \frac{\mu_{t,L}}{\sigma_k} \nabla k_L \right) + \alpha_L G_{k,L} - \alpha_L \rho_L \varepsilon_L + \alpha_L \rho_L \Pi_{kL} \tag{8}$$

$$\frac{\partial}{\partial t}(\rho_L \alpha_L \varepsilon_L) + \nabla \cdot (\rho_L \alpha_L \vec{u}_L \varepsilon_L) = \nabla \cdot \left(\alpha_L \frac{\mu_{t,L}}{\sigma_\varepsilon} \nabla \varepsilon_L \right) + \alpha_L \frac{\varepsilon_L}{k_L} \times (C_{1\varepsilon} G_{k,L} + C_{2\varepsilon} \rho_L \varepsilon_L) + \alpha_L \rho_L \Pi_{\varepsilon L} \tag{9}$$

The representative computational grid for the experimental system investigated in this work is shown in Fig. 1. It consists of a cylindrical vessel with 5 cm internal diameter and 1 m bed height packed with catalyst spherical particles 2 mm diameter. The catalytic bed is meshed in tetrahedral cells by means of the FLUENT preprocessor GAMBIT 2. The mesh quality was analyzed using the skewness criteria and the results were made to be grid independent. Numerical simulations were compared previously to experimental data in order to validate the predicted hydrodynamic parameters pressure drop and liquid holdup. The simulated operating conditions were 10-30 bar pressure and temperatures from 290 to 500 K. Gas and liquid mass flow rates were in the range 0.10 – 0.70 and 0.05 – 15 kg/m^{2}s, respectively.



The system domain is discretized by an unstructured finite volume method using the CFD solver FLUENT 6.1. The gas flow rate at the distributor is defined via inlet-velocity-type boundary condition with gas volume fraction charging according to the specifications made in the simulations. The flow model is based on solving Navier-Stokes equations for the Eulerian-Eulerian multiphase model along with multiphase *k*-**ε** turbulence model. The governing differential equations are solved using iterative solution to the discrete form of the mathematical model using a PISO algorithm for pressure-velocity coupling with first order implicit formulation for unsteady integration and first order upwind scheme discretization for spatial derivatives. The gas and liquid are described as interpenetrating continua and equations for conservation of mass and momentum are solved for each phase. The transient calculations were made for two-phase flow starting with different time steps and the converged solution is assumed when the scaled residuals of all variables were smaller than 10^{-4}.

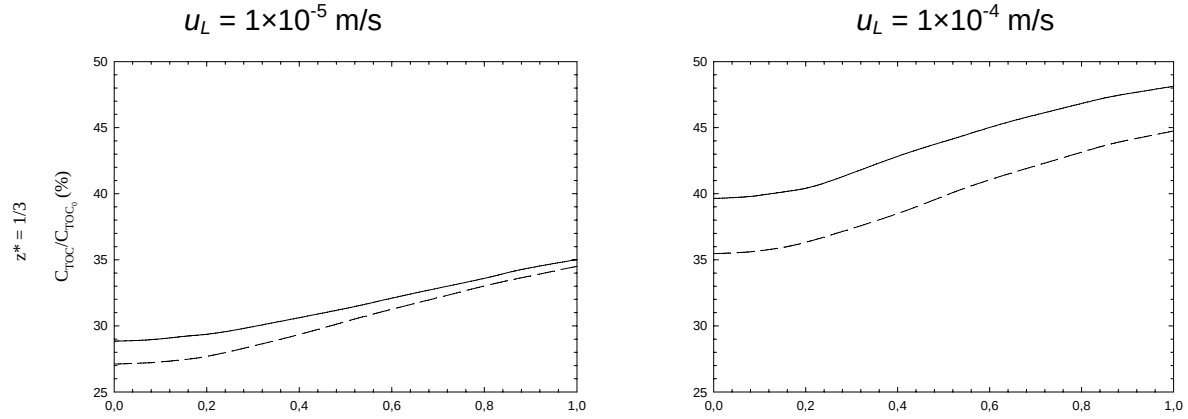
Fig.1 – Tetrahedral mesh used in TBR simulations

3 Results and Discussion

Figure 2 shows the TOC concentration profiles predicted by the CFD model at different relative heights ($z^* = z/H$) for two liquid superficial velocities (u_L) at P = 10 and 30 bar, when the catalytic wet air oxidation is simulated at 200 ºC. Comparing TOC radial profiles at z^* = 1/3, CFD predictions showed that TOC conversion is higher with low liquid superficial velocities (Fig. 2a), as expected. In fact, high liquid velocities correspond to low residence times for the pollutant to be oxidized in the catalyst surface leading to poor decontamination efficiencies in terms of organic carbon removal (Fig. 2b). At the same column height, a ten time increase for the liquid phase shifted the TOC conversion from 71.2 to 60.4% at 10 bar in the reactor centre. At 30 bar, the related shift is from 72.9 to 64.5% of TOC degradation. Therefore, the effect of liquid flow rate seems to have more significance in the TOC conversion rather than the operating pressure. Indeed, at $u_L = 1\times10^{-4}$ m/s, the radial profile for the TOC concentration is more pronounced than with low liquid superficial velocities so that we have a TOC conversion difference of 6.2 and 8.5% at 10 bar between the reactor centre and the wall; at 30 bar this conversion difference became 7.4 and 9.3%.

At the same operating pressures and liquid superficial velocities, TOC concentration profiles are plotted now at z^* = 2/3 in Figs. 2c) and d). According to these plots, the radial TOC concentration was likely to dissipate as we move forward along the packed bed. At $u_L = 1\times10^{-5}$ m/s, the TOC conversion is 90.1 and 90.5% at 10 and 30 bar. As one can conclude, the effect of operating pressure is also vanishing but if we increase the liquid superficial velocity up to 1×10^{-4} m/s, the TOC conversions are 82.9 and 84.9% for 10 and 30 bar, respectively. Hence, the outcome of liquid superficial velocity is still remarkable even at z^* = 2/3. Nevertheless, the conversion difference attained for the reactor centre and the wall is almost insignificant having a minor magnitude of 2.1 and 2.0% for the lowest liquid flow rate and at 10 and 30 bar, whereas at $u_L = 1\times10^{-4}$ m/s the computed differences were 4.2 and 4.9%, respectively.

At the trickle-bed reactor exit (z^* = 1), Figs. 2e) and f) compare the TOC concentration profiles for the bulk phase at the same liquid superficial velocities and operating pressures. As soon as we reach the reactor outlet, the effect of pressure can now be disregarded so that we have roughly the same TOC conversions at 10 and 30 bar, specifically 96.9 and 97.0% at $u_L = 1\times10^{-5}$ m/s, respectively. If we operate at $u_L = 1\times10^{-4}$ m/s, its influence is also negligible being the corresponding TOC conversions of 90.2 and 91.0% at 10 and 30 bar. Moreover, the radial TOC concentration profile obtained at $u_L = 1\times10^{-5}$ m/s for z^* = 1 showed that we have closely no conversion differences between the centre and the reactor wall: 0.6 and 0.7% TOC for 10 and 30 bar. As a matter of fact, only 2.2 and 2.4% of TOC conversion difference was computed for 10 and 30 bar between the reactor wall and centre when operated at the highest liquid superficial velocity, $u_L = 1\times10^{-4}$ m/s.



a) b)

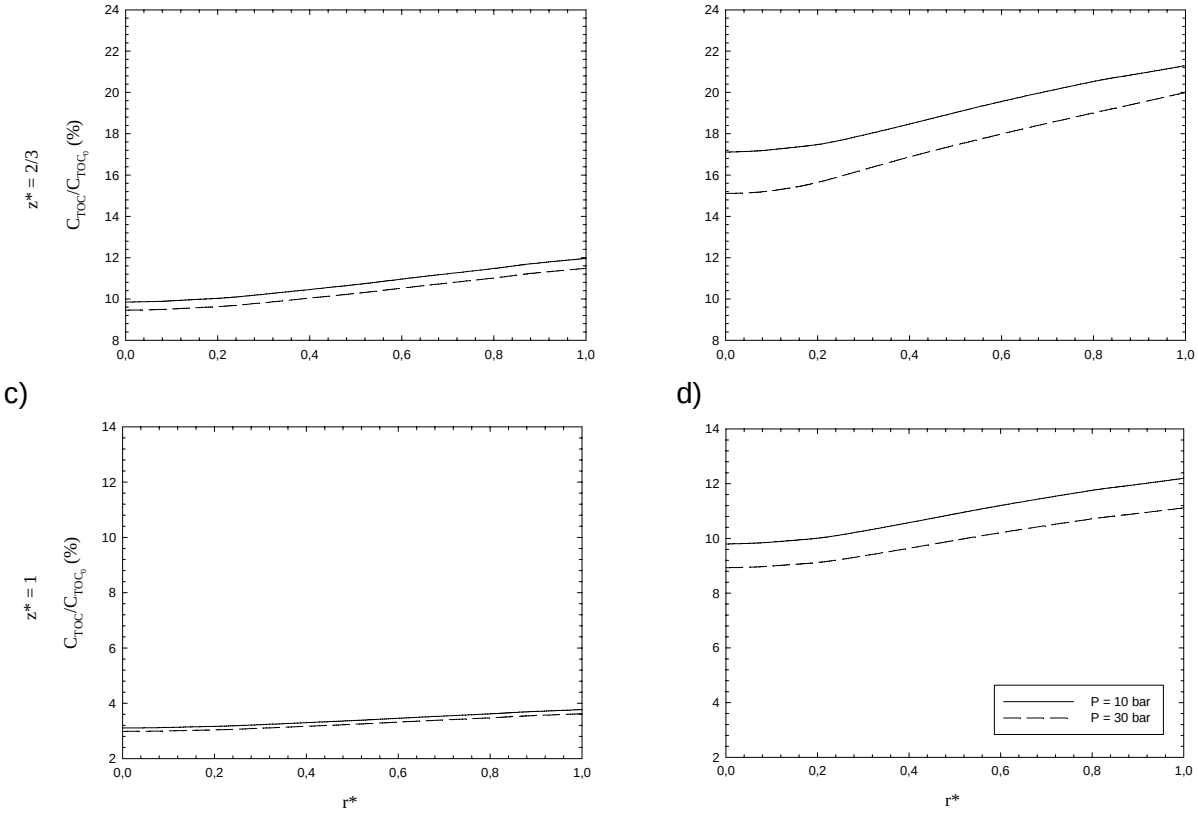


Fig. 2 – Radial profiles of dimensionless Total Organic Carbon concentration at different bed heights for different liquid flow superficial velocities and isobaric operating conditions (*T* = 200 ºC)

In Fig. 3 it is shown the TOC degradation in steady-state for an isometric view of twenty-five catalytic layers, radially.

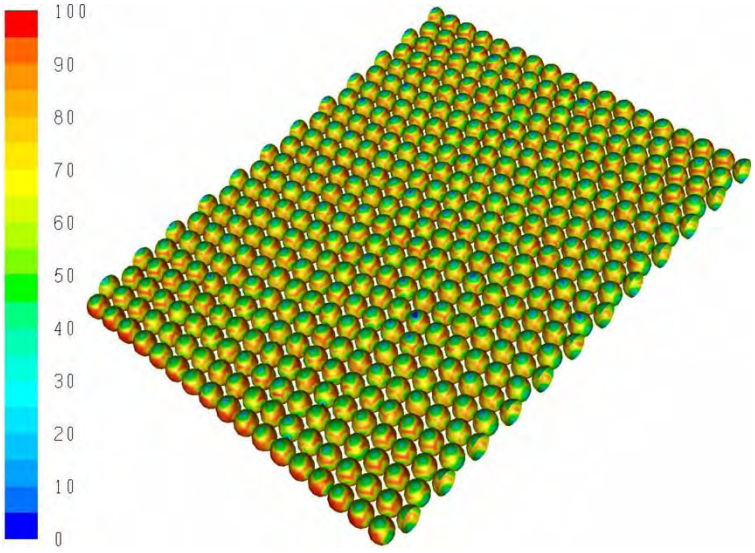

Fig. 3 – Total Organic Carbon degradation map for 25 catalytic layers in steady-state

According to Fig. 3, it is possible to detect different TOC concentration profiles in the catalyst surface corresponding to different oxidation rates. This fact is related to the liquid holdup distribution achieved in the trickle-flow regime so that different wetting levels can be detected, which can cause insufficient reactant or pollutant feeding to the catalyst surface. This fact can be further evaluated in terms of liquid and gas distribution with interface

tracking methods. In a broad range of gas and liquid flows studied at different operation conditions, CFD demonstrated the considerable effect of temperature, pressure, gas-liquid flows in the catalytic wet air oxidation of phenolic wastwaters (Lopes and Quinta-Ferreira, 2007b) evaluating the ultimate axial TOC conversion attained for the trickle-bed reactor.

Therefore, the Euler-Euler multiphase model is a promising tool and a rational choice for flow simulation in packed beds, if good closures for fluid/fluid and fluid/particle interactions are incorporated in the hydrodynamic model. The CFD approach can state that external catalyst wetting can be investigated in downflow flow mode performing a benchmark of reaction parameters encountered in the commercial-scale TBR deployment for CWAO technology.

4 Conclusions

This work is devoted to the performance evaluation of trickle-bed reactor designed for advanced wastewater treatment. A computational flow model based on Euler-Euler two-fluid treatment was developed for the simulation of catalytic wet air oxidation in the multiphase flow reactor. Interphase coupling exchange terms were integrated in the momentum balance equation providing a hydrodynamic model for the computation of total organic carbon concentration profiles at different bed heights.

CFD predictions demonstrated considerable radial profiles mainly at low axial coordinates. The model was used to investigate the effect of operating pressure and liquid superficial velocities in the organic carbon removal of a simulated phenolic wastewater. Several computational runs showed that operating pressure had small influence when compared with different liquid flow rates in the TOC degradation of syringic acid. Moreover, the operating pressure is only relevant for low axial coordinates whilst the liquid flow rate effect is always responsible for significant differences of TOC removal efficiencies and extensive radial profiles.

Finally, the Eulerian model was used to investigate the catalyst wetting efficiency reported indirectly by different TOC degradation rates. The catalyst surface map revealed likely the existence of trickling flow conditions under unsteady-state operation mode.

Topic: Integration of life sciences & engineering

Abstract

For the discrimination of water molecules during the drying process of a squid, multifunctional water molecules were separately characterized by water proton-NMR and moisture diffusivity (*De*) analysis methods as a function of the moisture content (W_0). The proton-NMR spectrum showed the appearance of three peaks at the specified chemical shifts with different ppm's, indicating three different species (species-A, -B, and -C) distributed in the squid muscle, each of which had a characteristic behavior of the correlation time (τ_C) as a function of the W_0. The modified moisture content linearly increased in the whole range of W_0 for species-A suggesting that it can be attributed to water species. Species-C showed no change without depending on W_0, indicating a characteristic species different from the water species. Species-B was difficult to be assigned to any species without a presumption as some hydrogen species binding with protein molecules.

The τ_C of species-A was drastically varied at W_0 = 120%-d.b., indicating two further categories, i.e., species-A_1 and -A_2, depending on the dehydration degree. For species-A_1 at W_0 > 120%-d.b. (region I), the τ_C was 4.8×10^{-9}s independently of the W_0, whereas, for species-A_2 at W_0 < 120%-d.b. (region II), the τ_C decreased from 1.2×10^{-7} to 1.0×10^{-8} s with increasing the W_0. Species-A_1 and -A_2 were further examined by *De* analysis. For species-A_1, *De* and the activation energy of moisture diffusivity (E_D), respectively, indicated identical values of 1.8×10^{-6} m^2/h and 17 kJ/mol, without depending on the W_0 in the range of W_0 =120 ~ 360%-d.b. (region I). For species-A_2, the two parameters clearly varied as $De = 1.7\times10^{-6}$ ~ 0.6×10^{-6} m^2/h and E_D = 25 ~ 35 kJ/mol, with decreasing the W_0 from 120 to 30%-d.b. (region II). Species-A_1 and -A_2 were assigned as free water and slightly restricted water, respectively.

Species-C was accurately assigned as a lipid by relating to the spectra of proton NMR spectroscopy of squid-liver lipid.

1 Introduction

Many researchers have attempted to evaluate multifunctional water species in biomaterials. Various results have been reported so far because of the dynamic variation of water species depending on the kind of biomaterials and the experimental conditions, especially with regard to their dehydration degree. To evaluate the states of water molecules, physicochemical analysis has generally been applied for various biomaterials. Caurie (1971) and Rockland and Nishi (1980) classified the water species of food products into physisorbed and chemisorbed water by the model of adsorption isotherms. Lichfield and Okos (1992)

* Corresponding author. Tel + 81-138-34-2600. E-mail:konishi@techakodate.or.jp

reported gaseous water and liquid water in pasta based on the variation of diffusivity (*De*). In previous papers by our group (Konishi *et al.* 2001; Konishi & Kobayashi 2003), two water species were demonstrated as weakly restricted and strongly restricted water by using the dynamic behavior of *De* .

For a more direct identification of the water species, the ^{1}H-NMR method has frequently been used (Yoshikawa & Ohsaka 1980). Bodurka *et al.* (1996) demonstrated free water and bound water in the rabbit lenses based on the relaxation time difference of the water species. Miedziejko *et al.* (1996) distinguished free water and bound water in a triticale seed cell based on the time assessment of ^{1}H-NMR spin-spin relaxation. Almost all results reported have been under static conditions, even though the water species dynamically shift depending on the moisture contents and situation. For a further identification of the water species, a dynamic analysis under a dehydration operation should be conducted.

In the present study, by using the dynamic analysis of the ^{1}H-NMR with effective diffusivity (*De)* analysis, the objectives sought were (1) to quantitatively discriminate the water species by the ^{1}H-NMR method in a wide range of moisture contents (W_0) and to reconfirm the reproducibility due to the dehydration and hydration operations; and (2) to additionally classify the water species by the dynamic behaviour of *De*.

2. Experimental

A Japanese common squid (50mm square and 8±1.5mm in thickness, initial moisture content of 300 ~ 360%-d.b. (dry base, W_D)) was used as a model sample. Drying air with a flow rate of 0.7m/s was introduced into a drying room passing through a rectifiable compartment without regulating the humidity. The drying temperature was electrically controlled within ±2ºC at given temperatures. The sample was placed in a stainless steel net basket (10 meshes) that was mechanically hung from a strain gage transducer in the dryer. During the drying process, a poultice-up process (designated as PUP) was operated to keep the moisture distribution in the squid sample uniform. For the PUP, the samples were stored in an incubator for 36h, the temperature of which was regulated at 2°C. The PUP was operated at a given moisture content (W_0) in the range of 15 ~ 285%-d.b. The sample weight was continuously recorded by the output of a strain-gage transducer using a data-logger. Thirty, 40, and 50°C were chosen as the drying temperatures (T_D). In the present drying conditions, it was previously reconfirmed that all the drying operations for the squid were within a falling-rate period. The diffusivity (*De*) of a sample at given moisture content was evaluated by

$$\frac{W - We}{W_D - We} = \left(\frac{8}{\pi^2}\right)^3 exp\left(\frac{-\pi^2 \cdot De \cdot t}{4} \cdot \left(L_a^{-2} + L_b^{-2} + L_c^{-2}\right)\right) \cdots (1)$$

where W is the moisture content at the drying time t, We is the equilibrium moisture content, W_D is the initial moisture content of a drying fresh sample, t is the drying time, and L_a, L_b, and L_c are the half-distances of the sample width.

For the characterization of the moisture species in the squid, a nuclear magnetic resonance (NMR) technique was used to measure the ^{1}H-NMR spectra and a spin-spin relaxation time (T_2) of water protons. Squid samples cut into 2×2×10mm pieces were inserted into an NMR sample tube (4mm in inner diameter and 180mm in length). ^{1}H-NMR spectra were obtained using a JEOL A-500 FT-NMR spectrometer operating at 500MHz for protons. The observed frequency width was 20 kHz. The 90º pulse width was 12.5 *μs*, and the number of pulse repetitions was 8. The proton chemical shifts were measured by using a slight amount of water containing deuterium oxide as an external reference. All the NMR measurements were performed at 23.5±0.5ºC. The spin-spin relaxation times, T_2, were obtained by the CPMG method and from the obtained T_2, the correlation time of a water

proton, τ_C , was evaluated.

For the readsoption of water, the dried sample was stored into a humidifier for a given time; the temperature and humidity of the humidifier were regulated at 23.5±0.5ºC and 90±5% respectively. The W_0 for the water-readsorbed sample was controlled by the storage time in the humidifier.

Further detailed experimental procedures and the evaluation details of *De* have been presented elsewhere (Konishi *et al*. 2001).

3. Results and Discussion

3.1. Dynamic Multiplicity of Water Species Distinguished by the ^{1}H-NMR Method

3.1.1. Dynamic Behavior of the Spectra of Proton NMR Spectroscopy for Fresh Squid Muscle

As has been demonstrated by many researchers (Miwa *et al*. 2003; Lechert 1981; Barara *et al.* 1999; Labbé *et al.* 2002), water species in solid materials are classified into various restricted strengths based on physicochemical data, indicating physisorbed, chemisorbed, strongly restricted, and weakly restricted water. In a previous study (Konishi *et al*. 2001), two different types of water species were distinguished in a fish paste sausage. One was a strongly restricted water species characterized by a lower *De*, and the other was a weakly restricted water species with a higher *De*. Our attention is focused on a more direct identification of water species retained in foods by using the ^{1}H-NMR method.

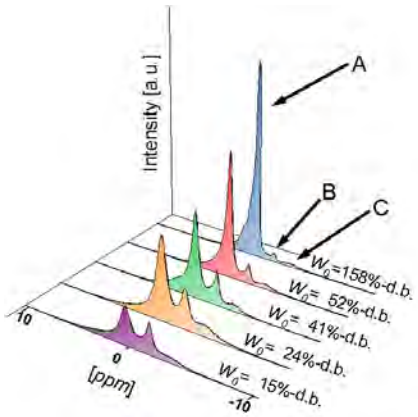

Fig.1 Dynamic behavior of ^{1}H-NMR spectra for species-A, -B, and -C in the squid muscle in the course of a drying operation

Figure 1 is an illustration of a typical example for the ^{1}H-NMR spectrum of the squid muscle with W_0 = 41%-d.b. Three peaks can be clearly recognized, indicating three different proton species, named species-A, -B, and -C, each of which has a different ppm value, 0.42, -1.43, and -3.14ppm, respectively. Our interest focuses on a characterization of the three species based on the dynamic behavior of each species in the course of a drying operation. The peak height of species-A drastically decreased, and that of species-B gradually decreased with the progress of dehydration, whereas species-C indicated no change. The individual behavior strongly indicates that the three species have their own characteristics with different natures and states, as demonstrated in the following sections.

3.1.2. Characterization of Species-C

For the assignment of species-C, two additional experiments were conducted. First, the ^{1}H-NMR spectra of squid liver lipid were effectively used. Figure 2(A) illustrates the dynamic behavior of ^{1}H-NMR spectra influenced by the squid liver lipid. The peak at the chemical shift of -3.37ppm clearly increased with increasing the dipping time into the lipid. Second, ^{1}H-NMR spectra of

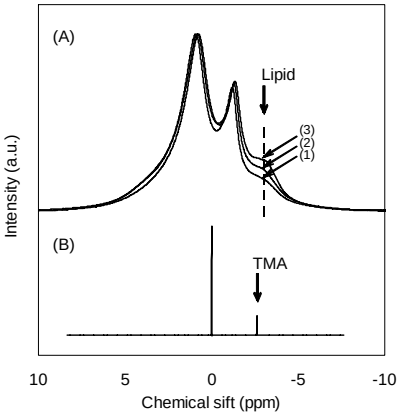

Fig.2(A)NMR spectra of squid muscle influenced by dipping into the squid liver lipid for (1) zero, (2) 1 and (3) 24 hrs, (B)Spectrum of proton NMR spectroscopy of the 30% TMA solution.

trimethylamine (TMA) were compared, as shown in Fig. 2(B). The peak of TMA exactly indicated that the chemical shift of -2.62ppm different from that of species-C. This chemical shift was consistent with the results proposed by Toussaint *et al.* and Howell *et al.* (Toussaint *et al.* 2002; Howell *et al.* 1996). These two pieces of evidence strongly demonstrate that species-C can be attributed to a lipid and not TMA.

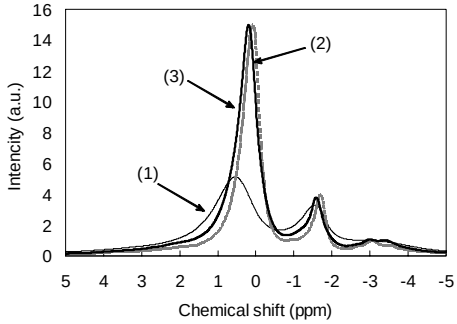

Fig.3 Reproduced dynamic behavior of ^{1}H-NMR spectra for species-A, -B and -C in the squid muscle derived from a dehydration and water re-hydration operations: (1)under the drying operation at W_0 = 18%-d.b., (2) after the re-hydration of water for sample (1) up to W_0 = 45%-d.b. and (3) under the drying operation at W_0 = 45%-d.b.

3.1.3. Reproduced Dynamic Behavior of Species-A Due to the Readsorption of Water

The reproducibility of species-A due to the removal and readsoption of water moisture is important evidence to reconfirm whether or not species-A result from dehydration and water addition. Figure 3 is an illustration of the dynamic behavior of the ^{1}H-NMR spectra for the species-A due to the repeated operation of dehydration up to W_0 = 18%-d.b. (curve (1)) and re-hydration from W_0 = 18%-d.b. up to W_0 = 45%-d.b. (curve (2)). Curve (3) is obtained in a continuous drying operation. Comparing curves (1) and (2) with curve (3), the exact reproducibility of the species-A can be appreciated, suggesting that species-A is the result of the water moisture retained in the squid muscle.

The reproducibility of species-A can be recognized again by further evidence, namely, the τ_C-dynamic behavior due to the repeated operation of dehydration and water readsorption. Figure 4 is an illustration of the dynamic behavior of τ_C for species-A as a function of the W_0 due to the readsorption of water in comparison with a continuous drying operation (broken curve (a)). All the readsorption curves (solid lines) nearly follow the continuous dehydration curves (broken line). All the readsorption data fall on a continuous drying curve of the broken line. The good reproducibility obtained again demonstrates that species-A is due to water moisture retained in the squid muscle.

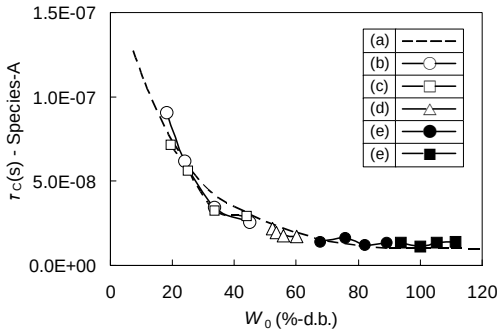

Fig.4 Reproducibility of τ_C(species-A) observed between the dehydration and the water-readsorption operations: (a) under the continuous drying operation from W_0 = 120%-d.b. to 10%-d.b., (b) after the gradual readsorption of water from W_0 = 18%-d.b. to W_0 = 45%-d.b., (c) from W_0 = 20%-d.b. to W_0 = 44%-d.b., (d) from W_0 = 50%-d.b. to W_0 =60%-d.b., (e) from W_0 = 68%-d.b. to W_0 = 89%-d.b. and (f) from W_0 = 94%-d.b. to W_0 = 111%-d.b.

3.2. Further Discrimination of the Water Species

3.2.1. Discrimination of Water Species-A by τ_C

As pointed out in Fig.3, species-A has a good reproducibility due to the dehydration and the readsorption of moisture. Based on this characteristic behaviour, it could be assumed that species-A should mainly contribute to the dehydration of squid muscle. Focusing on whether or not species-A consists of one species of water molecule, a further discrimination of species-A can be attempted. Figure 5 illustrates the τ_C as a function of the W_0. The τ_C-W_0 curve obtained

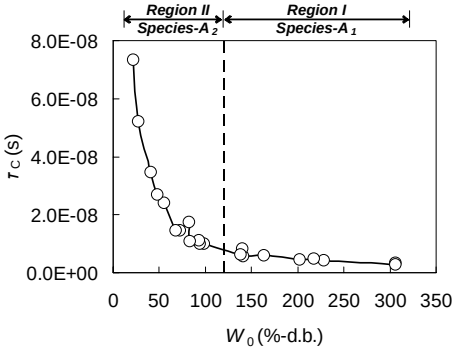

Fig.5 Discrimination of species-A_1 and -A_2 recognized by τ_C-W_0 dependency

is clearly divided into two regions, I and II, at W_0 = 120%-d.b., a slight decrease for region I at W_0 >120%-d.b. and a steep decrease for region II at W_0 <120%-d.b. This characteristic difference between regions I and II strongly indicates, at least, two different water species, species-A_1 and -A_2, respectively. Since a higher τ_C means a larger restriction strength, species-A_1 may be assumed to be a free-water species and species-A_2, a weakly restricted-water species.

3.2.2. Discrimination of Water Species-A by Moisture Diffusivity (De)

For further discrimination of species-A_1 and -A_2, the moisture diffusivity (*De*) during the drying operation can be proposed as a possible parameter for water moisture mobility. Figure 6 is an illustration of the *De* as a function of the W_0. Two regions can again be recognized, indicating a constant *De* as $1.8\pm0.1\times10^{-6}$m^2/h at W_0 >120%-d.b. for region I and a steep increase of *De* from 0.6×10^{-6} to 1.7×10^{-6}m^2/h at W_0 <120%-d.b. for region II. Thus, two species can be recognized as species-A_1 and -A_2 based on the moisture mobility evaluated by *De*. Species-A_1 gives identical mobility without depending on the W_0, whereas species-A_2 indicates a linear increase of *De* with increasing the W_0.

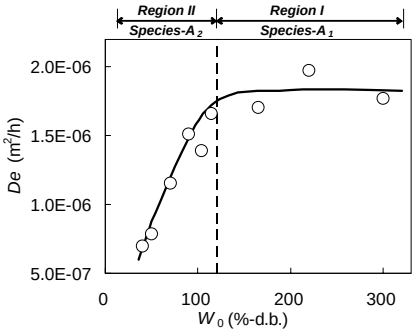

Fig.6 Discrimination of species-A_1 and -A_2 recognized by *De*-W_0 dependency

From the viewpoint of the mobile energy of diffusion water molecules, the activation energy (E_D) for the moisture diffusivity can be considered. Figure 7 is an illustration of the E_D as a function of the W_0. Again, the result indicates two regions, I and II. In region I, the moisture diffusivity has an identical activation energy, E_D = 17±0.2 kJ/mol, whereas region II exhibits a steep increase of E_D from 25 to 35 kJ/mol with decreasing the W_0. Again, species-A_1 and -A_2 can be recognized as corresponding to regions I and II, respectively. The diffusion activation energy of species-A_2 steeply increases with the progress of dehydration. Taking this result into account with the steep decrease of *De* in Fig. 6, the diffusion difficulty of species-A_2 is dynamically accelerated by the decrease in the W_0.

The question of how the obtained water moisture mobility can be related to the water molecules evaluated by the ^{1}H-NMR method is intriguing. Focusing the τ_C as a function of the E_D. using Figs.5 and 7, one may understand that species-A_1 gives identical E_D = 17±0.2 kJ/mol and $\tau_C = 4.8\pm1.5\times10^{-9}$ s, whereas species-A_2 indicates a linear increase of the τ_C with increasing the E_D. From these results, it is evident that species-A_1 has an identical τ_C and E_D in region I and that species-A_2 exhibits a linear increase of E_D and τ_C with the progress of dehydration in region II. In conclusion, the higher τ_C (higher restriction) contributes to the higher mobile energy.

Based on the large number of data obtained for *De*, E_D and τ_C and their reproducibility, two different states may be reasonably proposed, namely, free water (species-A_1) and weakly restricted water (species-A_2). Further identification of the two species, however, is hardly warranted by the present experimental data.

On the characterization of species-B, we have no any evidences to evaluate physicochemical nature except some presumption as a proton species retained by protein molecules.

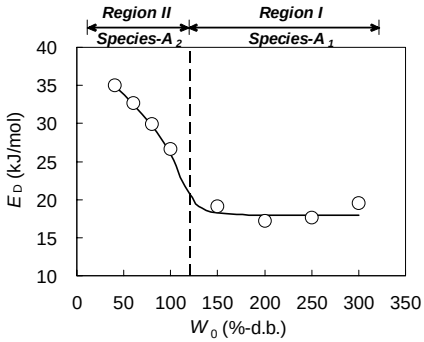

Fig.7 Discrimination of species-A_1 and -A_2 recognized by E_D-W_0 dependency

4. Conclusions

The dynamic behavior of water moisture retained in squid muscle under a drying operation was characterized in detail by the correlation time (τ_C) of the ^{1}H-NMR method accompanied with the dynamic change of the moisture diffusivity (*De*) and the activation energy (E_D) of the diffusivity, as a function of moisture content (W_0). The water species was clearly classified into two different species, i.e., species-A_1 and -A_2. The two species were characterized as follows: (1) species-A_1 has identical *De*, E_D,and τ_C and is named as free water at W_0 >120%-d.b., (2) species-A_2 shows a steep increase of E_D, T_P, and τ_C, at W_0 <120%-d.b., in contrast to the steep decrease of *De* with decreasing the W_0, and is classified as weakly restricted water.

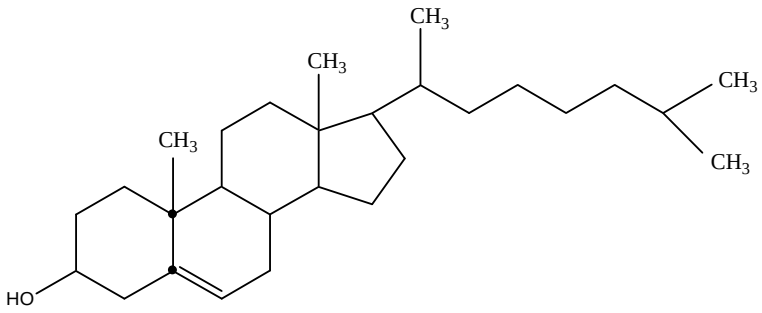
Keywords: Cholesterol; Triacylglycerides; Phospholipids; Nanofiltration
Topic: Advancing the chemical and biological engineering fundamentals

Abstract

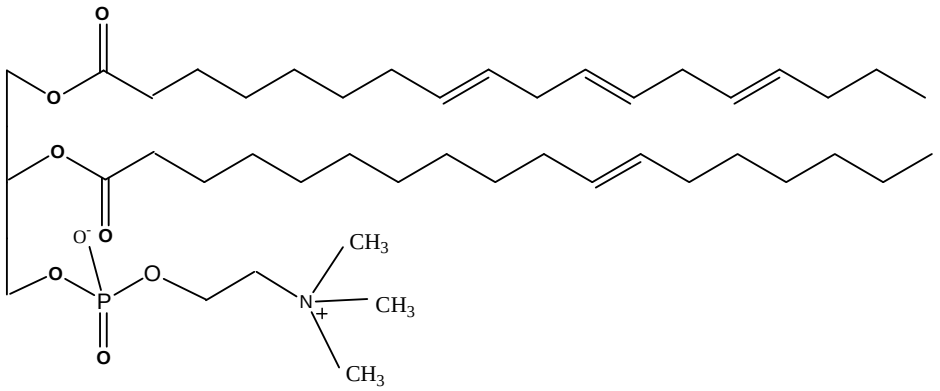
Three components of the egg yolk which are extracted in ethanolic solution are interesting in the field of the nutritional supplements. These three components are triacylglycerides (65%, w/w), glycerophospholipids (28%, w/w) and cholesterol (5%, w/w). This work is in relation with the separation of interesting components using membrane processing. The first components to be separated is the cholesterol because of its relationship with cardiovascular disease. This has been done by nanofiltration which is a technique able to separate compounds which molecular weights range between 200 to 2000 $g.mol^{-1}$. Differents nanofiltration membranes have been tested, with different cut off. Only a little influence on the separation has been notices with these different membranes. Then, the best separation conditions have been determined with the best membrane.

1 Introduction

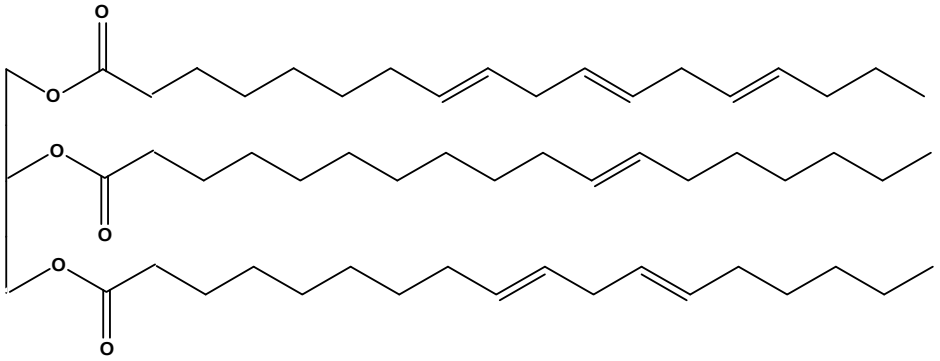
The lipids contained in egg yolk are principally triacylglycerides (65%, w/w), glycerophospholipids (28%, w/w) and cholesterol (5%, w/w). The structure of these compounds are presented in figure 1. A more or less selective extraction of these lipids can be performed using various organic solvents such as diethyl ether, methyl chloride, ethyl acetate, propane/butane, hexane, benzene, ethanol (Tokarska and Clandinin, 1985) or supercritical CO_2 in the presence or the absence of ethanol (Rossi et al., 1990). In our case, after extraction, these products were recovered in 95% ethanol. The lipid concentration in ethanol ranged from 3 to 15%, w/w. The lipids present in the ethanol were glycerophospholipids (760 $g.mol^{-1}$), 80%, and a mixture of cholesterol (386.7 $g.mol^{-1}$) and triacylglycerides (860 $g.mol^{-1}$), 20%.



CHOLESTEROL



PHOSPHOLIPIDS



TRIACYLGLYCERIDES

Figure 1: Compounds structures

Glycerophospholipids contain fatty acids that can be highly polyunsaturated. They can thus be considered as a source of essential fatty acids in C18 or conditionally essential fatty acids in C20 or C22 for the families of ω6 (molecules composed of a polyunsaturated carbon chain with two or more double bonds, the first double bond being located on the 6th carbon atom from the terminal methyl) and ω3 (the first double bond is located on the 3rd carbon atom). Thanks to their surface-active properties, glycerophospholipids, once completely purified, can be used in the preparation of emulsions of lipids in water used in the fabrication of food additives or even pharmaceuticals. For these applications, the amount of cholesterol in egg yolk is a problem. Cholesterol ingestion can increase cholesterol concentration in the blood, which is a marker linked to the risk of arteriosclerosis and coronary diseases. It is therefore of interest to eliminate the cholesterol from the lipids extracted from egg yolk.

2 Material and methods

The solutions to treat results from ethanolic extraction of the egg yolk lipids contained in egg yolk powder. The solution are purified by filtration. These real solutions have been used for separation of cholestorerol because synthetic solutions can have some different behaviour due to the variety of compounds in the real solutions.

The pilot plant we used (Figure 2) allowed us to work on membranes with an industrial elementary surface and to collect results for easy scaling up. The installation consists of a 25 L metapolyacrylate tank (A) containing the feed solution. This tank is connected to the membrane module D by a feed line 2 made of stainless steel and its temperature is regulated by a heat exchanger. This feed line consists of a high-pressure pump B equipped with a variator. The retentate is recovered through circuit 3. On its way back to tank A, it passes

through a regulating valve E. In order to keep the initial solution volume constant and to prevent possible fouling of the membrane, ethanol may be added to tank A at a flow rate equal to that of the permeate flux (diafiltration step). This ethanol is taken from tank G and is maintained at the same temperature T as that of the fluid circulating in 2. It is fed into tank A by means of a pump F through circuit 4 in which two pressure detectors P1 and P2 allow measurement of the pressure drop (ΔP = P1 - P2) and transmembrane pressure (TMP = (P1 + P2)/2). The diafiltration step (addition of ethanol from tank G) is stopped when the concentration of cholesterol in tank A reaches a value corresponding to the minimum concentration of cholesterol desired and the filtration operation goes on, which is expressed by the variation of triacylglyceride and phospholipid concentrations in the retentate A. When the dead volume of the plant is reached (0.5 L), the nanofiltration operation is stopped. After every operation the membrane is rinsed with ethanol.

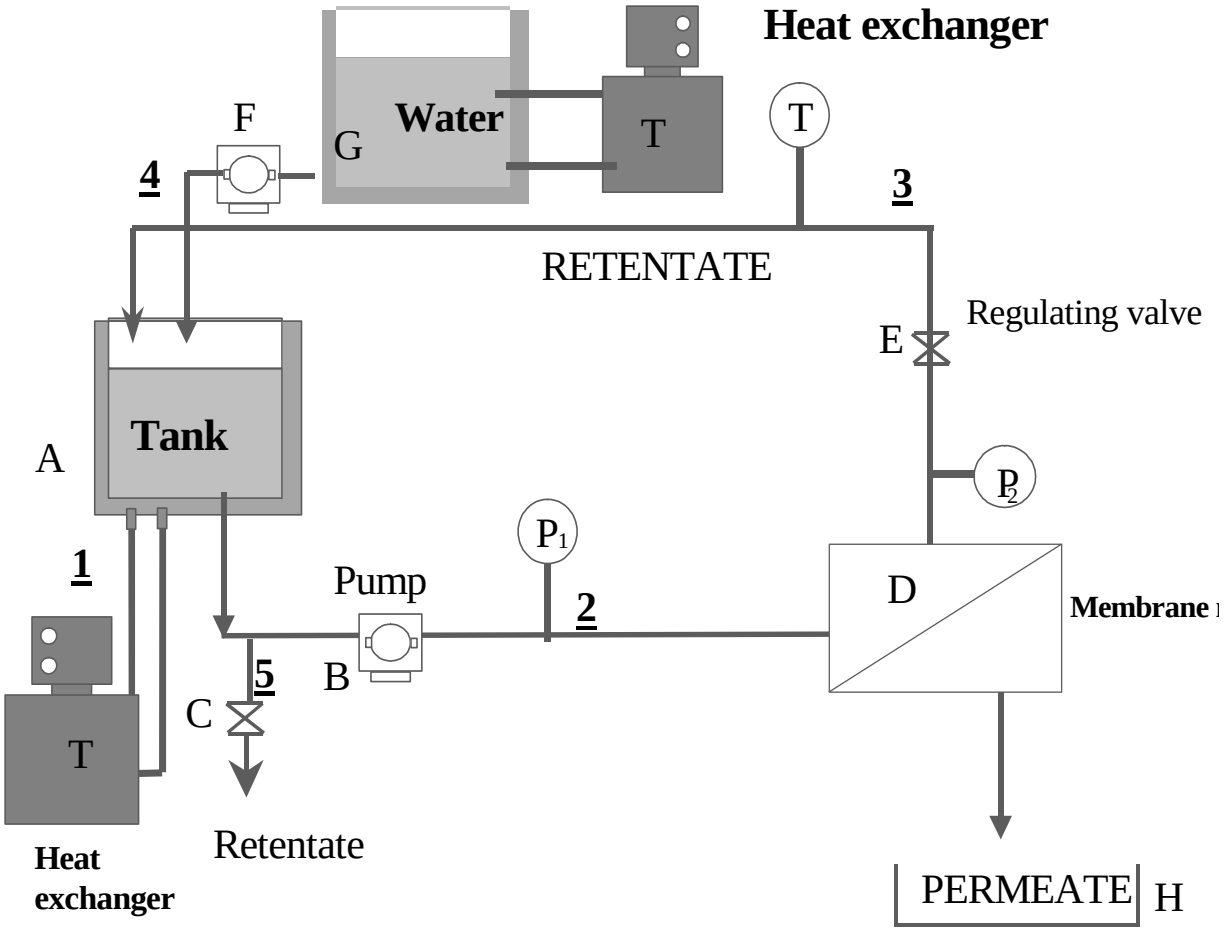


Figure 2: Pilot plant

For each separation (different membranes and operating conditions) samples of permeate and retentate are simultaneously collected for analysis. The retention factor RF of each compound was calculated from the analysis following the relation (1):

$$RF = (1-Cp/Cr) \times 100 \qquad (1)$$

with RF the retention factor (%), Cp the concentration in the permeate ($g.L^{-1}$) and Cr the concentration in the retentate ($g.L^{-1}$) at the same time.

3 Results and discussion

No information was found in the literature that would help estimate the performances of filtration or even of membrane processes for the separation of this type of mixture. In view of the size of the compounds, we decided to use a process of nanofiltration. However, the initial mixture was complex and the treatment was made difficult by the following: (i) The molecular weights of the compounds were quite similar: 386.7 $g.mol^{-1}$ for cholesterol, between 850 and 1020 $g.mol^{-1}$ for triacylglycerides and between 760 and 878 $g.mol^{-1}$ for phospholipids, (ii) The solution was ethanolic. The stability of a membrane in an organic solvent such as ethanol depends on the physicochemical characteristics of the solvent and of the membrane. The membrane-solvent interaction may result in swelling, plasticization or dissolution of the membrane material and subsequent loosening of the membrane structure, leading to modified separation properties and/or loss of mechanical strength under pressure. Besides, the cut-off of a membrane determined in aqueous solutions (e.g., as provided by the manufacturer) is insufficient to characterize its Molecular Weight Cut Off ($g.mol^{-1}$) (MWCO) in organic solutions. The MWCO of a membrane varies depending on the solute and the solvent. Tsui et al. (2004) reported that low lipid rejection could be due to lipid-membrane interactions that cause plasticization of the polymer, leading to membrane swelling and reduced lipid rejection.

The aim of this work was the fractionation of a complex and real ethanolic solution. The membrane cut-off could not be taken as the main criterion for the selection of the best membrane, and this for several reasons: the molecular weights of the different compounds were similar and the membrane cut-offs were defined by each manufacturer according to a specific protocol. Moreover even if these cut-offs had been more precisely defined, extrapolating to organic solutions would have been hazardous. It is very difficult to take into account the effects of the electric charges in an ethanolic medium, and no information is available concerning the membrane behaviour with regard to an alcoholic medium. However, we clearly showed that fractionation was possible with a cellulose acetate membrane. We selected a cellulose triacetate membrane (CK 2540 F 30D, from the firm Osmonics), with an area of 2.5 m2 and a cut-off of 350 Da for an industrial experiment. This membrane was selected because cellulose acetate is a hydrogen bond acceptor and cholesterol is the only one of the three compounds to contain a hydrogen bond.

We studied the influence of some operating parameters on the permeate flux and defined the optimum conditions of transmembrane pressure and flow rate (figure 3): for a constant TMP, if the flow rate decreases, the permeate flow rate decreases. The membrane is well regenerated after each experiment with a simple wash with pure ethanol. The variation of the retention coefficient as a function of the concentration leads us to consider that the upstream solution has a kind of “organisation” which constitutes an important resistance to mass transfer. The cholesterol being the problem, the possibility to separate this compound by an appropriate membrane is an important breakthrough in the domain of nutraceutics and nutritional supplements.

The cholesterol has been removed from the ternary mixture as it is shown in figure 4. The permeation of cholesterol compared to phospholipids is better for low concentration (during the diafiltration step, figure 5). So by having a longer diafiltration step, the removal of cholesterol will be achieved and the losses in phospholipids (5%) were limited. However, in view of the results obtained, increasing the diafiltration time will enable us to reach our objective of 80% of cholesterol removal. Actually, the diafiltration time should be 5 times the space time if the retentate is well mixed which is not our case. On the other hand a too long diafiltration will drives to important losses in phospholipids. Some experiments have to be done to have the optimal time and conditions for the diafiltration step.

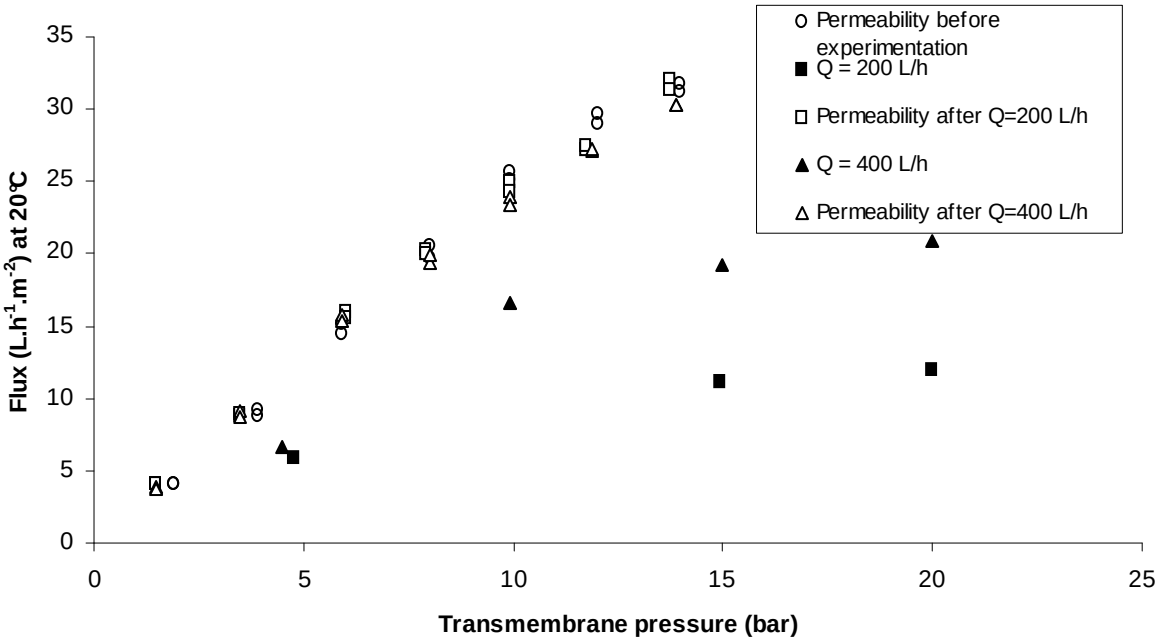

Figure 3: Variation of the permeate flux as a function of the transmembrane pressure for different flow rates (T_{ave} = 20°C, V_0 = 5 L)

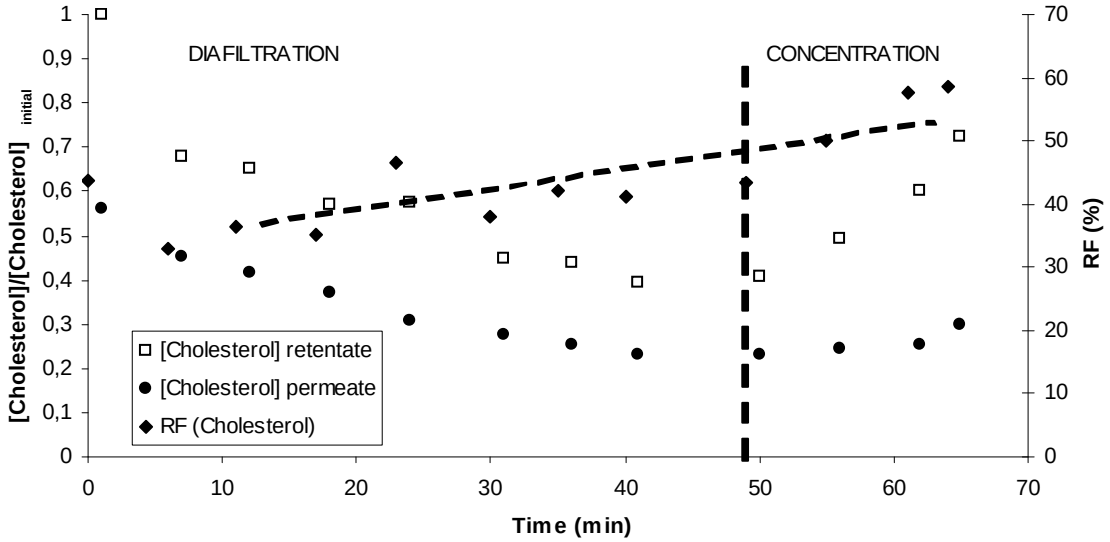

Figure 4: Variation of the cholesterol concentration and retention factor versus time (T_{ave} = 20°C, TMP = 15 bar, Q= 300-350 L.h^{-1}, V_0 = 15 L)

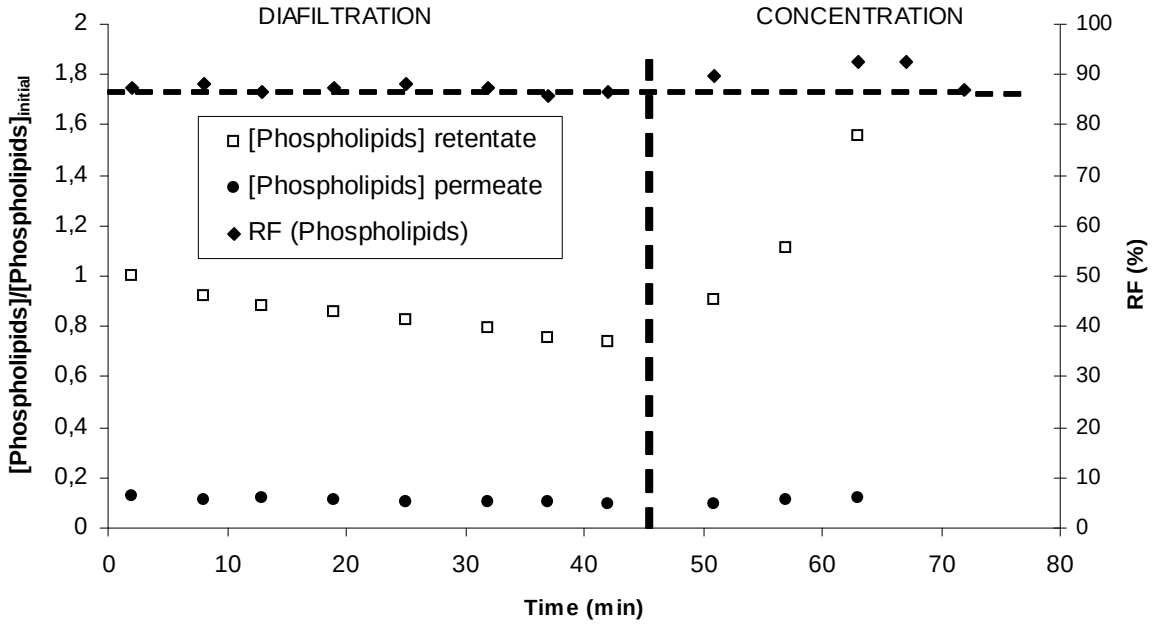

Figure 5: Variation of the phospholipids concentration and retention factor versus time (T_{ave} = 20°C, TMP = 15 bar, Q = 300-350 $L.h^{-1}$, V_0 = 15 L)

Conclusion

The nanofiltration has been tested in this study to eliminate cholesterol from egg yolk in ethanolic solution in order to make nutritional supplements. This method was efficient because the cholesterol has been removed and the losses of other products of interest have been limited. This separation technique is also very interesting for this industry area because of the safety of these processes. This process can be used for a lot of other separations in paraphamaceutical or pharmaceutical industries. It could be used to eliminated an unwished or dangerous product, as in our case, but it also could be used to recycle active substance. Going further in the field of nanofiltration in organic solvent, it will be necessary to test others solvents than ethanol and to understand in deep the interactions solvent membranes.

Topic: Advancing the chemical and biological engineering fundamentals

Abstract

In this work, the extraction of beer aroma compounds by pervaporation was studied, using polyoctylmethylsiloxane/polyetherimide (POMS/PEI) composite asymmetric membranes. A design of experiments, using a response surface methodology (RSM), was applied to obtain the hyper-surface of the process responses. The process factors or independent variables selected were the feed temperature, feed velocity and permeate pressure, while the process responses were the permeate flux, the selectivity towards selected aroma compounds (high alcohols and esters) and the relationship between the concentration of these class of aromas in the permeate. RSM methods generate polynomial models that relate the operation conditions and the process responses, which are thus useful for predicting purposes or for processes optimization. A good agreement between the experimental results and the predicted values was observed, therefore allowing process optimization that was experimentally validated.

1 Introduction

Beer aroma profile is constituted by many volatile organic compounds at very low concentration (ppm level), which are responsible for its flavour. Compounds from several chemical groups, such as alcohols, esters, aldehydes, lactones, carboxylic acids, phenols and ethers, can be found on beer composition, imparting it a particular flavour. For instance, esters are responsible for sweet and fruity flavours, while aldehydes are associated to the beverage freshness. Alcohols, which are the major group of aroma compounds in this beverage (ethanol is the compound in highest quantity), confer an alcoholic, fruity and immature flavour to the beer (Catarino et al., 2007).

Beer treatment processes, such as pasteurization or dealcoholization, submit it to extreme conditions (namely high temperatures) that cause the loss of important aroma components. The aroma recovery from beverages is therefore becoming a critical food processing operation (Karlsson and Trägårdh, 1997).

In order to overcome the beer aroma loss, particularly in processes aiming non-alcoholic beer production, it is possible to extract the aroma compounds before submitting the beverage to the heat processing (Mendes et al., 2007). Nowadays there is observed an increasingly offer in processes for aroma extraction, being membrane-based processes most promising. Pervaporation gained an important role on this area due to its high selectivity and the possibility of being carried out at low temperatures, which is advantageous for removing thermosensitive compounds (Karlsson and Trägårdh, 1997).

The main goal of this study was the extraction of beer aroma compound by means of pervaporation. A response surface methodology (RSM) with a central composite design

* Corresponding author. Tel + 351-22-5081695. E-mail:mendes@fe.up.pt

(CCD) was used to analyze the effect of critical operation conditions on the process performance and to select the operation conditions that optimize the process responses.

2 Experimental

In all experimental runs a regular alcoholic beer, from the same batch, was used as feed solution; membranes made of POMS/PEI, gently provided by GKSS (Geesthacht, Germany), were applied.

Pervaporation experiments were carried out using a semi-batch lab unit (Mendes et al., 2007). The laboratorial set-up is illustrated in Figure 1.

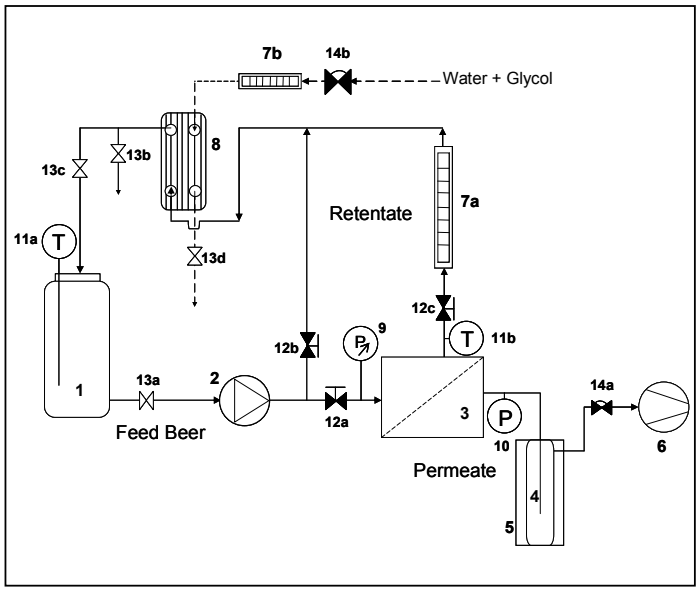

Figure 1. Pervaporation lab set-up.

Beer stored in the feed tank (1 – cf. Figure 1) was circulated with a centrifuge pump (2, Efacec, Model E-JETMA/A100) through the membrane cell (3) which membrane effective area is 107.46 cm^2. Part of the feed returned back to the tank through a plate heat exchanger (8, Arsopi, Model FH00-HJ-15, with 0.20 m^2 transfer area) and the rest as retentate stream. In the membrane cell, the feed aroma compounds permeate through the membrane, due to the vacuum applied to the downstream side by means of a vacuum pump (6, Boc Edwards, RV5). Once the aroma compounds leave the membrane as vapour, a condensation system was connected before the vacuum pump in order to condense the permeate. The condensation system consisted in a stainless steel cold trap (4), which was immersed in liquid nitrogen at -196 ºC, stored in a dewar flask (5). Three needle valves (12a, 12b and 12c) regulated the feed pressure and the flowrate of feed and retentate streams. A manometer (9) measured the feed pressure while the downstream pressure was determined by a pressure sensor (10, Druck, PMP 4010), which was regulated by a diaphragm valve (14a) placed at the vacuum pump inlet. The feed and membrane cell temperatures were read using two thermocouples (11a – C.L.V. PT100, 11b – Eurotherm, PR12-K-15-200) and they were adjusted by tuning the refrigerated fluid flow rate in a diaphragm valve (14b). Two rotameters (7a and 7b) measure the retentate and cooling water flowrate.

The operating conditions selected in the design of experiments analysis were the feed temperature, feed velocity and permeate pressure because preliminary runs showed that feed pressure has almost no effect on the responses considered. According to the CCD, implemented using JMP5.1, SAS software, the levels of the process factors are those depicted in Table 1. Note that axial value (α) is equal to the unity, because it was aimed to perform experiments considering only operation conditions within the factor's levels, in order to explore the entire region of operation/interest.

Table 1. CCD factors and respective levels.

Factor	Symbol	Level				
		-α	-1	0	+1	+α
T_f (ºC)	x_1	5.0	5.0	10.0	15.0	15.0
v_f (m·s^{-1})	x_2	0.1	0.1	0.3	0.5	0.5
P_l (mbara)	x_3	1.0	1.0	10.5	20.0	20.0

The process responses considered were the permeate flux, the selectivity towards selected aroma compounds and the relationship between the aromas concentration in the permeate. The most important beer aroma compounds are high alcohols and esters. The chosen selected aroma compounds for quality control were ethyl acetate - EA and isoamyl acetate - iAA (esters) and propanol - Pr, isobutanol - iB and amyl alcohols - AA (high alcohols).

The permeate flux, J_p (kg·m^{-2}·s^{-1}), the selectivity towards aromas against ethanol, $\alpha_{i/E}$, and the high alcohols/esters ratio, *A/E*, were evaluated by the following equations:

$$J_p = \frac{m_p}{a\,t} \quad (1) \quad ; \quad \alpha_{i/E} = \frac{w_{p,i}/w_{p,E}}{w_{b,i}/w_{b,E}} \quad (2) \quad \text{and} \quad A/E = \frac{C_{high\ alcohols}}{C_{esters}} \quad (3)$$

were m_p is the mass of condensed permeate, *a* is the effective membrane area, *t* is the permeation time, and w_p and w_b stand for the mass fractions on the condensed permeate and on the feed bulk, respectively. Subscripts "*i*" and "*E*" denote the aroma compound and ethanol, respectively. $C_{high\ alcohols}$ and C_{esters} are the concentrations of high alcohols and esters, respectively.

Aromas concentrations were analyzed using a gas chromatograph (Varian Star 3400) and the ethanol content was determined using and an Alcolyzer Plus (Anton Paar) meter.

3 Results and discussion

Using the experimental results of all the 17 CCD runs (data not shown), second order polynomial models were fitted, which describe the influence of the main operation conditions on the pervaporation responses. The significance of the models was verified based on the analysis of variance (ANOVA) of the results (Montgomery, 2001). The relation between process responses and process factors is described by the following equations:

$$J_p \times 10^5 = 3.781 + 1.560X_1 + 0.311X_2 - 1.869X_3 - 0.329X_1X_3 + 0.918X_3^2 \quad (4)$$

$$\alpha_{Pr/E} = 1.272 + 0.027X_1 + 0.004X_2 - 0.150X_3 + 0.043X_1X_2 \quad (5)$$

$$\alpha_{iB/E} = 2.460 + 0.073X_1 + 0.073X_2 - 0.345X_3 + 0.095X_3^2 \quad (6)$$

$$\alpha_{AA/E} = 2.599 + 0.174X_1 + 0.072X_2 - 0.600X_3 + 0.243X_3^2 \quad (7)$$

$$\alpha_{EA/E} = 18.619 - 2.910X_1 + 2.057X_2 + 1.838X_3 - 0.920X_1X_3 - 1.612X_2^2 \quad (8)$$

$$\alpha_{iAA/E} = 24.292 - 4.612X_1 + 3.678X_2 + 4.138X_3 - 1.881X_1X_3 - 1.841X_2^2 - 0.881X_3^2 \quad (9)$$

$$A/E = 0.719 + 0.196X_1 - 0.105X_2 - 0.259X_3 - 0.046X_1X_2 - 0.024X_1X_3 + 0.061X_2X_3 + 0.052X_2^2 + 0.142X_3^2 \quad (10)$$

were X_1, X_2 and X_3 are the coded process parameters (cf. Table 1), which are determined from the real factor values (and their null points and variation intervals) as follows:

$$X_1 = \frac{x_1 - 10}{5}; \quad X_2 = \frac{x_2 - 0.3}{0.2}; \quad X_3 = \frac{x_3 - 10.5}{9.5} \quad (11)$$

A comparison between experimental results and predicted values, obtained by Equations 4 to 10, is represented in the parity plots shown in Figure 2.

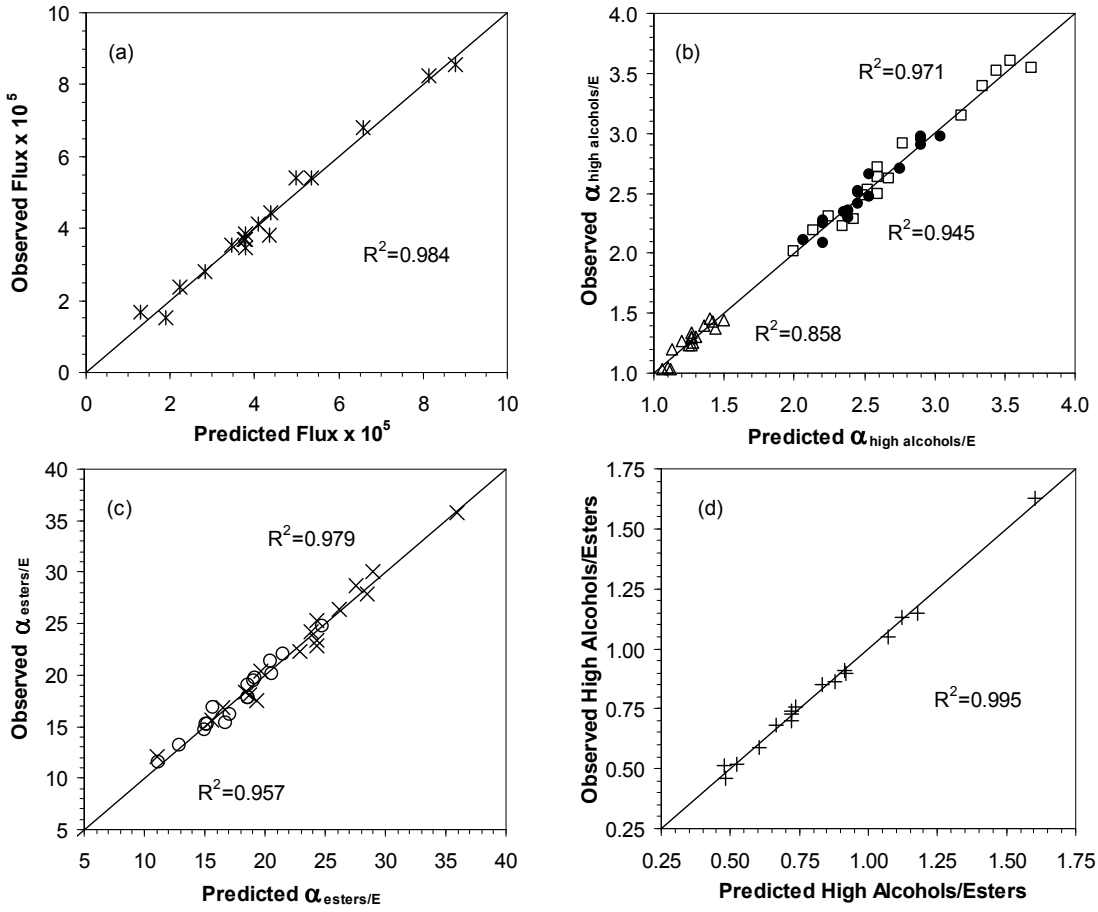

Figure 2. Comparison between predicted values and experimental results for: (a) permeate flux ($kg \cdot m^{-2} \cdot s^{-1}$); (b) high alcohols selectivity (△ propanol, ● isobutanol, □ amyl alcohols); (c) esters selectivity (○ ethyl acetate and × isoamyl acetate); and (d) high alcohols/esters ratio.

Figure 2 shows a good agreement between observed and predicted values (values very close to the plot's diagonals), meaning that the residuals are vey low. On the other hand, coefficient of determination (R^2) varied from 0.858 to 0.995, which is reasonably acceptable.

From these results, it is verified that esters show higher selectivities than high alcohols, according to the following order: isoamyl acetate > ethyl acetate > amyl alcohols > isobutanol > propanol. These results are consistent with the ones found by Börjesson et al. (1996).

The developed models can be used to predict the effect of the operation variables on process responses. Figures 3 and 4 show the surface response plots of the permeate flux and of the ratio between high alcohols and esters concentrations as a function of the independent variables, respectively. One can observe that permeate flux increases with temperature due to the increase of membrane permeability with such variable (Arrhenius dependence) and that it also slightly increases with the feed velocity (Figure 3a). On the other hand, the higher the permeate pressure the lower the membrane flux, due to the decrease of the process driving force, according to the solution-diffusion model (Karlsson et al., 1995). The effect of the operation conditions on the aromas selectivity's assumes different trends according to the compounds nature. In general, high alcohols selectivity increases with temperature (X_1), due to their transport activation energy being higher than that of water. High alcohols selectivity also slightly increases with feed velocity (X_2), meaning that they are affected by concentration polarization, and finally it decreases with permeate pressure (X_3), due to their low volatilities (cf. Eqs. 5, 6 and 7). On the other hand, esters selectivity decreases with temperature. It increases strongly with feed velocity, since they are the most permeable compounds and consequently, they are highly affected by concentration polarization. Esters selectivity also increases with permeate pressure due to their high

volatilities (cf. Eqs. 8 and 9). As a result, the ratio between high alcohols and esters concentrations increases with temperature but decreases with feed velocity and permeate pressure (cf. Figure 4 and Eq. 10). These results are also in agreement with other studies previously reported (Lipnizki et al., 2002; Karlsson et al., 1995).

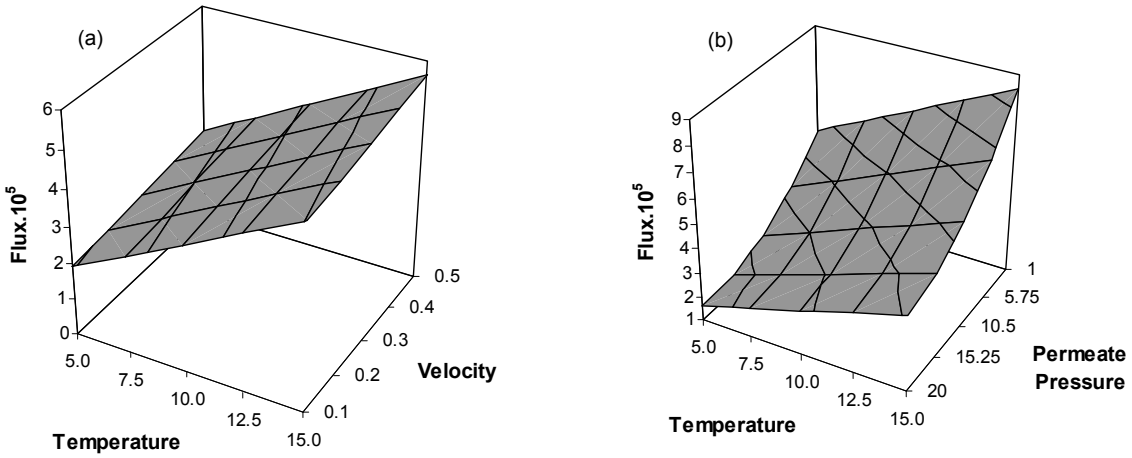

Figure 3. Influence of process variables on the permeate flux: (a) feed temperature and feed velocity, keeping permeate pressure at middle point (10.5 mbara); (b) feed temperature and permeate pressure, keeping feed velocity at middle point (0.3 $m \cdot s^{-1}$).

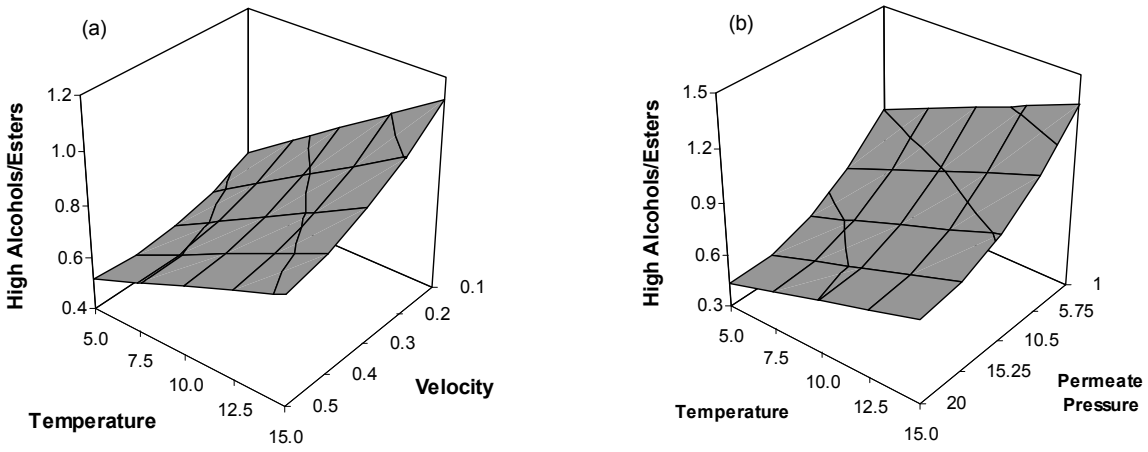

Figure 4. Influence of process variables on the high alcohols/esters ratio: (a) feed temperature and feed velocity, keeping permeate pressure at middle point (10.5 mbara); (b) feed temperature and permeate pressure, keeping feed velocity at middle point (0.3 $m \cdot s^{-1}$).

In order to optimize all the responses simultaneously (maximization of permeate flux,aroma selectivity's and high alcohols/esters ratio), the desirability fuction was applied (JMP5.1, SAS), giving the same importance (weight = 1) to all the responses The optimal operation conditions found were the following: 12.4 ºC for feed temperature (x_1), 0.45 $m \cdot s^{-1}$ for feed velocity (x_2) and 1.00 mbara for permeate pressure (x_3). For these conditions, the predicted responses and intervals of variation are given in Table 2, along with the experimental values, which were performed to validate the adequacy of the models. From Table 2 it is observed that observed process responses lie whithin the predicted range of confidence, except for amyl alcohols selectivity and high alcohols/esters ratio, although they show acceptable values. Hence, it can be said that the developed models were reasonably valid and thus useful for process optimization.

Table 2. Results of optimization conditions and confirmation runs.

	$J_p \times 10^5$ ($kg \cdot m^{-2} \cdot s^{-1}$)	$\alpha_{Pr/E}$	$\alpha_{iB/E}$	$\alpha_{AA/E}$	$\alpha_{EA/E}$	$\alpha_{iAA/E}$	*A/E*
Min predicted	7.26	1.31	2.87	3.39	14.46	17.10	1.07
Target	7.82	1.44	3.01	3.59	15.97	19.06	1.12
Max predicted	8.38	1.56	3.14	3.78	17.48	21.03	1.17
Observed	8.15	1.53	3.11	3.89	15.50	18.31	1.26

4 Conclusions

RSM was used for studying the extraction of beer aroma compounds by pervaporation and analyzing the effect of operation conditions on the process responses. The responses which were aimed to optimize were the permeate flux, beer aroma compounds selectivity's and high alcohols to esters ratio on the permeate.

Analysis of variance and surface plots revealed that permeate flux increases with temperature and feed velocity, whereas it decreases with permeate pressure. In contrast, these factors have different significances and influences on the aromas selectivity's, depending on their nature. High alcohols selectivity's increases with temperature and feed velocity while it decreases with permeate pressure; esters selectivity is negatively affected by temperature and is positively affected by velocity and permeate pressure. Consequently, high alcohols/esters ratio increases with temperature and decreases with feed velocity and permeate pressure.

Since process variables have different/opposite effects on the responses, the Desirability function was used for optimizing the trade-off between multiple responses. The responses in the optimum conditions were experimentally confirmed, meaning that the developed models were reasonably accurate.

Abstract

Membrane processes have been intensely developing during the last decades, and mainly in dairy industries. Considering the feed effluent complexity, concentration polarization (CP) phenomenon and fouling are accentuated limitations for the development of membrane dairy filtration processes. Knowledge of the wall shear stress developed at the membrane science is fundamental to reduce those phenomena. In our work, we studied the repartition of the wall shear stress on cylindrical, square, triangular and hybrid channels by numerical simulation for various operating parameters. We aimed at establishing predictions for different commercial ceramic membranes and predict the geometry that tends to enhance mass transport characteristics by enhancing hydrodynamics conditions. Numerical simulations are performed over a typical range of Reynolds numbers inside different channel geometry under laminar and turbulent conditions. Consequently, this paper intended to enhance the performances of these processes by maximizing the average wall shear stress on the membrane surface by numerical simulation. A comparison with experimental results has been realized and a good agreement is obtained. Given those conclusions, we designed a new membrane according to the whole CFD results consistent with experimental results.

1 Introduction

In dairy industries, microfiltration is more and more used for milk sterilizing and casein separation. Ultrafiltration is currently the most used process for applications as protein separations or milk composition standardization. Considering the feed effluent complexity, concentration polarization (CP) phenomenon and fouling are accentuated limitations for the development of membrane dairy filtration processes. The accumulation of materials near the membrane, with the deposition of colloids and suspended solids triggers the reduction of its performances. Fouling strongly depends on the wall shear stress that occurs from radial velocity gradient during the filtration step. So, better knowing the wall shear stress is fundamental to reduce the fouling phenomena. Enhancing turbulence to the membrane surface: Dean vortices (Moulin et al., 1999), dynamic filtration (Koutsou et al., 2004) and unsteady flows (Krstic et al., 2002) enables indeed to increase the mass transfer coefficient and sweep the deposition at the surface (Noriatsu et al., 2001).

* Corresponding author. Tel (+ 33) 4 42 90 85 01. E-mail:philippe.moulin@univ-cezanne.fr

It was shown, in previous works on various effluents filtrations, that the limiting permeate flux was linked to the wall shear stress by a phenomenological relation $J_{lim} = A\tau^n$ with J_{lim} the limit permeate flux ($m.s^{-1}$) and τ the wall shear stress (Pa) (Manno et al.,1998 ; Moll et al., 2007). The simplified approach considered for our work was "the higher the shear stress, the higher the permeate flux". No mass transfer model was used. So, our work aimed at finding the channel geometry that shows the optimal wall shear stress to reduce uttermost the fouling. We also determined the influence of the channel section and the membrane process parameters (transmembrane pressure (TMP), flow rate…) on the wall shear stress characteristics. Given these results, the final purpose was to design the most appropriate membrane for the intended application.

2 Materials and methods

For this aim, numerical modelling tool appears as the most appropriate (Ghidossi et al. 2006). It permits to better apprehend complex mechanics and to reduce experiments number. Computational Fluid Dynamics (CFD) has become an effective tool to attain these objectives more quickly and cost effectively.
Numerical simulations were made for high Reynolds numbers in complex geometries. A large range of MF and UF cases was studied in this work for a more accuracy prediction of the wall shear stress. The problem was studied in 3D. The grid was refined near the wall with the intention of resolving the laminar sub-layer. We used RNG k-ε model for it appears in literature as preferentially used in turbulent flow. We consider the wall as impermeable. This assumption could be validated: (i) in ceramic membrane, the permeate flow is often lower than 2% of the circulating flow; (ii) it was shown that the wall shear stress can be calculated in permeable tube with the value obtained in no permeable tube and the value of permeate flow (Moll et al. 2007).

3 Results and discussion

3.1 Influence of the membrane channel geometry

The raw simulation results enable to obtain the variation of the wall shear stress according to the section of the channel for different flow velocities. On Figure 1 are represented the caracteristics of the wall shear stress for the different geometries studied. A logical and periodic variation of wall shear stresses according to the perimeter is obtained for all inlet velocities and simulated geometries. As expected, the cylindrical geometry develops a constant wall shear stress. For the other geometries, the results obtained by numerical simulation prove that the distribution of wall shear stress presents a maximum which is located in the middle of the side and a minimal value at the angle of the square for any rate of flow (laminar or turbulent flow).
The variation of the wall shear stress on the triangular geometry has many analogies with those observed on the square geometry. Indeed, a maximum of wall shear stress is observed in the middle of each edge which decreases progressively until reaching a minimal value on the corner for a constant section. Considering only the maximal values of the wall shear stress, the optimal configuration is the triangular one and secondly the square and cylinder geometries.
The simulations showed that there is no influence of the velocity on the ratio τ_{local}/τ_{max}. Only the geometry has an influence on this ratio and the importance of the dead zones created. The Figure 2 synthesizes simulated results and represents the variation of the average wall shear stresses for different geometries. It appears that the wall shear stress reduces with an increasing channel section. The cylindrical geometry offers the highest values in term of wall shear stress for the smallest section (4.0 mm^2). For the largest sections, the triangular geometry is more advantageous. The square geometry shows lower performances.

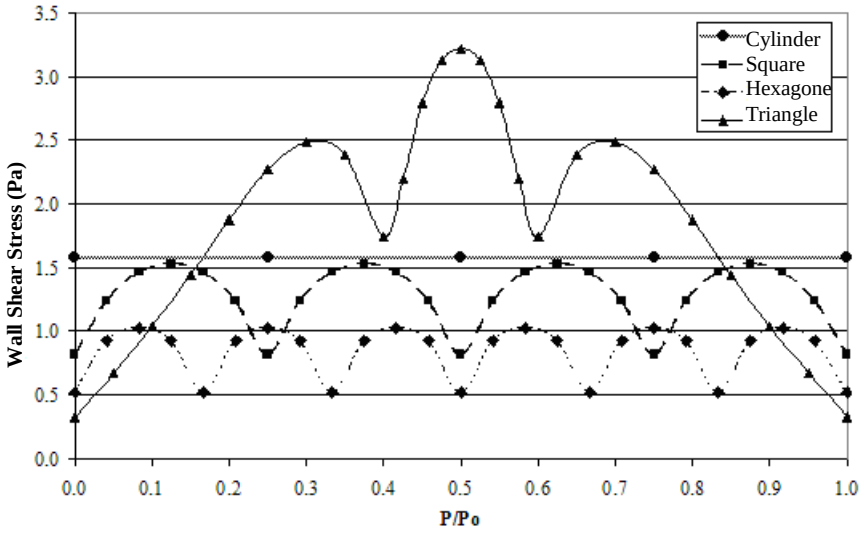

Figure 1. Variation of the wall shear stress vs. perimeter position for different channel geometries(Re = 1128, S = 4 mm^2)

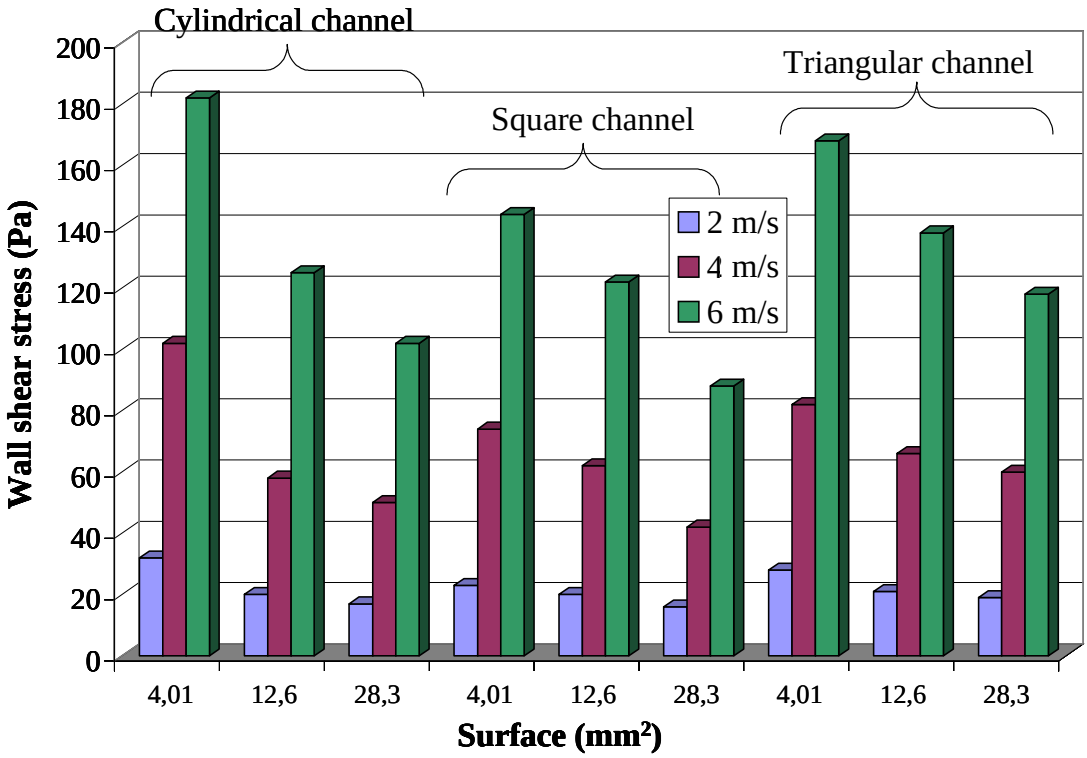

Figure 2. Variation of average wall shear stresses vs. channel surfaces for different geometries and different velocities

It is possible to obtain the local values of the wall shear stress by numerical simulations and to calculate an average value with the perimeter. Given those studies, we can design a new membrane prototype more appropriate for the complex filtration process when it comes to dairy effluents. The Evolution prototype has a hybrid form channel. Considering the effluent of milk, which is strongly fouling and pressure losses triggering, large channel sections were chosen for industrial productivity reasons. The choice of the channel shape is justified by the efficiency of the triangular geometry for high values of channel sections. Nevertheless, the angles are subjected to a rapid fouling, which affects the process performances during the filtration step and the regeneration step. We chose to round the corners so as to obtain a

heart-like channel shape, as shown on Figure 3, more likely to satisfy industrial objectives.

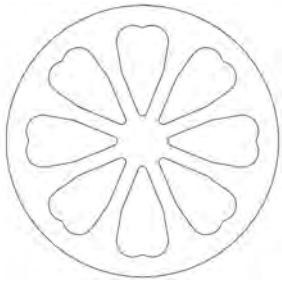

Figure 3. Hybrid shape of the Evolution membrane

The advantage of our simplified approach is the global view of the system Disadvantage is: predicting permeate flux is impossible and only comparisons are acceptable. An experimental campaign was necessary to validate this approach.

3.2 Validation of the modeling results and comparison of commercial membrane performances

The results of milk ultrafiltration campaigns are presented on Figure 4. The milk characteristics are given in Table 1. The reversible resistance was experimentally measured after rinsing the membrane after the filtration process, for different commercial ceramic membranes (15 KDa) with various geometries and sections. This characteristic shows how the wall shear stress influences the reversible resistance whatever the membrane geometry or section considered.

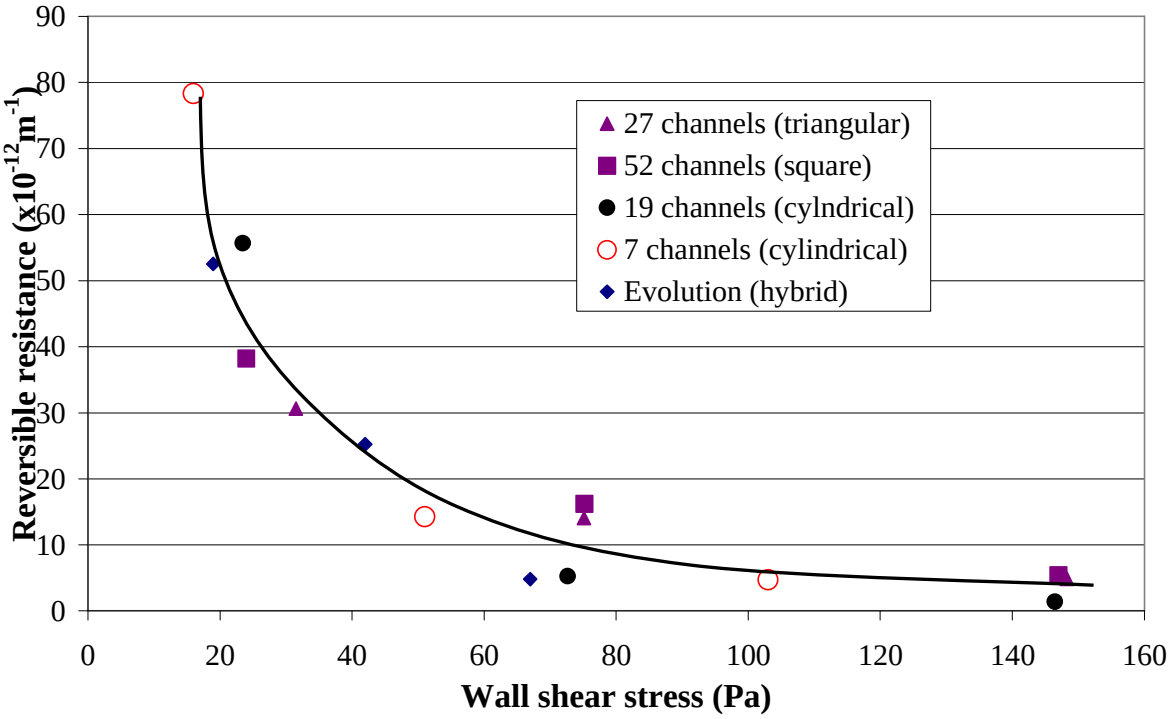

Figure 4. Variation of the reversible resistance vs. wall shear stress for different membranes

For all geometries, irreversible fouling also decreases with an increasing wall shear stress, so our simplified approach is validated.

Table 1. UHT milk composition

Compounds	Concentration ($g.L^{-1}$)
Glucids	49
Grease matter	39
Casein	25,6
Lactose	46
Calcium	1,2
Salt	9
Water	900
Density	1030

Moreover this figure shows an identical behaviour of the reversible resistance according to the wall shear stress values given by simulations, whatever the membrane considered: this validates our simulations results. Furthermore, beyond a value of ≈70 Pa for the wall shear stress, the reversible resistance remains very low, so it is of high interest to privilege geometries that enable to reach such an average value of wall shear stress.
The ultrafiltration experimental campaign enabled us to compare the commercial membrane performances. The results are shown on Figure 5 that represents the membrane production in term of permeate flux ($m^3.h^{-1}$) as a function of the process tangential velocity.

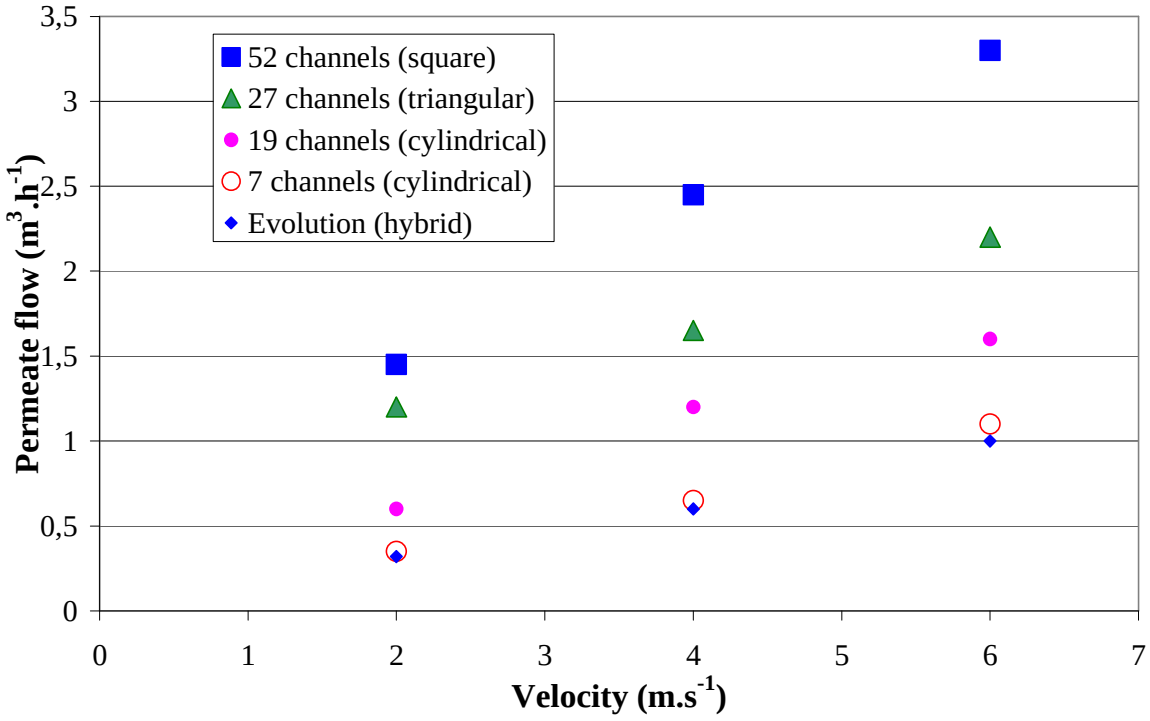

Figure 5. Variation of the permeate flow vs. tangential velocities for different membranes (TMP 2 bars)

Considering those results, the 52 channels membrane shows the most interesting performances and presents the real advantage to offer a surface definitely more important than the other geometries considered (0.50 m²). So, the production in term of permeate flux is expected to be more important than the other membranes. The 27 channels membrane with large channels (0.35 m²) section appears as interesting configuration. The choice of this geometry is coherent to permit an optimization. Nevertheless, the drawbacks previously developed of such geometries must be taken into account: the problem given by the corners in square and triangular geometry facilitates fouling what presents a weak point for the industrialization. Following the performances hierarchy, 7 channels (0.15 m²) or 19 channels

(0.25 m^2) membranes present larger sections and give high and similar performances. Considering fouling issues, the cylindrical geometry can show advantages that could counterbalance the lower production rate. Finally, the Evolution prototype shows interesting performances. The permeate flux produced is similar to the 7 channels cylindrical membrane performances.

4 Conclusion

This modeling work relies on the simplified approach: “the higher the shear stress is, the more satisfactory the permeate flux will be”. So, our simulation results enabled us to obtain the variation of the wall shear stress according to the section of the channel for different flow velocities under laminar and turbulent conditions. We compared the influence of different parameters such as the channel geometry, the channel section and the operating parameters on the process performances. The channel geometry was then optimized by maximizing the average wall shear stress on the membrane surface. A comparison with experimental results obtained during milk ultrafiltration campaigns has been realised and a good agreement is obtained. Moreover an identical behaviour of the reversible resistance according to the wall shear stress values given by simulations, whatever the membrane considered is showed. This shows our simulation results and modelling approach are validated. So, this methodology is relevant to design new membrane geometries intended to specialized applications. In this study, we concentrated on the complex and fouling effluent of milk and dairy co-products. Finally, a compromise between membrane area, channel geometry and energy consumption must be taken into account for optimizing those processes.

Abstract

The effect of the feed streams pulsation on the flow dynamics in a Confined Impinging Jets (CIJ) reactor was studied in this work. Different frequencies and amplitudes are studied. The out phase pulsation of the opposed jets with frequency close to natural oscillation frequencies enhances the order of the system, yielding a well defined vortices street. The results showed that the amplitude of the jets oscillations has a strong effect on the flow dynamics, up to the extreme case where the imposed pulsation completely drives the dynamics of the system.

Introduction

Confined impinging jets (CIJ), where two opposed jet streams impinge each other in a confined mixing chamber have a wide range of applications, mainly for the production of polyurethanes in Reaction Injection Molding, RIM, and in precipitators. The flow regime in the mixing chamber can be oscillatory or self sustainable chaotic. In self sustainable chaotic flow regimes, the jet streams engulf each other in evolving vortices throughout the mixing chamber, see Figure 1 for $Re = 150$. In oscillatory flow regimes both streams flow segregatedly throughout the mixing chamber, see Figure 1 for $Re = 100$. In self sustainable chaotic flow regimes the vortices formation is associated with strong oscillations of the jets' impingement (Teixeira et al., 2005) that present frequencies around typical values, while the oscillatory flow regimes present low amplitude oscillations with very well defined frequency. Erkoç et al.(2007) reported the usage of dynamic measurements of static differential pressure signal between the two impinging jets for the determination of oscillations typical frequencies at both flow regimes.

The flow field structures occurring at self sustainable chaotic flow regimes are the main mixing mechanisms in the RIM process and other CIJ mixers, as shown in Santos et al. (2005). The efficiency of mixing in such kind of processes is critical for the quality of the product as shown from the polymerization works of Kolodziej et al. (1982 and 1986). When fast reactions are present and short mixing times are required it is of outmost importance to operate the CIJ mixers at self sustainable chaotic flow regimes. In case of RIM the process wide spreading has been seriously compromised due to failure of operation at chaotic flow regimes, either self-sustained or imposed.

From the very early works on RIM of Malguarnera and Suh (1977) it was reported that to establish a self sustainable chaotic flow regime, the Reynolds number has to be above a certain value and the momentum ratio of the jets has to be equal to one. Erkoç et. al. (2007) showed that even if these conditions are satisfied, the continuous operation of RIM at self sustainable chaotic regime is not assured, as for the same conditions, both oscillatory or self sustainable chaotic regime can be observed.

On way to assure mixing is to modulate/pulsate the jets' flowrate. The process of enhancing mixing through modulation/pulsation of the inlet flow streams is called active mixing. Bierdel and Piesche (2001) were the only authors to discuss the pulsation of jets and test the effect of pumps flow pulsation on the beginning of convective mixing in RIM. Active mixing in other CIJ reactors was studied by Deshmukh et al. (2000 and 2001), Zhongliang et al. (2002), Ito et al.(2006), although only its effect on mass transfer was analysed.

In this study, mixing is not engaged from the pulsation, since the flow field in the mixing chamber at the Reynolds number value of 300 here studied has natural advective chaotic pattern. The purpose here is to scrutinise the interaction between the flow natural oscillations and the imposed jets oscillations, namely its effect on the flow dynamics and on the shape and evolution of the natural advective chaotic patterns formed downstream the opposed jets impingement point.

CFD Model

The flow field was simulated with Fluent™ using a 2D model of the mixing chamber introduced and validated previously by Erkoç et al. (2007). Detailed results from the 2D model CFD simulations have been previously presented (Santos 2003,Santos et al.,2002 and Santos et al.,2005). Here the injectors averaged Reynolds number, Re, is defined for the 2D geometry as

$$Re = \frac{\rho \overline{v}_{inj} w}{\mu} \qquad \text{eq1}$$

where w is the injector width, which is 1.5 mm, μ is the viscosity that here is $20\text{mPa}\cdot\text{s}$, ρ is the density that here is 1200kg/m^3 and $\overline{v_{inj}} = 3.333\text{m/s}$ is the time and space average fluid velocity at the injectors. The chamber width is 10mm and the chamber height is 50mm, the injectors are locate at 5mm from the close top of the mixing chamber. The boundary conditions were set as no slip in the walls, and the liquid leaves the chamber from a pressure outlet set at atmospheric conditions. The dynamic simulations were always started from a steady state solution of the flow field for $Re = 300$. The pulsation of the jets is performed according to the following equations:

on the left injector $$v_{inj}(t)_l = \overline{v_{inj}} + A_l \overline{v_{inj}} \sin(2\pi f t) \qquad \text{eq2}$$

on the right injector $$v_{inj}(t)_r = \overline{v_{inj}} + A_r \overline{v_{inj}} \sin(2\pi f t + \varphi) \qquad \text{eq3}$$

where A_l and A_r are the left and right pulsation amplitudes, respectively, f the pulsation frequency and φ the phase displacement between the right and left injector pulsation.

Results

The previous studies of Erkoç et al. (2007) reported that in CIJ the jets impingement point oscillates with a natural oscillation frequency, ϕ. The jets impingement point oscillation frequency is around $\phi = 200\text{Hz}$ for a fluid with $\mu = 20\text{mPa}\cdot\text{s}$ in the defined 2D geometry at $Re = 300$. The tested jets flow rate oscillation frequencies are $f = \phi/2 = 100\text{Hz}$, $f = \phi = 200\text{Hz}$, and $f = 2\phi = 400\text{Hz}$ z. The simulated cases are all at $Re = 300$ and summarized in Table 1. All simulations were performed dynamically using a fixed time step of

10^{-4} s. The x component velocity, v_x, was recorded in the axis of the chamber at a distance of $z = 5$mm from the top (at the jets impingement point: P1).

Table 1 Summary of simulated active mixing strategies

Case Number	Pulsation Strategy	Amplitude and Frequency
1	No Pulsation	$A = 0$
2	Only one jet is pulsed	$A_l = 0.50$, $f = \phi$
3	On-Phase	$A_l = A_r = 0.50$, $f = \phi$, $\varphi = 0$
4	Out-of-Phase	$A_l = A_r = 0.25$, $f = \phi$, $\varphi = \pi$
5	Out-of-Phase	$A_l = A_r = 0.50$, $f = \phi$, $\varphi = \pi$
6	Out-of-Phase	$A_l = A_r = 1.00$, $f = \phi$, $\varphi = \pi$
7	Out-of-Phase	$A_l = A_r = 0.50$, $f = 2\phi$, $\varphi = \pi$
8	Out-of-Phase	$A_l = A_r = 0.50$, $f = \phi/2$, $\varphi = \pi$

Figure 2 shows the streamlines, at some selected time instants, of the dynamic simulations of the eight defined cases. The same flow behaviour previously reported in Santos *et al*.of the formation of a vortex street downstream the jets impingement point is observed for the eight cases. Some differences are yet observable between the flow fields:

- The vortices in Cases 2 and 3, corresponding to one side oscillation and on-phase oscillation, are more distorted, less rounded, than the case of no pulsation.
- The cases with out-of-phase pulsation present greater regularity of the vortex street, namely Cases 4, 5, 6 and 8 except for Case 7, where pulsation frequency is 2ϕ.

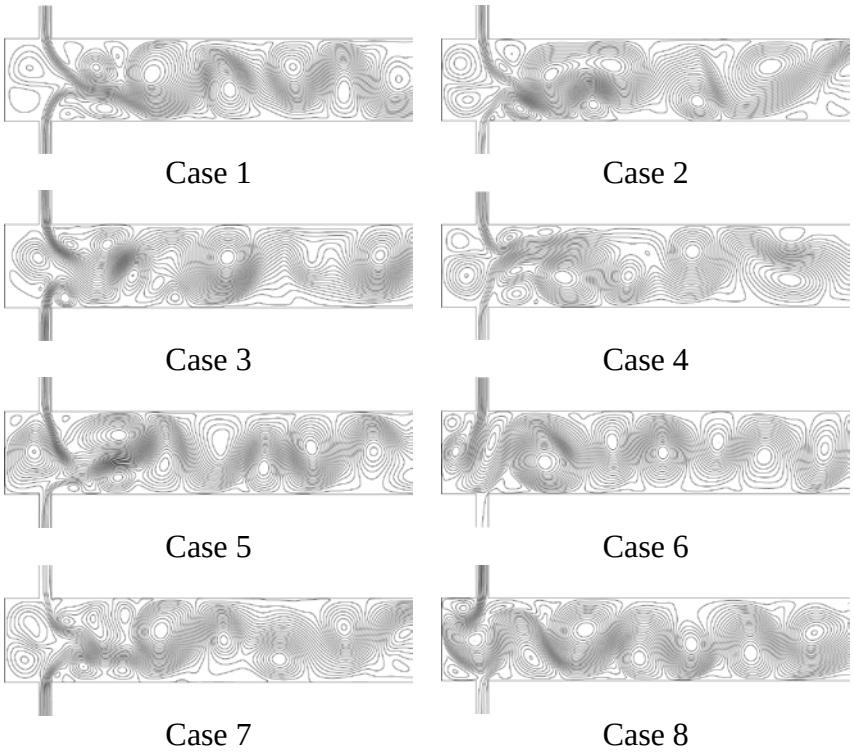

Fig. 2. Streamlines of flow field in the mixing chamber from the dynamic simulations at average *Re*=300, using different pulsation strategies.

For a clear image of the pulsation effect on flow dynamics, in Figure 3 it is presented the power spectra of the velocity time histories at the impingement point, P1, for the simulated

cases. The highest spectral energy values obtained from the spectra are listed in Table 2.

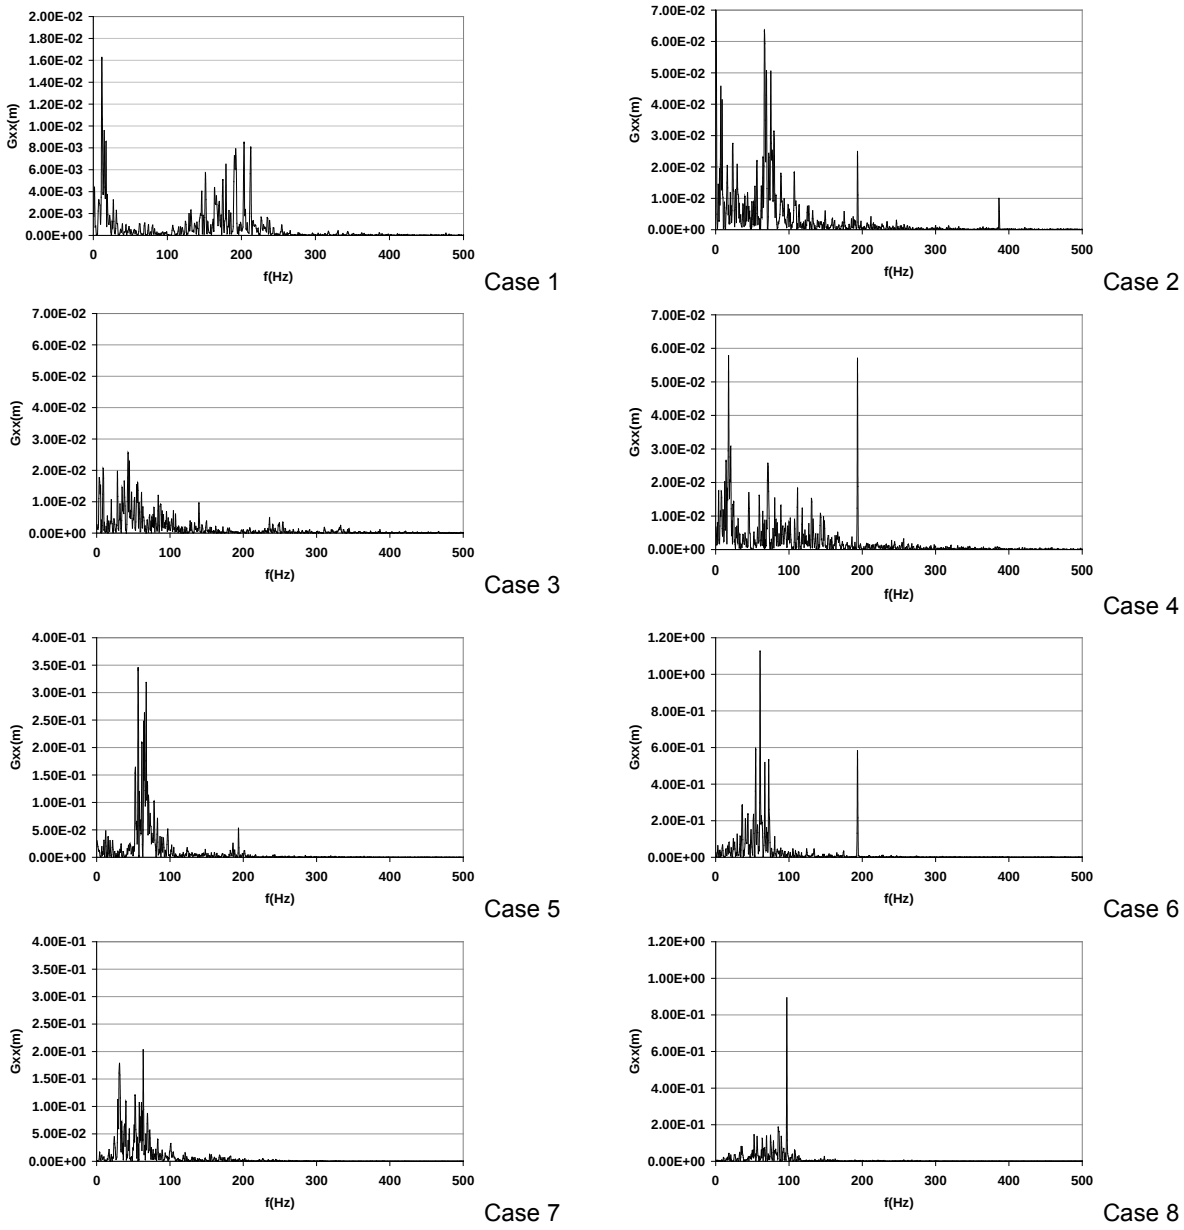

Fig. 3. Power spectra at the impingement point from the dynamic simulations at average Re=300 using different pulsation strategies.

For Case 1, where there is no pulsation applied to the system, typical frequency of the jets oscillations is $\phi = 200\text{Hz}$. The energy of the jets oscillation is much smaller than for the cases with forced pulsation as seen from Table 2, where the maximum energy value is seen to be almost one order of magnitude less than from the out-of-phase pulsation cases with $f = \phi$.

When only one of the jets is pulsed, the appearance of a lower frequency peak, between 50 and 100Hz, is observed, as can be seen in Figure 3 for Case 2. The on-phase pulsation, Case 3, presents the lowest energy peaks, since both jets are pulsated simultaneously, their strengths keep balanced and there is no significant disturbance of the jets oscillation. When a jet loses its strength, it is not compensated by the opposed jet, which is also retracted, and on the other hand when a jet increases its strength it is matched-up by the opposed jet.

Table 2 Maximum energy levels from the power spectra of v_x around f=200Hz, at the impingement point.

Case Number	Max Energy, m
1	0.00843
2	0.0247
3	0.00168
4	0.0571
5	0.0530
6	0.583
7	0.000921
8	0.894 *

The cases promoting the highest dynamics of the jets oscillations are the ones with out-of-phase perturbations, mostly the ones with the highest amplitudes. At $A_l = A_r = 1.00$, the jets oscillations are mainly determined from the imposed pulsation.

On the other cases, $A_l = A_r = 0.50$ there is a strong interaction between the flow field natural oscillations and imposed oscillations by pulsation. The resulting power spectrum, see Figure 3, shows both the influence of the natural flow oscillation, Case 1, and of the imposed jets oscillation. This result suggest that the flow field somehow preserves its own dynamics up to pulsation values of 50% of the inlet flow rate.

For Cases 4 to 6, streamline maps of Figure 2 show the earlier appearance of fully developed vortices, and when $A_l = A_r = 1.00$ the vortices are generated at the jets inlet region, which is the reason for the increase of the energy peaks in the range of 50 to 100Hz. For the double frequency oscillations, where $f = 2\phi$, Case 7, the natural flow oscillations and the imposed oscillations interact in a complex fashion cancelling the high energy peaks above 100 Hz.

The highest energy peak is obtained with a pulsation frequency of $\phi/2$, which is close to the flow oscillation frequency at the vortex street region. The pulsation frequencies probably set the whole system into resonance. From the streamlines in Figure 2, the earlier formation of the fully developed vortices at the impingement point occupying the entire mixing chamber width and evolving in perfect order to the outlet is clearly observed for Case 8.

Conclusion

In summary we studied the effect of opposed jets pulsation on the mixing dynamics and vortex formation on flow field dynamics inside the CIJ reactor. The flow dynamics had a strong effect from the pulsation frequency:

- With values close to the natural jets oscillation frequencies, ϕ, pulsation enhances the regularity of the system which results in a clear oscillatory behaviour of the jets at the impingement point.
- With values close to the natural frequency of the fully developed vortices, $\phi/2$, pulsation can force the frequency of the fully developed vortices passage and make it more orderly.

It was observed that the amplitude of the pulsation also has a strong effect on the flow field:

- Lower amplitudes can not impose to the system dynamics.
- Higher amplitudes, close to 100% of the flow rate, can completely dominate the dynamics of the flow field.

The other studied parameter was the impact of the pulsation strategy, which has shown that the strategies consisting of out-of-phase jets pulsation impose more clearly its dynamics to the system, since the displacement of the jets impingement point is completely determined

from the pulsation. One side oscillation and on-phase oscillation were not able to impose a clear influence on the flow field.

Topic: Integration of life science & engineering

Abstract

The intensification of the extraction process in ultrasonic fields is addressed, emphasizing its advantages in obtaining hypoglycemic extracts with great economical potential from medicinal plants: flavonoids and polyphenol acids from *Cynara scolymus L.* (artichoke) leaves and *Arctium lappa L.* (burdock) roots and sweet diterpenic glycosides from *Stevia rebaudiana Bert.* leaves.

The objective of this work was to isolate favourable extraction conditions for a fast and reliable protocol of ultrasound-assisted extraction (UAE). Compared with classic methods like maceration, heat and/or stirred extraction, the UAE has higher productivity, defined as the quantity of the extracted product with respect to time and volume of mixture. The efficiency of the classic extraction was investigated with respect to the solvent used, the ratio of sample quantity to solvent volume, the plant material granulation size and the time of extraction.

The quantification of flavonoids and polyphenolic acids from autochthonous medicinal plants was performed with a spectrophotometric method, while the diterpenic glycosides of Paraguayan plant were measured by HPLC.

1 Introduction

Plants containing large amounts of flavonoids and polyphenolic acids have been used in the traditional medicine of many different cultures. Recent papers have focused attention to the biological activity and therapeutic potential of these compounds. These properties give them a prime role in the prevention of various diseases associated with oxidative stress, such as cancer and cardiovascular and neurodegenerative diseases, metabolic diseases (Sharaf-Eldin et al., 2007).

Extracts of leaves of the plant *Stevia rebaudiana Bertoni*, have been used for many years in traditional treatment of diabetes in South America. Stevia leaves contain diterpene glycosides, stevioside and rebaudioside as the most abundant. Recently, it was demonstrated that stevioside stimulates the insulin secretion both *in vitro* and *in vivo* (Gregersen et al., 2004).

The mechanical effects of ultrasound (formation and destruction of small cavities in the solvent) induce a greater penetration of solvent into cellular materials and improve mass transfer. Ultrasounds can also disrupt biological cell walls, facilitating the release of its contents. In contrast to conventional extraction, where there is no external field in which the fluid is placed, plant extracts diffuse across cell walls since the ultrasounds cause cell rupture over a short period Ultrasound can increase extraction kinetics and even improve the quality of extracts. Use of ultrasound-assisted extraction is recommended for thermo-labile compounds, whose properties may be altered under thermal extraction due to temperature beyond critical

* Corresponding author. Tel + 40726-209-800. E-mail:alupului_ani@yahoo.com

point. Ultrasound-assisted extraction was proved to be an efficient method for extracting polyphenolic acids and flavonoids, steroids and triterpenoids (Vinatoru, 2001).

2 Materials and Methods

2.1 Reagents and plant material

Stevioside (S3572, assay ≥98% - HPLC - form: solid , colour: white, free soluble in water and ethanol, solubility H_2O: >20 mg/mL, storage temperature: 2-8°C, chemical name: 4α-13-[(2-O-β-D-Glucopyranosyl-β-D-glucopyranosyl)oxy]kaur-16-en-18-oic acid β-D-glucopyranosyl ester, chemical formula: C38H60O18, molecular weight: 804.87) was used as standard chemical for HPLC analysis. Gallic acid and Rutoside were used as standard chemicals for spectrophotometric analysis.

Chromatographic grade – double distilled water, HPLC grade acetonitrile, aqueous ethanol and distilled water were used as extraction solvents and mobile phase.

Folin-Ciocalteu reactive, sodium carbonate 10%, sodium acetate 100 g/L and aluminium trichloride 25g/L were used as regents in spectrophotometric analysis.

The plant material consists of dried leaves of *Stevia rebaudiana* purchased from the Paraguay Medicine Market, harvested in 2007, dried leaves of *Cynara scolymus* (artichoke) and dried roorts of *Arctium lappa* (burdock), harvested in 2007, both from Romania. They were stored in dark ermeti tight bags to protect them from humidity and light and, before each bunch of experiments, they were cut into pieces of the appropriate equivalent diameter.

2.1 Experimental setup

Three ultrasonic baths (T420 Elma, T460 Elma, and T570) working at 35 kHz frequency and an output power of 70 W, 170 W and 320 W respectively were used during the experiments. For stirring and heating a TK-22 Magnetic stirrer with heating was used. For chromatographic measurements, a HPLC system Agilent Technologies 1200 series model with UV-VIS detector was used. The filtrate was separated from the residual plant material by vacuum pump filtration irrespectiv of the extraction process used get it.

2.2 Ultrasound assisted extraction

Samples of 10 g of dry leaves from *Stevia rebaudiana* and *Cynara scolymus* and dry roots from *Arctium lappa* with particles sizes of 0.315 mm equivalent diameter were mixed with distilled water for *Stevia* leaves and water/ethanol mixture of 55% for *Artichoke* leaves and *Burdock* roots, using 1/5 (w/v) sample weight to solvent volume ratios. Then these mixtures were placed into the ultrasound assisted extractors at room temperature.

The ultrasonic baths were filled with liquid water into which glasses with samples were placed and sonicated from 30 seconds up to 15 minutes at 70 W, 170 W and 320 W output power respectively.

2.3 Dry residue analysis. Extractive values

According to the Romanian Pharmacopoeia (10th edition) approximately 2 g (2 ml) of extract was placed into a flat-bottomed glass dish (36 mm diameter and 28 mm height) covered to prevent evaporation of solvent before weighting. After weighting, the extract was dried in oven at 103^0C for 3 h. The content of extractive substances in the plant material was calculated from the mass of dry extract and the initial mass of plant subject to experiment. The concentration of extractive substances in the liquid extract was calculated from the mass of dry extract and the volume of liquid extract. The extractive value of the soluble compounds from the extract was calculated as a mass percentage of dry residue (g/100 g extract).

2.4 Determination of steviol glycosides percentages using HPLC

Standard solution (2.2 mg/5 mL) of stevioside was prepared in the mobile phase consisting of mix HPLC grade acetonitrile and bi-distilled water (80:20, v/v). Standard series in the concentration range of 100-1000 µg/mL were obtained from the stock solution. The mobile

phase was used as solvent for all HPLC studies. The HPLC analysis conditions were performed by isocratic elution at 40^0C column temperature with a flow rate of 0.4 mL/min, separations being carried out using Supelcosil LC-NH2 or equivalent (length: 15 - 30 cm; inner diameter: 3.9 - 4.6 mm). All solvents were filtered through a 0.22 µm Millipore filter. Volumes of 5 µL extracts prepared from each sample were directly injected into HPLC then the peak areas at the characteristic wavelength of the steviol glycosides were measured. The UV-VIS detector was set to 210 nm and peak areas were integrated automatically using Agilent software. The instrument was calibrated pumping mobile phase through it until a drift-free baseline was obtained. The Agilent software recorded the chromatograms of the sample standard solution.

All the computations concerning the quantitative analysis were performed with external standardization of the measured peak areas. The results were obtained as the mean value of three separate injections. Using the measured peak areas of stevioside from the sample solution and of the standard solution, the percentage of the extracted stevioside was computed as: % stevioside = [Ws/W] x [Aa/As] x 100, where Ws is the mass of stevioside in the standard solution (mg), W is the mass of sample (mg), As and Aa are the peak area of stevioside from standard and sample solutions.

2.5 Determination of flavonoids and polyphenolic acids percentages using spectrophotometer

Determination of the phenolic acids and flavonoids content was performed according with the methods presented in Romanian Pharmacopeia (10^{th} edition).

The method was implemented using a Spekol 1000 Series spectrophotometer with VIS detector.

All the calculations concerning the quantitative analysis were performed with external standardization by measurement of absorbance of a specific wavelength of light.

Stock solutions of gallic acid (0,1g/L) and rutoside (0,1 g/L) were prepared in distilled water (v/v). Standard series in the concentration range of 25- 200 µg/mL for flavonoids and 4-16 µg/mL for polyphenols acid were obtained from the stock solution.

Volumes of 2 mL solution prepared from each sample were placed into quartz cuvettes into the spectrophotometer and analised.

The total content of polyphenols was determined with Folin-Ciocalteu reactive and Na2CO3 10%, the maximum of absorption of thr obtained coloration, with respect to the calibration curve. The polyphenols are expressed in mg/g gallic acid correspondents at a final set concentration of 16 µg/mL.

The total content in flavonoids was measured with ethanol solution of aluminium trichloride 25g/L and sodium acetate 100 g/L, throughout the evaluation of the maximum of absorption of obtained coloration, relatwith respect to the calibration curve. The total content of flavonoids is expressed in mg/g rutoside correspondents related to a final set concentration of 200 µg/mL.

The blank solutions were prepared in the same conditions as the samples and are used for all spectrophotometric experimental studies.

Quantification was realized by measuring the absorbance at the wavelength 430 nm for flavonoids and 765 nm for polyphenolic acids to determine the concentration of a known solute in a given solution by the application of the Beer-Lambert law, which states that the concentration of a solute is proportional to the absorbance. Optical density, or OD, is the absorbance per unit length, although it is sometimes used as a synonym for the absorbance with a base-10 logarithm. The results were obtained as a mean value of three separate samples.

3 Results and Discussions

3.1. Results

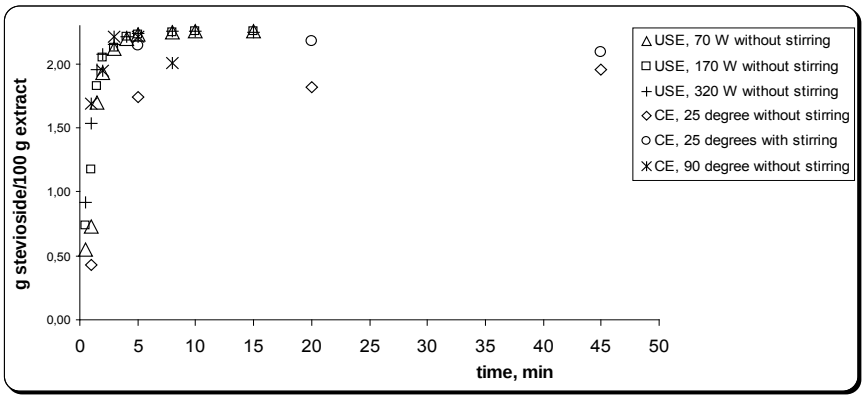

Figure 2. Time profiles of ultrasound-assisted extracted stevioside from Stevia rebaudiana (ultrasonic bath). Influence of the output ultrasound power on the extraction yield (70 W, 170 W and 320 W respectively)

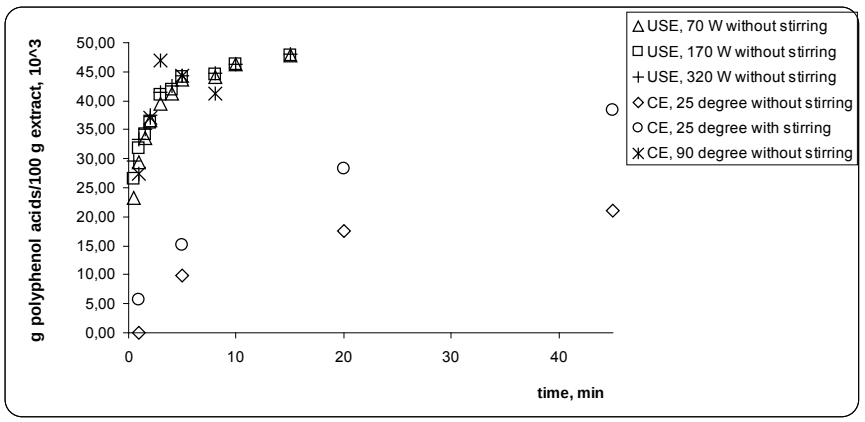

Figure 3. Time profiles of ultrasound-assisted extracted phenolyc acids from Cynara scolymus (ultrasonic bath) – the rest is the same as in Figure 2

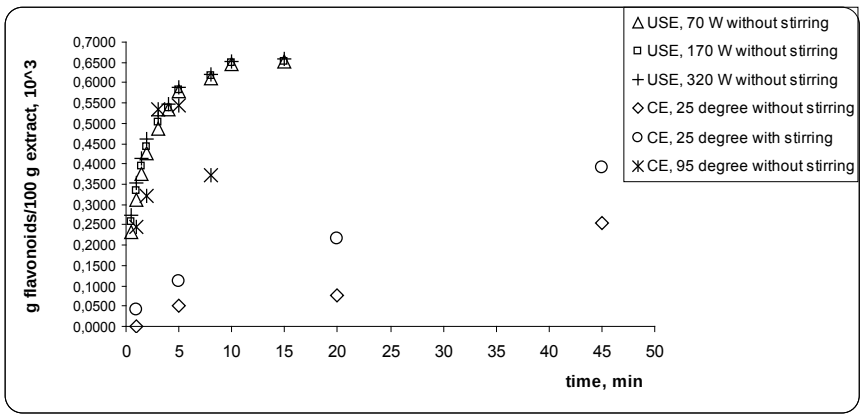

Figure 4. Time profiles of ultrasound-assisted extracted flavonoids from Cynara scolymus (ultrasonic bath) – the rest is the same as in Figure 2

The results of the ultrasound assisted extractions are presented, *per see* or compared with the classical extractions, in Figures 2 to 6. We used the results for classical extraction, presented already in details in two papers (Alupului and Lavric, 2008 a&b) as reference for comparison with the ultrasound-assisted extraction.

The influence of the equivalent diameter of dry leaves and of the solvent nature upon the ultrasound assisted extraction yields has been already presented in the paper (Alupului and Lavric, 2008 a).

Further on, we will present the results of ultrasound assisted extraction protocol in comparison with the classic extraction findings.

Figure 2 depicts the extracted stevioside time profiles sing three crescent output power for the ultrasonic fieled. It is worth mention that these are not the absobded powers, but still could give a hint about the rate at which the extraction ceases. A comparison with maceration is done presenting the time profiles of the extracted stevioside with or

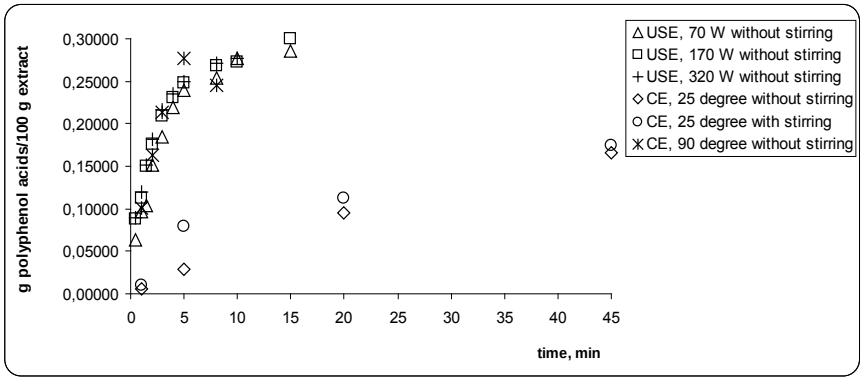

Figure 5. Time profiles of ultrasound-assisted extracted phenolyc acids from Arctium lappa (ultrasonic bath) – the rest is the same as in Figure 2

without agitation and, also, with decoction.

The same, but this time for phenolyc acids from *Cynara scolymus* is done in Figure 4, while in Figure 5 the time profiles are for flavonoids from *Cynara scolymus*. Figure 6 shows the results of the extraction process in ultrasonic fields or classically for the flavonoids from *Arctium lappa.*

3.2. Discussions

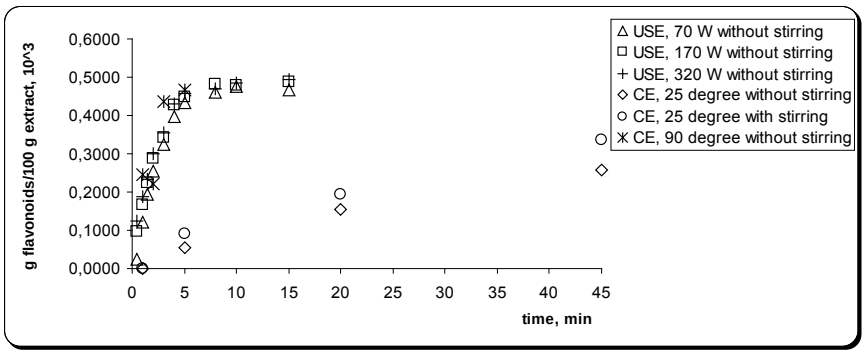

Figure 6. Time profiles of ultrasound-assisted extracted flavonoids from Arctium lappa (ultrasonic bath) – the rest is the same as in Figure 2

Generally speaking, like any other process governed by thermodynamic equilibrium, the extraction of active principles from plant parts is an asymptotic process, vanishing when the driving force becomes zero. One efficient way to improve the extraction rate is to increase the kinetic energy of the contacting fluid. When this supplemental kinetic energy was introduced from outside into the liquid phase through heating and/or stirring, the process rate was increased and the extraction process becomes faster, as can be observed for all experiments. Although it helps the diffusion process, stirring is not as efficient as heating, though thermal degradation of the valuable compounds starts manifesting when, at the extraction temperature of 90°C as in the present study, the contact time is too long.

When using ultrasound waves as intensification technique, the extraction rate increases dramatically, due to the direct transfer of the kinetic energy from the field to the liquid throughout the formation and destruction of very small cavities. There are at least two side effects o this kinetic energy transfer: the local disruption o the cell wall, with beneficial effect upon releasing the active principles in the liquid phase and rapid temperature increase, due to the violent friction and, consequently, mechanical energy dissipations.

When the extraction develops in the presence of an ultrasonic field, the stevioside concentration attains its maximum value after less than ten minutes (see Figure 2 for details). Good results for flavonoids and polyphenolic acids from *Cynara solymus* and *Arctium lappa* were obtained also, less than 15 minutes being necessary for the process to complete (see Figures 3 to 6 for details). This is the effect of the sharp increase of the local turbulences, which increase the mass transfer and also boost mixing of the liquid, thus maintaining the highest possible driving force. Increasing the power of the ultrasonic field hasn't an observable effect, since there is a rate of energy absorption into the liquid which attains a maximum for a satu-

ration level of output ultrasonic power lower than 70 W. This saturation level should be in connection with the liquid mass implied in the extraction process. Due to these side effects, mainly to the local temperature increases but also to the sudden local kinetic energy changes, ultrasounds are detrimental when the mixture is overexposed, as can be seen in Figures 2, 4 and 6.

Compared to maceration, ultrasound assisted extraction increased the productivity and decreasing the time of completion. With respect to hot extraction, whose performance is by far better than maceration, ultrasound assisted extraction has the main advantage of working at ambient temperatures, thus avoiding the thermal overexposure.

Like hot extraction, ultrasound assisted intensification needs special equipment to be functional, which means higher investments, and electricity to produce the ultrasonic waves, which means higher operating costs than maceration. So, a soundly economic analysis should be done, in order to choose the best extraction procedure.

4 Conclusions

Ultrasound assisted extraction (UAE), as a new extraction method, was used to extract stevioside, polyphenolic acids and flavonoids from *Stevia rebaudiana* leaves, *Cynara scolymus* leaves and *Arctium lappa* roots.

Comparing with other extraction methods, UAE has excellent advantages, such as shorter extraction time and higher yield extraction. Compared with classical extraction methods like maceration and hot extraction, the ultrasound assisted extraction proved to be a simpler but more effective procedure to obtain active compounds from medicinal plants; it works at lower temperatures, avoiding thermal degradation and higher rates, a very important asset for industry.

UAE is expected to offer a new way for the production and analyses of the plant extractions, and the modernization of pharmaceutical engineering herbal medicine.

Topic: Systematic methods and tools for managing the complexity - PAT.

Abstract

The kinetic behaviour of the reaction system during the hydrolysis of *p*-nitrophenyl butyrate (PNPB) catalysed by a single-site mutant of *Fusarium solani pisi* cutinase immobilized on zeolite NaY was followed using UV/Vis *in situ* diode array spectrophotometry.

Spectral band-fitting techniques allowed the use of this spectroscopic technique to obtain quantitative data on the concentrations of the various species present in an aqueous reaction medium with solid catalyst particles. This methodology overcame the problems arising from the variable light scattering produced by the catalyst particles. Kinetic modelling of the reaction system was used to estimate the reaction rate constants involved.

1 Introduction

Process analytical technologies may provide outstanding contributions for the quality control of various production processes, namely in the food and pharmaceutical industries (Lopes et al., 2004) and they will also have a significant impact in laboratory experimental data interpretation.

Herein, the reaction kinetics of the hydrolysis of PNPB catalysed by a single-site mutant of *F. solani pisi* cutinase, supported on zeolite NaY, was followed using *in situ* UV/Vis diode array spectrophotometry. PNPB is an ester whose hydrolysis is commonly employed to characterize the activity of lipases (Almeida et al., 2004). To exploit the benefits of a heterogeneous catalyst, both in terms of ease of separation from the reaction medium and in terms of stability of the biocatalyst, the enzyme was supported on zeolite NaY by physical adsorption.

In aqueous media, the highly dispersible solid catalyst particles produce very significant interference

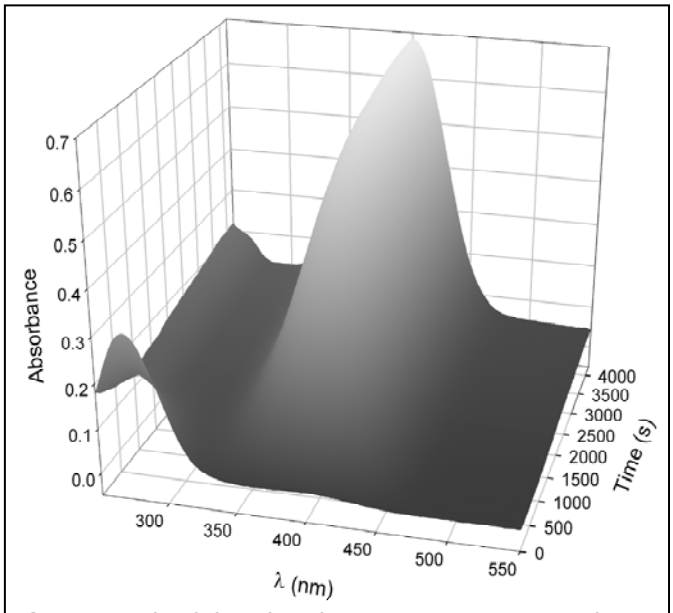

Fig. 1 Graph of the absorbance spectra captured over the course of the hydrolysis of PNPB catalyzed by cutinase T179C immobilized on zeolite NaY.

* Corresponding author. E-mail: francisco.lemos@ist.utl.pt

with the absorption measurements. This effect is further aggravated by the dynamic behaviour of the light scattering phenomena caused by the random breakdown of catalyst particle aggregates over the course of the reaction. Combining a high-throughput data acquisition technique, such as diode array spectrophotometry, with spectral band-fitting methods allowed the retrieval of quantitative data on the concentrations of the various species present in the reaction medium, thus enabling us to perform a kinetic analysis of the reaction.

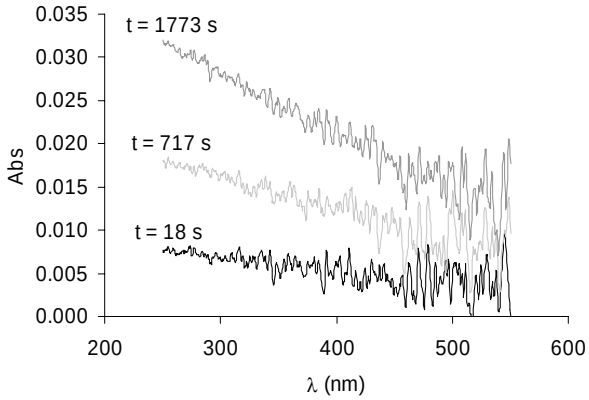

Fig. 2 Evolution of the absorbance during a blank (NaY in buffer) PNPB hydrolysis assay due to the presence of the zeolite

2 Experimental

A *F. solani pisi* cutinase single site mutant T179C was selected from a complete saturation mutagenesis library (Brissos et al., 2008). Zeolite NaY (Union Carbide, Si:Al = 2.5) was used as a support after calcination and the enzyme was immobilized by adding 400 $mg_{zeo}.mL^{-1}$ to a 20 $mg_{enz}.mL^{-1}$ solution in 50 mM potassium phosphate buffer pH 8.5 for 30 min, subsequently washed and vacuum dried for 6 h.

The hydrolysis of PNPB was followed *in situ* using an Ocean Optics USB2000® UV/Vis diode array spectrophotometer equipped with a Mikropack® DH-2000-BAL deuterium-halogen light source and a computer running the Spectra Suite® software. The reactions took place in a cell with a reaction volume of 1 mL, at 30 ºC and with magnetic stirring. A stock solution of PNPB (Sigma, 98 %) 3.5 mM in acetonitrile (Merck, HPLC grade) was prepared and kept at 0 ºC. For each assay, 0.25 mg of catalyst and 990 μL of phosphate buffer were placed in the cell and the reaction was started by the addition of 10 μL of the PNPB solution.

Reference spectra (molar absorptivities, ε) in the 250<λ<550 nm range were obtained from an orthogonal calibration set (Brereton, 2000) prepared with standard solutions of PNPB and its product *p*-nitrophenol (PNP). No absorption was detected with the other product, butyric acid. A reference spectrum of the zeolite suspension was obtained with a weighed average of the spectra collected during a blank assay.

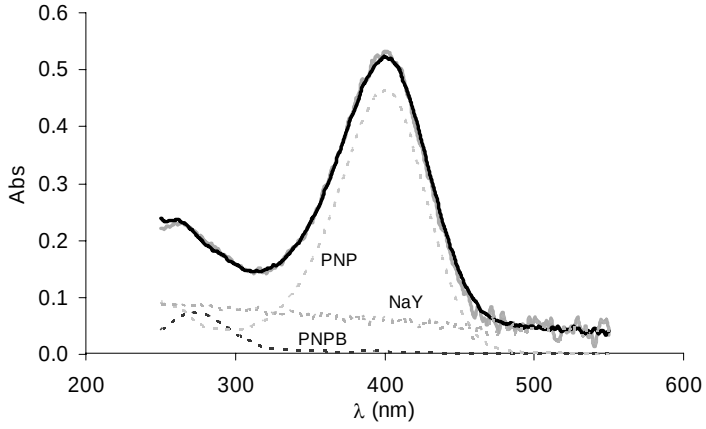

Fig. 3 Band-fitting procedure used to determine the concentration of the species present in the reaction medium during the hydrolysis of PNPB catalyzed by 0.25 mg of zeolite NaY-supported cutinase T179C at a reaction time of 2513 s. The absorbance contributions from PNPB, PNP and the solid catalyst are added to calculate the total simulated absorbance (—), which is then fitted to the experimental absorbance (—) by a least-squares method using the concentrations as the fitting parameters

3 Results and discussion

Throughout each assay, the spectrophotometer collected light intensity spectra that were converted to absorbance using the dark and reference spectra (Eq. 1). A 3D graph showing the evolution of the spectra with the reaction time is depicted in Fig. 1.

$$Abs = log_{10}\left(\frac{I - I_{dark}}{I_{reference} - I_{dark}}\right) \quad \text{(Eq. 1)}$$

From this graph, focusing on the λ_{max} values for PNPB (273.52 nm) and PNP (402.06 nm), it can be seen that the absorbance of both species increases simultaneously after ~2000 s. However, according to the stoichiometry of the reaction (1:1), the sum of PNPB and PNP concentrations was expected to remain constant throughout the assay.

To clarify this observation, an experiment was performed under the same conditions, in the presence of NaY, but without enzyme or PNPB (blank). The results presented in Fig. 2 show that the absorbance increased over time for all wavelengths. This effect is most likely the result of the breakdown of zeolite particle clusters caused by stirring in the reaction cell and by the interaction between the hydrophilic zeolite crystallites and the aqueous reaction medium. Thus, the particles in suspension become progressively finer, intensifying the light scattering effects over time. This change in the aggregation state of the catalyst seems to depend on several factors, including the initial aggregation state, which is very difficult to control.

Realizing that the presence of the zeolite would affect the measurements by contributing to the absorbance value, it became necessary to determine the concentrations of PNPB and PNP over time not only considering $\varepsilon_{PNPB}(\lambda)$ and $\varepsilon_{PNP}(\lambda)$, but also an "$\varepsilon_{NaY}(\lambda)$" to account for the variable light scattering effect caused by the zeolite. This "artificial" NaY absorptivity was determined by a weighed average of the spectra acquired during the NaY assay. The NaY absorptivity has an associated virtual NaY concentration, which can be roughly seen as the concentration of light scattering particles and is

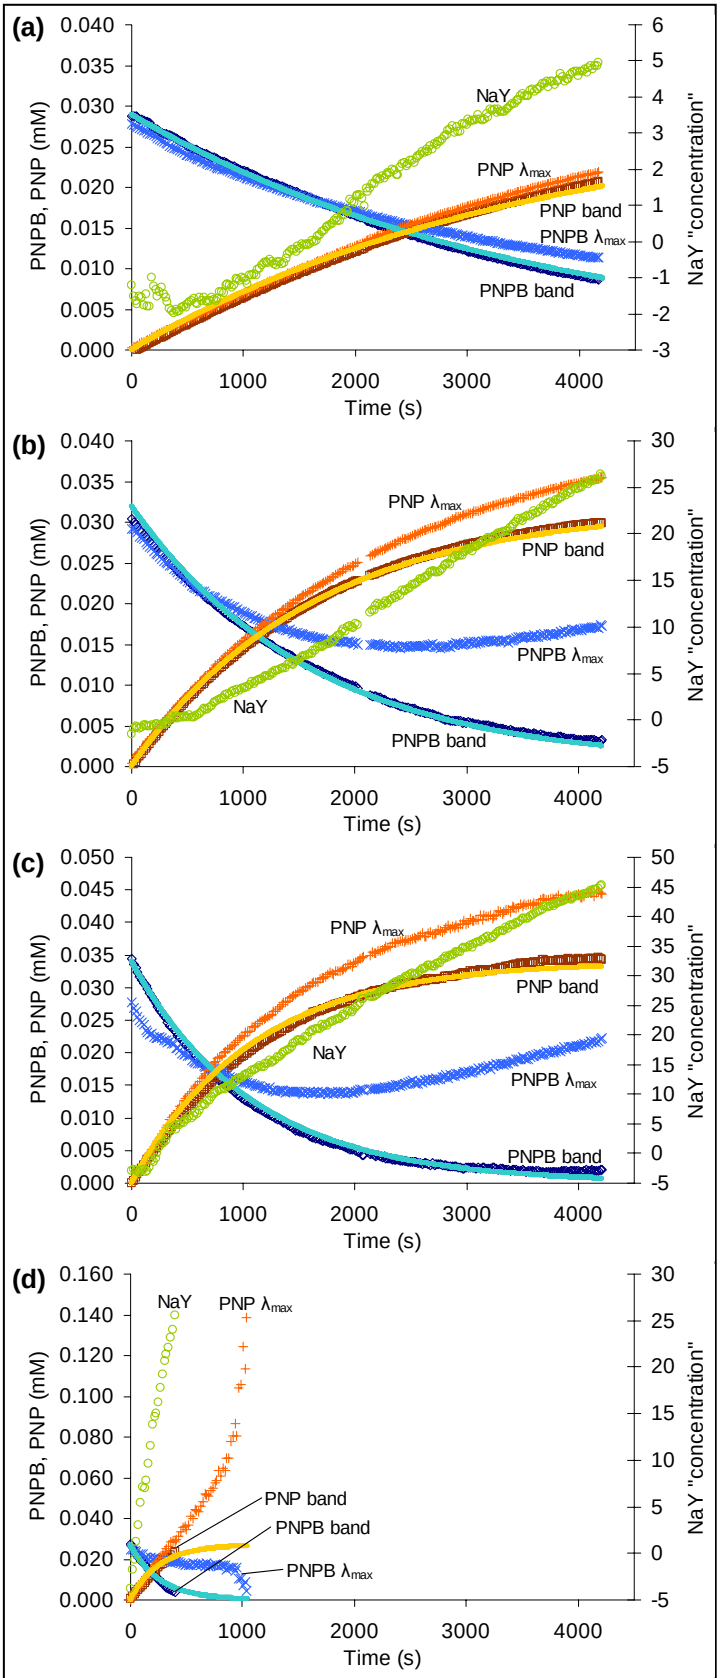

Fig. 4 Hydrolysis of PNPB catalysed by **(a)** 0.10, **(b)** 0.25, **(c)** 0.50 and **(d)** 1.0 mg.mL^{-1} of NaY-supported cutinase T179C. Concentrations determined with $\varepsilon(\lambda_{max})$ (PNPB ×, PNP +) and by band-fitting, using $\varepsilon(\lambda)$ and accounting for the NaY effect (PNPB ◊, PNP □, "NaY" ○). The lines are the result of kinetic modeling.

expected to increase with time due to the change in the aggregation state of the solid catalyst.

The concentration profiles of the various species were determined by decomposing each spectrum (at a fixed reaction time) into a linear combination of the previously recorded standard spectra (represented by the absorptivities as a function of λ), as illustrated in Eq. 2.

$$Abs_{simulated}(\lambda,t) = \varepsilon_{PNPB}(\lambda)\times C_{PNPB}(t) + \varepsilon_{PNP}(\lambda)\times C_{PNP}(t) + " \varepsilon_{NaY}"(\lambda)\times "C_{NaY}"(t) \qquad \text{(Eq. 2)}$$

An example of this band-fitting procedure for a single reaction time is shown in Fig. 3.

The graphs in Fig. 4 present a comparison between the profiles obtained by band-fitting and the concentrations calculated by simply using the conventional spectrophotometric method: applying Beer's law to the data obtained at the maximum absorption wavelengths, $\varepsilon_{PNPB}(\lambda_{max})$ and $\varepsilon_{PNP}(\lambda_{max})$, and not considering the effect of the zeolite. Four biocatalyst concentrations were assayed in the hydrolysis of PNPB, so as to determine the influence of this variable on the reaction kinetics and on the monitoring technique itself.

Accounting for the presence of the zeolite and introducing this information into the spectral decomposition notably improved the concentration profiles obtained. Indeed, the concentrations of both PNPB and PNP now stabilize at the end of the assay, as expected.

The zeolite "concentration" curves determined for each case are different not only in magnitude but also in shape, suggesting that the aggregation state of the catalyst at the starting point and over the course of each assay is difficult to control.

Estimates of the typical error values of the band-fitting procedure were computed by a standard bootstrapping methodology (Manly, 2006) with 20 simulations for a single time point of an experiment. So, choosing for example a catalyst concentration of 0.25 mg.mL^{-1} (Fig. 4b), at t = 376 s, yielded values of the half-width of the confidence intervals (significance level, α, of 0.05) for C_{PNPB}, C_{PNP} and "C_{NaY}" of, respectively, 0.04 %, 0.06 % and 7.2 %. This was considered acceptable, given that "C_{NaY}" contributes the least to the final spectrum composition (Fig. 3).

For a catalyst concentration of 1.0 mg.mL^{-1} (Fig. 4d), after approximately 1000 s no more absorbance measurements could be made because the zeolite particles in solution disperse the light beam to such a large extent that it caused the detector to receive a lower light intensity than the dark spectrum acquired at the start of the experiment, which results in error when using Eq. 1. The light intensity of the reference minus the dark spectra for each catalyst concentration used is displayed in Fig. 5. When 1.0 mg.mL^{-1} of catalyst is used, the light intensity reaching the detector is very low from the very start of the experiment, and this situation is aggravated over time as a result of the increase in light dispersion caused by the particle breakdown. This constitutes a clear limitation of the technique presented herein.

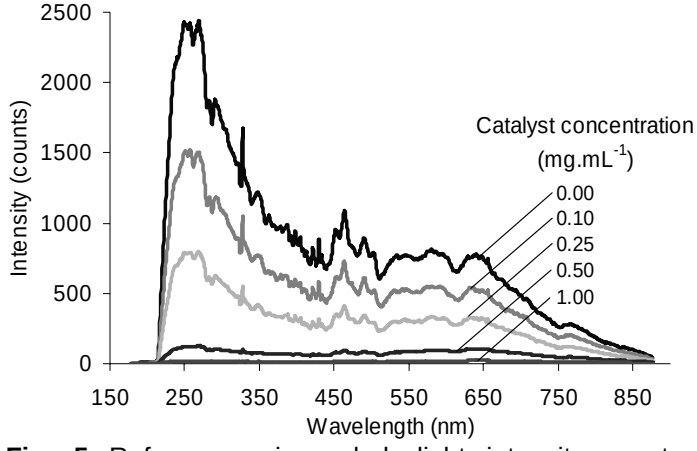

Fig. 5 Reference minus dark light intensity spectra obtained at the start of the PNPB hydrolysis experiments with several zeolite NaY-supported cutinase T179C concentrations

Kinetic modelling

Kinetic modelling was performed using the concentration profiles data

for each catalyst concentration. For the assay with 1.0 mg.mL^{-1} of catalyst, only the initial fraction of experimental data was selected. The reaction was considered first order, reversible and with a large excess of water (pseudo-first order), so the system was described according to the scheme displayed in Fig. 6 and the resulting material balances (Eq. 3).

$$\frac{dPNPB}{dt} = -\frac{dPNP}{dt} = -\frac{dHBut}{dt} = -k_1.PNPB + k_{-1}.PNP.HBut \qquad \text{(Eq. 3)}$$

The equations corresponding to the material balances of the relevant species (PNPB, PNP, HBut) were solved using Euler's method and the model was fitted to the experimental results by a least squares method. The initial concentrations of PNP and butyric acid were both assumed to be 0 and k_1, k_{-1} and $PNPB_{init}$ were used as fitting parameters. The resulting model curves (Fig. 4) provided a reasonably accurate description of the experimental data after band-fitting, but not for a simple application of Beer's law.

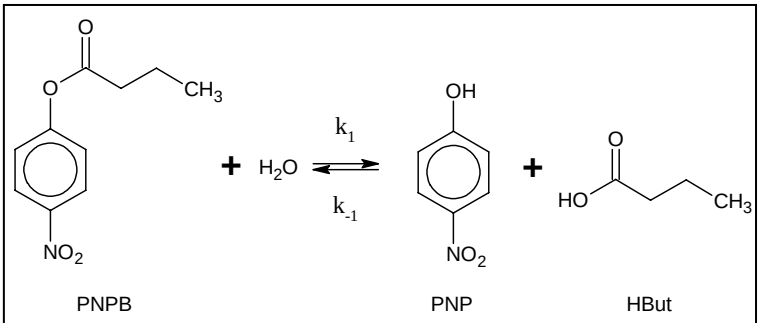

Fig. 6 Reaction scheme for the hydrolysis of PNPB

The forward reaction kinetic constant, k_1, obtained from the model fitting was plotted against the respective catalyst concentration (Fig. 7). The kinetic constant k_1 varies linearly with the catalyst concentration up to 0.50 mg.mL^{-1}. It can be observed that at 1.0 mg.mL^{-1} of zeolite, the value obtained by modelling is significantly higher, probably as a result of the absorbance measurement difficulties previously discussed. The bootstrapping technique described earlier was employed to obtain an estimate of the error of the parameters fitted during the kinetic modelling process. The half-widths of the confidence intervals (α = 0.05) for k_1, k_{-1} and $PNPB_{init}$ were, respectively, 0.2 %, 3.9 % and 0.2 %, as averaged from the 4 fittings shown in Fig. 4.

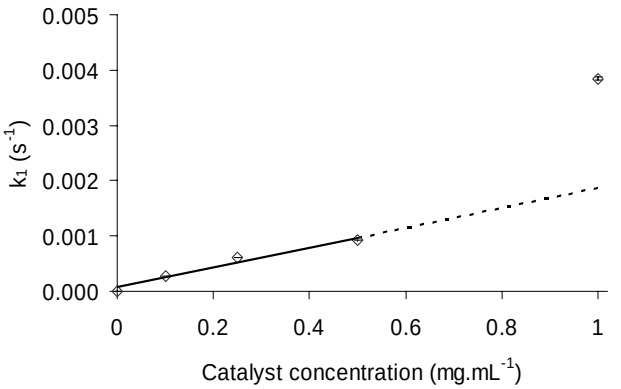

Fig. 7 Modelling results obtained for the kinetic constant k_1 with each catalyst concentration. The line represents a linear regression (R^2 = 0.96)

4 Conclusions

In the work described herein, spectral band-fitting techniques based on *in situ* diode array spectrophotometry allowed quantitative measurements in a liquid reaction medium containing a highly dispersible heterogeneous catalyst, despite its non-predictable interference pattern. However, this method can only be used with catalyst concentration values below a certain limit, which is dependent on the properties of the solid being used, *e.g.* hydrophilicity. Above this value, the particles completely block the beam pathway and no light reaches the detector. In the present case, we were able to apply this technique to catalyst concentrations up to 0.50 mg.mL^{-1}.

Synthesis of tripropionin from crude glycerol the by-product of biodiesel production

Zsanett Herseczki, Gyula Marton
Cooperative Research Centre for Environmental and Information Technology, University of Pannonia, H-8200 Veszprem, Hungary

Keywords: glycerol, tripropionin, fuel additives
Topic: Advancing the chemical and biological engineering fundamentals or Sustainable process-product development through green chemistry

Abstract

Glycerol is a by-product obtained during the production of biodiesel. An increase in biodiesel production would decrease the market price of glycerol. The objective of this study is to investigate glycerol purification and esterification. Crude glycerol from a Hungarian biodiesel factory was partly refined, soaps, water, methanol and pigments were removed and glycerol containing salts was used for certain esterification reactions. The best result of glycerol esterification by propionic acid at 100% conversion of glycerol with selectivity to tripropionin larger than 94% was obtained in case of H_2SO_4 catalyst using continuously water removal. Ion exchange resins were also investigated. A potential process for utilization of crude glycerol was created, which can be applied not only for tripropionin production but production of other glycerol esters like glyceryl triacetate, glyceryl tributyrate. Effect of tripropionin blending on engine performance characteristics and environmental repercussions were studied.

1 Introduction

Biodiesel has high potential as liquid transportation fuel because of its environmental benefits such as minimal emission of CO_2 when compared to regular diesel fuel. Biodiesel is produced from vegetable sources (soybean, sunflower, canola, cotton seed, rapeseed and palm oil) and animal fats using the processes such as micro emulsions, thermal cracking (pyrolysis) and transesterification. Of the several methods available for producing biodiesel, transesterification of natural oils and fats is the most common method. Transesterification is the reaction of fat or oil with an alcohol to form esters known as biodiesel and glycerol using a catalyst. Approximately 10% of the converted feedstock is released as crude glycerol. Hungarian government has planned to produce 150 000 t of biodiesel by 2010, it means that 15 000 t/year glycerol is expected from biodiesel production. This product fraction comprises several impurities, e.g. residues of vegetable oil and esters, salts, different alkaline catalysts and water. Although biofuels such as biodiesel and bioethanol represent a secure, renewable and environmentally safe alternative to fossil fuels, their economic viability is a major concern. The implementation of biorefineries that co-produce higher value products along with biofuels has been proposed as a solution to this problem. The biorefinery model would be especially advantageous if the conversion of byproducts or waste streams generated during biofuel production were considered. Glycerol-rich streams generated in large amounts by the biofuels industry, especially during the production of biodiesel, present an excellent opportunity to establish biorefineries. Once considered a valuable ‘co-product’, crude glycerol is rapidly becoming a ‘waste product’ with a disposal cost attributed to it.
As glycerol is a nontoxic, edible, biodegradable compound, it will provide important environmental benefits to the new platform products. Lower cost glycerol could open significant markets in polymers, ethers, esters and other compounds. From a technical standpoint, glycerol’s multifunctional structure can be exploited by several different means.

One alternative is to esterify glycerol with organic acids (e.g. acetic acid) or anhydrides (e.g. acetic anhydride) and produce oxygen-containing components, which could have suitable properties for use for example in fuels or solvents.
Our aim was to study esterification of glycerol by propionic acid and investigate the field of application of the product.

2 Experimental

Catalyst and chemicals

The commercial strong acid ion-exchange resins Amberlysts (A15 and 36) from Sigma-Aldrich were used as esterification catalysts. Wet ion-exchange resin (A36) was washed with methanol and dried to remove water and impurities from the catalyst pores. A15 in a dry form was used directly. Pure glycerol (99,5%), activated-carbon and calcium-hydroxide were obtained from Spektrum-3D Ltd. (Hungary). Pure glycerol was used for the initial baseline reactions. Crude glycerol was obtained from Öko-Line Hungary Ltd. (Hungary). Propionic acid (>99%), methyl isobutyl ketone (>98,5%), n-hexane (>96%), phosphoric acid and sulfuric acid were obtained from Sigma-Aldrich.

Apparatus and procedure

Due to the fact that composition of crude glycerol obtained from Hungarian biodiesel factory (1. Table) differs from composition offered by Mc Ketta (soaps, more water and salt), a new purification process had to be developed.

Table 1: Composition of G-phases obtained from Hungarian biodiesel factories

Material	**Composition (wt %)**
Glycerol	45-50
Water, methanol	10-15
Salt	10-15
Soaps	30

According to references, the following views were accepted during our purification process:

Due to the high viscosity of the crude glycerol all purification steps were carried out at elevated temperature. In this way we were able to decrease the load of agitators. It is not practical to eliminate the methanol from crude glycerol at the beginning of technology, because it has a favorable advantage of diluting the mixture. It is advisable to dilute the crude glycerol with water to reduce the viscosity.

First step of our refining process was acid treatment. Phosphoric acid was used to reach pH=3 and mixture was stirred at 80 °C, for 1 hour. After the treatment free fatty acid derived from soaps were separated from crude glycerol by simple phase separation.
Next step was neutralization to separate applied acid in excess. Calcium-hydroxide was used for precipitation, optimal pH of neutralization was found to be around 4,8. Formed $Ca_3(PO4)_2$ was eliminated by simple filtration. Filtrate coming from neutralization step is yellow or light brown, if it is necessary, pigments and odor can be eliminated by adsorption on activated-carbon (2 wt%/ crude glycerol). Bleached solution contains only water, methanol and salt. Removal of whole amount of water can be achieved only by distillation at 80°C under vacuum (~ 3kPa). Unfortunately, normal boiling point of glycerol is rather high (290°C) and glycerol oligomerization starts over 200°C, so extremely deep vacuum should be used to distill glycerol from heavies (inorganic salt). Specific use of chemicals depends on the composition of crude glycerol.
The esterification reactions were carried out in a glass flask (500 ml) with magnetic stirring.
Propionic acid was used in excess to shift reaction equilibrium towards the product. Reaction were carried out by straight – forward distillation in absence of entraining solvents and by

help of entraining solvent (MIBK or n-hexane) to remove water azeotropically. The unreacted propionic acid and residual water were distilled off at 80-100°C under reduced pressure (3 kPa). The most difficult problem in connection with crude glycerol refining is removal of salt which is formed during neutralization of the catalyst (KOH, NaOH). Due to the fact that presence of salt does not disturb the reaction and it is insoluble in tripropionin, this problem can be solved by simple filtration.
In a typical run, 46 g (0,5 mol) of glycerol and 222 g (3 mol) propionic acid were used. 2 ml was used from H_2SO_4 and 10 g A15 and 12 g A36 were used in a typical run. Reactions were stopped at the end of water formation.

Analysis

The samples of reaction products were analyzed with a HP 5890 Series II gas chromatograph equipped with a Restek Rtx-5MS column (30m x 0,25 mm x 0,25 µm) and a HP 5971 MSD detector. Analyses were carried out with temperature program from 60 to 240°C (with a slope of 10°C min^{-1}) and 240°C for 2 min isothermally.

3 Results and discussion

The aim of this work was to study the influence of catalyst and the quality of raw material on esterification of glycerol with propionic acid.
The esterification of glycerol (G) with propionic acid (PA) is a complex of three acid catalyzed consecutive equilibrium reactions with formation of monopropionin (MP), dipropionin (DP) and tripropionin (TP). Summary of reaction is shown in Figure 1.

$$G + PA \leftrightarrow MP + H_2O$$
$$MA + PA \leftrightarrow DP + H_2O$$
$$DA + PA \leftrightarrow TP + H_2O$$

Conversion (X) is generally a good indicator of reaction progress. Conversion in the context of these reactions can be based on either glycerol or propionic acid. Glycerol reacts to form the stepwise ester products. However, since reacted glycerol may result in a mono-, di-, or tri-ester of glycerol, conversion is not a good indicator of the extent of reaction. Due to this fact selectivity (S) and yield (Y) were determined.

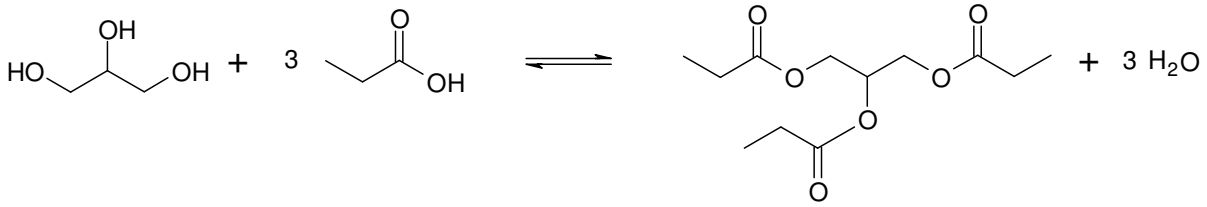

Figure 1: Reaction scheme for esterification of glycerol with acetic acid

As first step, reaction was carried out in presence of sulfuric acid. Forming water was removed by straight – forward distillation in absence of entraining solvents. The best result, 100 % conversion, 94 % selectivity and 94 % yield was received in presence of H_2SO_4 catalyst in case of pure glycerol as raw material. When glycerol containing salt was the raw material, the yield of tripropionin was ~ 83 % (Table 2). Due to the fact that amount of propionic acid decreases during the reaction quickly because it leaves with water, utilization of a structured packed tower to separate water or entraining solvent to remove water azeotropically at lower temperature is reasonable.
Homogeneous catalysts, although effective, lead to serious contamination problems that make essential the implementation of good separation and product purification protocols, which translate into higher production costs. The appropriate solid catalysts could be easily incorporated into a packed bed continuous flow reactor, simplifying product separation and purification and reducing waste generation.
Currently, the esterification of acids with alcohols is commercially achieved using liquid

catalysts, such as sulfuric acid, hydrofluoric acid, and p-toluene-sulfonic acid. The scientific literature contains a good number of reports about the use of heterogeneous acid catalysts for esterification. For instance, esterification has been carried out using ion-exchange resins such as Amberlyst-15 and Nafion with good results. In general, when using organic resins, the catalytic activity strongly depends on their swelling properties. Resin swelling capacity is fundamental since it controls substrate accessibility to the acid sites and, therefore, affects its overall reactivity. Once swelled, the resin pores usually become macropores. This means that big molecules with long hydrocarbon chains show no diffusion limitations and can readily access the acid sites in the bulk.

Table 2: Comparison of catalysts and quality of raw materials for esterification of glycerol

Raw material	Catalyst	Procedure	Reaction Time (min)	Distribution of products wt%				X_G %	S_{TP} %	Y_{TP} %
				Glycerol	MP	DP	TP			
Pure glycerol	H_2SO_4	Raschig r. tower distillation	155	0	0	5,1	94,8	**100**	**94**	**94**
Glycerol cont. salt	H_2SO_4	Raschig r. tower distillation	210	0	0	13,7	86,8	**100**	**83**	**83**
Pure glycerol	A15	Raschig r. tower distillation + n-hexane	660	0	0	11,9	88,4	**100**	**85**	**85**
Glycerol cont. salt	A15	Raschig r. tower distillation + n-hexane	715	0	0	74,8	25,2	**100**	**21**	**21**
Pure glycerol	A36	Raschig r. tower distillation + n-hexane	455	0	0	42,3	57,7	**100**	**52**	**52**
Glycerol cont. salt	A36	Raschig r. tower distillation + n-hexane	575	0	0	72,7	7,7	**100**	**7,6**	**7,6**
Pure glycerol	A15	Raschig r. tower distillation + MIBK	380	0	8,7	10,1	81,8	**100**	**74**	**74**
Pure glycerol	A36	Raschig r. tower distillation + MIBK	455	0	5,1	10,9	84,1	**100**	**79**	**79**

Despite of the fact that most ion-exchange resins are not stable at temperatures above 140 °C, which prohibits their application to reactions that require higher temperatures and inorganic acid catalysts are generally more suitable, Amberlyst 15 and 36 were investigated.
Due to the fact that the maximal operating temperature is 120°C in case of A15 and 150°C in case of A36 further improvement had to be achieved to decrease the reaction temperature, so the temperature of water-removal. A solvent had to be found which does not form an azeotrop with propionic acid and is able to remove water at lower temperature. Methyl isobutyl ketone (MIBK) and n-hexane are potential entraining solvents to remove water azeotropically. Boiling point of MIBK-water azeotrop is 87,9°C and it contains 24,3 wt%

water. After water-MIBK phase separation MIBK was recycled back to the reactor.
As it can be seen from Table 2 relatively high yield can be reached when raw material is pure glycerol. When raw material is glycerol containing salt reaction product contains mainly dipropionin.
There are not any information about boiling point of monopropionin and dipropionin in the literature, so it is difficult to estimate the possibility of tripropionin separation by distillation. Due to this fact further experiments need to be done to improve synthesis of tripropionin to receive ~100% yield and investigate the potential of mono-, di- and tripropionin separation.
Figure 2 shows a potential process for utilization of crude glycerol. This scheme can be applied to produce other glycerol esters like glyceryl triacetate, glyceryl tributyrate.
If esters of glycerol are produced from crude glycerol, some purification steps can be eliminated like previous distillation of water because water is removed azeotropically during ester formation. Preceding activated-carbon treatment is not necessary because esters of glycerol need to be likely decolorized at the end of the process.

Engine performance

Effect of tripropionin blending on engine performance characteristics and environmental repercussions were studied (Table 3). VW-AUDI 1.9 TDI engine was used for the measurements. Blended fuel contained 5 wt% tripropionin.

Table 3. Comparison of reference fuel and blended fuel

	Reference fuel	**Blended fuel**	**Change [%]**
THC [ppm]	35,6	37	**+3,9**
NO_X	767	768	**+0,1**
CO (V/V%)	0,0174	0,0163	**-6,3**
Smoke [FSN]	1,48	1,29	**-12,8**
Specific fuel consumption [g/kWh]	251	260	**+3,6**
$T_{exhaust}$ [°C]	524	520	**-0,8**

An increase of total unburned hydrocarbons (THC) in blended fuel was observed which must be in connection with the inadequate burnout of tripropionin. Due to the high oxygen content of tripropionin a decrease of CO, smoke and exhaust temperature was observed. Specific fuel consumption increased which can be explained by the measured lower maximal motor torque.

According to the engine performance characteristics and environmental repercussions tripropionin represents a promising material, which can be used as fuel additive. Further studies need to be done to find the optimal ratio of tripropionin in Diesel oil.

4 Conclusion

Crude glycerol is a considerable by-product of biodiesel production for which new uses are being sought. Purification of G-phase and esterification of glycerol with propionic acid using sulfuric acid and strong acid ion-exchance resins Amberlyst type were studied. The best result of glycerol esterification by propionic acid at 100% conversion of glycerol with selectivity to tripropionin larger than 94% was obtained in case of H_2SO_4 catalyst using continuously water removal. Homogeneous catalysts (H_2SO_4), although effective, lead to serious contamination problems. The appropriate solid catalysts could be easily incorporated into a packed bed continuous flow reactor, simplifying product separation and purification and reducing waste generation.
A potential process for utilization of crude glycerol was created, which can be applied not

only for tripropionin production but production of other glycerol esters like glyceryl triacetate, glyceryl tributyrate.
Tripropionin represents a promising material, which can be used as fuel additive to improve engine performance characteristics and environmental repercussions. Further studies need to be done to find the optimal ratio of tripropionin in Diesel oil and to examine other fields of application of this relatively new product.

The future sustainability of biodiesel

Renato H. Carvalho[1]*, Luís R. Vilela de Matos[1]

Topic: Multi-scale and/or multi-disciplinary approach to process-product innovation (Energy and environment).

Abstract

This paper shows Iberol perspective in what concerns to the future sustainability of biodiesel.

The significant imposed tax gap between gasoil and gasoline, resulted in a transportation fleet based on the first one. As an effort to decrease the gasoil dependence and at the same time, reduce the CO_2 emissions, biodiesel has become the most important biofuel in European Union (EU).

The biodiesel has to be considered as a complement to push ahead, the end of fossil diesel in a medium term, and never a total substitute. The competitiveness between biodiesel and fossil petrodiesel can only be equalised if the non-edible raw materials are used.

We are sure that soybean oil is in short time the answer since most protein comes from this proteoleaginous, increasing meal for the food chain in which results a by-product that can be considered as a non-edible oil and can be used to decrease the fossil fuels, producing biodiesel.

The by-products from the biodiesel production have a paramount importance in this type of market, having an enormous potential as feedstoks for other chemical products, such as, epichlorohydrin and propylene glycol, among others.

Biodiesel can be produced by a sustainable way, only if the right policies and attitudes are taken in a short term.

1 Introduction

The use of biofuels in the European Union is playing an increasingly important role. Both political issues such as, EU legislation, Kyoto protocol, Bali agreement, and market issues such as, economic opportunities, responsible business, encourage their use. Part of the raw-materials need to be imported from the outside of EU and, although biofuels have a green image, an increasing concern arises about the sustainability of the produced raw-materials (including impacts on biodiversity, displacement of food production and effectiveness in the greenhouse gas reduction).

The name biofuels can be generally defined as solid, liquid, or gas fuel derived from new biological material, distinguishing itself from the fossil fuels (long time dead biological materials under extreme conditions). However, for the transport sector, only two are considered due to the available quantities in the world, biodiesel and bioethanol. If we evaluate the macro-structure of these two, bioethanol has importance in south and north America, because the demand of gasoline is very high, and the availability of raw-materials such as sugarcane are abundant (Brazil). In contrast, bioethanol in Europe should not be produced since exists a large excess of gasoline that is exported. Another important point is

* Corresponding author. Tel +351 219 519 400. E-mail: Renato.Carvalho.Iberol@Sortico.pt

that edaphoclimatic conditions are not adequate for the production of economic raw-materials (sugarcane). This biofuel in Europe is produced from corn (maize), a raw-material that interferes with the food chain, as it happens in the USA.

Corn ethanol produced in the USA shows that one unit of fossil-fuel energy is required to create 1.3 energy units from the resulting ethanol. The energy balance for sugarcane ethanol produced in Brazil is 1:8 and the biodiesel energy balance is 1:2.5. Another indicative balance is the cellulosic bioethanol biofuel, known as second generation bioethanol, which has an energy balance of 1:2-36. Second generation bioethanol is produced from feedstock containing cellulosic biomass such as the stalks, leaves, and husks of corn plants, wood chips, and sawdust. This biofuel has an index between 2 and 36, depending of the production process; however, these are experimental values because these methods are not economically feasible and thus, they are not industrially implemented so far (National Geographic Portugal, 2007). As it can be seen, the production of biodiesel in Europe is the reasonable choice at short term.

One hundred years ago, Rudolf Diesel tested vegetable oil (peanut oil) as fuel for his engine, however, with the advent of cheap petroleum and optimisation of the crude oil fractions to produce gasoil and gasoline, only on emergency times it was used vegetable oil. Today, this kind of emergency situation has arrives once again in our lives and the consideration of biomass use has become more than necessary, not only from an economic point of view, but also because of environmental protection.

EU imports more than 20 million tonnes of biodiesel, so must be by far the biggest and most important biofuel, representing more than 80% of total biofuels production. The EU is the worldwide leader in biodiesel production, both in terms of biodiesel capacities and production. In 2006 it was produced 77% of world-wide biodiesel production and in 2007 produced 5.7 million tonnes. An alternative fuel like biodiesel can be technically feasible, environmentally acceptable and readily available but it is not until now economically competitive, due to the price of raw-materials as it can be seen in Figure 1 (EBB, 2006).

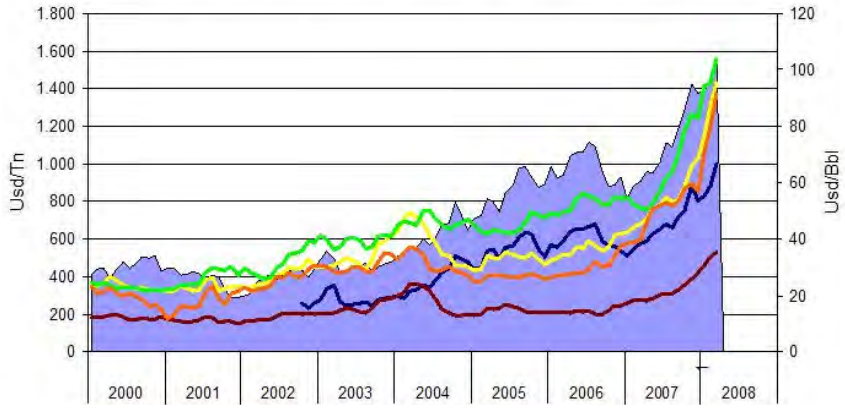

Figure 1- International commodities prices for petroleum, diesel, soybean, soybean oil, rapeseed oil, palm olein (Reuters, 2008).

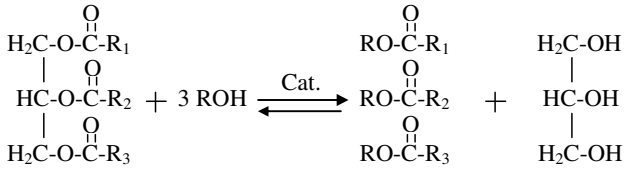
The cost of biodiesel varies depending on base stock, geographic area, variability in crop production from season to season, the price of the crude oil and other independent factors such as speculation in trade markets. The high price of biodiesel is in large part due to the feedstocks.

Since the economic growth is always accompanied by commensurate increase in the transports sector, this type of energy is gaining more and more importance due to the depleting of fossil fuel resources and also to avoid the monopoly of some oil-exporting countries. As a consequence of this depletion, the fuel price grows exponentially and the vegetable oils prices follow it. It is a mistake to think that biodiesel will be competitive in comparison with petrofuels. Methanol is also dependent today of a fossil fuel, since it is

produced from natural gas. Moreover, the limited oleaginous production implies limitations in vegetable oils production and thus, the demand is higher than the offer. The raw-materials are strongly dependent of the fossil fuels and speculations of prices.

Because of these mentioned situations, the biodiesel has to be considered as a complement, or adjuvant to push ahead, the end of fossil diesel in a medium term, and never a total substitute.

But what is biodiesel? The biodiesel is a renewable fuel that is produced by transesterification, in which a vegetable oil (edible and non-edible) or animal fat reacts with a short-chain alcohol in the presence of a catalyst, to form esters and glycerol (Marchetti et al., 2007). The major components of vegetable oils and animal fats are triacylglycerols (TAG; often also called triglycerides). This biofuel is biodegradable, non-toxic, sulphur-free and has low emission profiles as compared to petroleum diesel.



Other processes such as hydrotreating (NExBTL: catalytic hydrogenation of vegetable oils is not economically feasible) or even the second-generation fuel to blend with gasoil (Biomass To Liquid) that could replace biodiesel, are not well developed so far.

Because the growing of plants consumes CO_2, biodiesel has a closed carbon cycle dramatically reducing the CO_2. This allied with the desire to reduce dependence on foreign energy sources, manifesting itself through a variety of public policies over the years, have served to increase biodiesel use in the European Union (EU) (Knothe et al., 2005).

Industrially, the biodiesel is made mostly with rapeseed oil, palm olein, soybean oil and in small cases with animal fats. The parameters given by the specific European norm (EN 14214) are very restricted since they were based mostly on a biodiesel produced with rapeseed oil, thus it is not possible to produce an extreme biodiesel with only one type of oil/fat other than rapeseed oil of the referred ones.

In a global macro-economic point of view, the selection of the vegetable oil is very important, not only because of its cost but also due to the repercussions that this selection has in the world food structure. The competitiveness between biodiesel and fossil diesel can only be equalised if the non-edible raw materials are used.

Non-edible oil as raw materials, with enormous potential but still in development production, are obtained from plant species such as Jatropha curcas (Sarin et al., 2007), Pongamia pinnata (Meher et al., 2006) or microalgaes. Nevertheless, extreme biodiesel produced with these oils could not also fulfil totally the necessary specification of the EN 14214. These are indeed the expected raw material for the future biodiesel production, with enormous potentials due to the yield/crop and content of oil of the oleaginous. However, their massive production for the biodiesel industry is under development and thus cannot be at short term the answer to the biodiesel demand.

From all the mentioned above, only the soybean oil is each time more a non-edible oil (less than 5% is used in human alimentation). We can consider that in this case the principal product of the oil extraction is the soybean meal, very rich in proteins (44%), that is used in every animal feedstock, since soybean is considered a proteoleaginous. In addition, the soybean oil utilisation in human feed has very limitations. Given its economic value and availability, the soybean oil is nowadays a preferential raw material in the manufacture of biodiesel. However, as it was mentioned before, for example, the soybean oil presents an iodine index between 128 and 132, too high to meet the European specification of biodiesel in this parameter (equal to 120). Because of this fact, it is not currently possible in all EU

countries that have transposed these specifications, manufacture biodiesel entirely from soybean oil, it becomes necessary to incorporate other vegetable oils of higher costs, such as rapeseed oil from north of Europe and palm olein from tropical countries.

The European Mediterranean region has the appropriate edaphoclimatic conditions to produce soybean, which could have a significant contribution as endogenous production, not only oil, but mainly protein, in a similar comparison with the north appropriate edaphoclimatic conditions to produce rapeseed.

It can be conclude that soybean oil is in short term the answer since most protein comes from this proteoleaginous, increasing meal for the food chain in which results a by-product that can be used to decrease the fossil fuels, producing biodiesel.

Other way to promote the biodiesel and its future viability is the creation of conditions by governments to impose the biodiesel blending in every diesel, as well as, the removal of biofuels subsidies with the concomitant increasing of the diesel cost (a 5% biodiesel blending would increase ± 1 Euro cent on the diesel final cost).

Commercial production and consumption of glycerol were generally considered a reasonable indicator of industrial activity since it enters into such a large number of industrial processes. With the arrival of biodiesel, this biofuel industry has become practically a large consumer of methyl esters as the detergent industry and thus, resulted in a major production of glycerine (10% of the biodiesel production) that changed this market dynamic. The by-product nature of glycerol production leads to quite volatile price oscillations in the marketplace due to the stimulation or restrictions of the demand, to meet the available supply which is determined by factors outside the glycerol market. However, glycerine is a by-product with an enormous potential to substitute part of petrochemical feedstocks. The increasing abundance of glycerine, its renewability, and attractive pricing, make glycerol an appealing platform chemical to derive a family of commercially valued compounds (Figure 2).

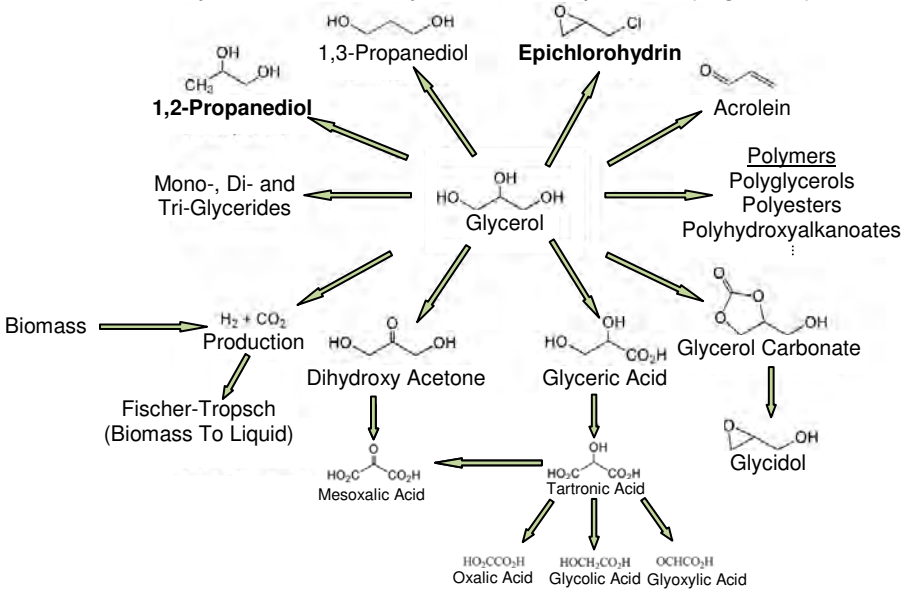


Figure 2- Platform chemical resulted from glycerol (Pagliaro et al., 2007).

The replacement of propylene from fossil origin by glycerine, that is a renewable and low-cost raw-material (Figure 3), has become very attractive to industry for the production of valued added chemicals, such as propylene glycol (1,2-propanediol) and epichlorohydrin.

Propylene glycol: the hydration of propylene oxide that is derived from propylene is then replaced by a liquid and vapour phase hydrogenation of the glycerine over a metal catalyst. Dow, Cargill, Archer Daniels Midland and Huntsman have recently announced plants to produce propylene glycol from glycerine.

Epichlorohydrin: a reaction of propylene with chlorine gas produces the allyl chloride which is further reacted to give dichloropropanol. This process can be replaced by the Solvay patent *Epicerol*, in which the glycerine reacts with hydrochloric acid over a catalyst that directly results in the dichloropropanol. This dichloropropanol in both processes is dehydrochlorinated with NaOH to give the final epichlorohydrin product. Hydrochloric acid is inexpensive and much safer in comparison with chlorine gas. Solvay started a 10.000 tonnes/year plant in France from glycerol and plan to start up a 100.000 tonnes/year plant in Thailand in 2009, due to the fast increasing demand for epichlorohydrin.

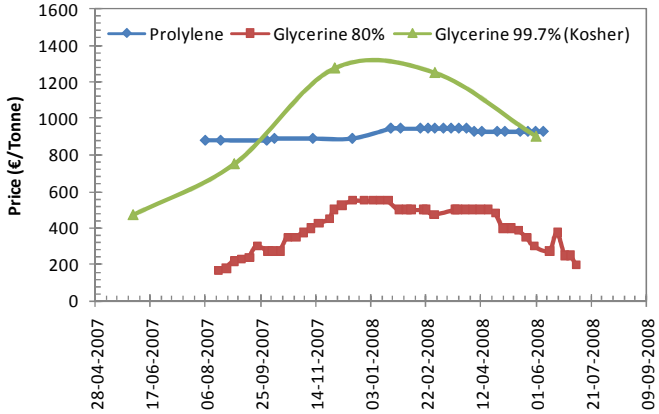

Figure 3- Prices of chemical compounds in Europe (Reuters, 2008 and ICIS, 2008).

In which respect to the international context, the EU market is disturbed by the continuing negative effects of "B99" (blending 1 part of diesel and 99 of biodiesel) from United States (US) with an export subsidy. With this unfair scheme the US producers can access the EU markets with a remarkable advantage, selling the biodiesel at the same or even at a lower price than the cost of EU industry's raw materials (EuropaBio, 2007).

The European parliament and council are creating a document with proposals for a Renewable Energy Directive (RED), which sets an overall binding target for the European Union of 20% renewable energy sources in energy consumption and a 10% minimum target for biofuels in transport by 2020 (Commission of the European Communities, 2008). The RED proposal introduces strict environmental sustainability criteria for the production of biofuels which gives the guidelines to each country transpose for their legislations, the sustainability criteria for the biodiesel production. Most importantly, the RED directive should provide a comprehensive set of sustainability criteria and calculation mechanisms for biofuels.

One of the major issues is the greenhouse gas balance biofuels that should assessed in a pragmatic and realistic way, both in terms of threshold and methodology. If the methodology is very restrictive, the 10% target of the threshold incorporation in 2020 will be very difficult to accomplish. This enforces the urgent need to establish a neutral set of criteria for assessing the GHG performances biofuels.

Another point of discussion is the understanding of the real influence of biodiesel in the food market. Some bad publicity is being made for the protection of individual interest and lobbies from specific markets that are indirectly involved. For example, EU biodiesel industry uses less than 3% of all imported palm oil. Before the implementation of biodiesel industry in the world economy, the lack of food for the poorest people was evident, however, with the development of the emergent countries like China, India, Indonesia and others, the fuel consumption and demand also increased. This led to the necessity for better human conditions and consumptions, resulting in a major demand of food and energy for these countries. There are a lot more causes than the biofuels production that increase the price of food and it is unreasonable to blame biodiesel for the major part of it. As it was said before, we have to distinguish between the good biofuels that are produced with non-edible raw-material and the bad biofuels that can interfere with the food market.

In the EU, biodiesel production can be done in accordance with sustainability principles and without endangering the food supply. The EU has to raise the oilseeds production from 23 million tonnes to the expected 35 million tonnes. Additionally, biodiesel production development will improve the EU self-sufficiency in terms of vegetable proteins as it was mentioned in relation to soybean. Today, the EU has currently a deficit in protein meals for animal feed. The development of biodiesel industry increases in 3 million tonnes this product since 2002 and the expected production should provide an additional 8 million tonnes by 2015-2020, thus increasing the EU self-sufficiency ratio from 20% to 30%. Europe still has available large Set-Aside areas that can be prepared and cultivated for these purposes.

2 Conclusions

The biofuels are not the ultimate solution of energy for the transport sector but is the short and medium term solution, pushing ahead the lifetime of petrofuels.

The main engines of increasing food costs worldwide include high crude oil prices, growing food demand in developing countries, droughts that have hurt crops globally, commodity speculators, the US dollar crisis and in the end, biofuels.

The right way to produce biodiesel it is indeed doing it with non-edible raw-material, in which the soybean oil has the major advantage of being a by-product of the seeds extraction process.

Europe has to increase its endogenous crops, not only to be more self-sufficiently in proteins, but also as consequence, by producing biodiesel, more self-sufficiently in fuels.

The by-products, such as glycerine, have an enormous effect and influence in the future sustainability of biodiesel.

Short term directives and legislation for sustainability criteria are mandatory to end the insecurity of the biofuels market and the enforced incorporation of biodiesel in petrodiesel is an important measure to take.

Topic: Sustainable process–product development through green chemistry

Abstract

Four technical lignins (Alcell, Indulin AT, Sarkanda and Curan 27-11P) were used as macro-monomers in the synthesis of polyurethane materials following two global approaches. In the first one Alcell and Indulin AT lignins were used directly as co-monomers in combination with a linear polycaprolactone (PCL) in order to produce polyurethane elastomers where lignin content varied between 10 and 25% (w/w) with respect to polyol mixture (PCL+lignin). The thermomechanical properties of the resulting materials were determined by dynamical mechanical analysis (DMA), differential scanning calorimetry (DSC) and swelling tests. In lignin-based elastomers Indulin AT showed to be more efficiently incorporated in the polyurethane network compared with Alcell lignin. Elastomers prepared with Indulin AT lignin exhibited a cross-linking density and storage modulus (rubbery plateau) higher than those of Alcell lignin-based counterpart and a lower soluble fraction. For both Alcell and Indulin AT based elastomers the glass transition temperature increased and extended over a wide temperature range with the increase of lignin content.
The second approach consisted of producing rigid polyurethane foams (RPU) using lignin-based polyols obtained after chemical modification by an oxypropylation procedure. Two polyol formulations (20/80 and 30/70, in what concerns the weight ratios between lignin and propylene oxide, PO), were used in RPU formulations and their content varied from 0 to 100% (w/w with respect to a commercial polyol, used as a reference). The resulting RPU foams were characterized in terms of density, mechanical properties, conductivity and morphology. The prepared RPU foams with lignin-based polyols presented properties, very similar to those obtained from conventional commercial polyols. RPU foams prepared with 30/70 polyols exhibited improved properties comparatively to those arising from 20/80 formulations. Exceptions were however detected in RPU foams prepared with all Sarkanda lignin based polyols and Curan 27-11P 30/70 formulation, which were found to be inadequate for RPU formulation.

1 Introduction

Polyurethanes are considered as one of the most versatile polymeric materials offering a wide range of products with various applications in diverse sectors. Rigid polyurethane (RPU) foams and elastomers belong to this class of products. Nowadays, due to economical and environmental concerns, the utilization and development of low-cost polyols from abundant and renewable biomass resources has gained an increasing attention in polyurethane industry. Lignin belongs to these biomass resources, and its application as a macro-monomer in polyurethane synthesis, has been the subject of several studies (Yoshida et al., 1990; Thring et al., 1998; Gandini et al., 2000).
Lignin is defined as a random, amorphous three-dimensional polymeric network, which does not possess a uniform, homogenous, well defined structure with well established repeating

units. Commercially available lignins are, most often, Kraft or lignosulfonates associated to the corresponding most commonly used industrial processes for wood delignification and fibres isolation (Kraft and sulphite, respectively). These lignins are largely used in dispersing and binding applications and a small part is employed in the production of specialty chemicals like vanillin and dimethylsulfoxide (Gosselink et al., 2004). Recently, sulphur-free lignins are becoming an emerging class of lignin products, partly motivated by environmental policies, but also, by less capital intensive associated technologies (Lora and Glasser, 2002).
The utilization of lignin as a macromonomer in polyurethane synthesis often follows two global approaches: (i) the direct utilization of lignin without any preliminary chemical modification, alone or in combination with other polyols (Yoshida et al., 1990, Evtuguin et al., 1998, Cateto et al., 2008) or, (ii) by making hydroxyl functions more readily accessible by chemical modification, such as esterification and etherification reactions (Glasser, 1989, Gandini et al., 2002, Nadji et al., 2005).
In this work, the two approaches were studied. Four technical lignins (Alcell, Sarkanda, Indulin AT and Curan 27-11P) representing softwood and non-wood lignin types and three pulp processes: Kraft, soda and organosolv (properties shown in table 1) have been used. In the first approach Alcell and Indulin AT were used directly as a co-monomer in combination with a linear PCL. PCL was introduced into the formulation to provide flexibility and enable polymerization in bulk. In the second approach the four lignin samples were oxypropylated and the resulting liquid polyols incorporated into RPU foams, alone or in combination with other commercial polyether-polyol.

Table 1. Properties of the technical lignins used in this work

Lignin Sample	Total OH (mmol/g)	Phenolic OH (mmol/g)	COOH (mmol/g)	Ash content (% w/w)
Alcell	5.26	3.81	0.23	0.05
Sarkanda	5.26	2.41	0.62	3.26
Indulin AT	6.99	3.95	0.39	3.06
Curan 27-11P	6.21	3.63	0.47	17.0

2 Material and Methods

2.1 Rigid polyurethane foams

Materials The lignin-based polyols used in this work were obtained from the oxypropylation of four technical lignins (Alcell, Indulin AT, Curan 27-11P and Sarkanda) as described elsewhere (Cateto et al., 2007). The following terminology will be used to identify the polyol formulations used in this work: L/PO/C (ratio between lignin, PO and catalyst content). The commercial polyether polyol (Lupranol® 3323), polymeric MDI (PMDI with a functionality of 2.7), silicone surfactant (SR-321 NIAX) and the catalysts NIAX and DMCHA were kindly supplied by Elastogran-BASF (France). Glycerol and *n*-pentane were obtained commercially.

Foam Preparation Polyurethane foams were prepared by mixing, during 1 minute, the polyol or polyol mixture in combination with glycerol (10%, w/w), surfactant (2%, w/w), water (2%, w/w) and a catalyst combination (2%, w/w of a mixture with equal amounts of DMCHA and NIAX). Thereafter, *n*-pentane was added (20%, w/w) and the mixture was stirred during 30 s. Finally, the polymeric isocyanate was added and the resulting mixture vigorously stirred until the foam started to grow. Foams were left to cure during 24 hours at room temperature. The weight percentage of glycerol, surfactant, water, catalysts and, *n*-pentane are given relatively to total weight of polyol. The isocyanate/hydroxyl ratio (NCO/OH) chosen was of 1.1.

Foam Characterization For density and compression tests, foams were cut into cube specimens of 50×50×50 mm^3 dimensions and thereafter conditioned during 40 hours at 23ºC and 50% of humidity. The densities of the foams were determined according to ASTM D1622 standard method. The specimens were weighted and its dimensions measured. Density was calculated by dividing the mass and volume obtained for each specimen. Compression tests were conducted according to ASTM D1621 standard. Measurements were performed using a tensile instrument (Instrom model 4501) in the direction perpendicular to foam growth. A load

was applied at a crosshead speed of 5 mm/min until the specimen was compressed to approximately 15% of its original thickness. Conductivity measurements were conducted according to ASTM C177 standard. Specimens with a diameter of 90 mm and thickness of 4 mm were cut and placed in an apparatus developed to measure the thermal conductivity of insulating materials. This apparatus is composed of two plates maintained with a temperature differential. The thermal conductivity of the samples was determined when the thermal equilibrium was reached and a uniform temperature gradient thought the sample was attained. Morphology analysis of RPU foams was performed on a Quanta 200 FEI field emission scanning electron microscope (SEM). The samples were cut and gold coated before scanning. The used accelerating voltage was of 12.5 Kv and the sample was observed both in the free-rise and free-rise perpendicular directions.

2.2 Polyurethane elastomers

Materials and Formulations The lignin-based polyurethanes were prepared starting with 4,4'-methylene-diphenylene diisocyanate (MDI), policaprolactonediol (PCL) with an average molecular weight of 750 (PCL750) and two different technical lignins, Indulin AT from Meadwestvaco (South Carolina, USA) and Alcell from Repap, with different weight contents (10, 15, 20 and 25%). PCL was kindly supplied by Solvay Interox (Cheshire, UK) and MDI was commercially obtained from Aldrich.

Elastomers Preparation Lignin and PCL were degassed overnight under vacuum at 60 ºC. MDI (Aldrich) was purified by heating at 60 ºC and filtered through a heated filter just prior use. Lignin and PCL were weighed in an analytical balance in the desired proportions and the mixture homogenised by stirring during 1 hour at 80 ºC. Then, molten MDI was added and the reaction mixture thoroughly stirred during 30 s and rapidly transferred into a Teflon mould. The obtained films were left to cure during 24 hours at 80 ºC.

Elastomers Characterization Differential Scanning Calorimetry (DSC) experiments were performed using a DSC Q100 differential calorimeter (TA Instruments) working in modulated mode. Analyses were carried out from -60 to 200 ºC with a heating rate of 5 ºC/min. The oscillation period and the amplitude were 60 s and ± 1 ºC, respectively. Dynamical Mechanical Analysis (DMA) of lignin-based elastomers was carried out using a RSA3 (TA Instruments) equipment working in tensile mode. The measurements were performed at a constant frequency of 1 Hz, strain amplitude of 0.03% and a distance between the jaws of 10 mm. The heating rate was 5°C.min^{-1} and the temperature ranged from -100 to 200 ºC. The width of the samples varied from 3 to 5 mm.

3 Results and Discussion

3.1 Rigid polyurethane foams from lignin- based polyols

Oxypropylated lignin was incorporated into RPU foams formulations without performing any purification concerning the homopolymer and catalyst (KOH) contents removal. Thus, several RPU foams were prepared by varying the lignin-based polyol content from 0 to 100% (w/w). Additionally, for the 20/80/5 based formulation a more detailed study was performed. RPU foams with 25, 50, 75 and 100% (w/w) of lignin-based polyol were prepared. For the 30/70/2 formulations only foams containing 50 and 100% (w/w) of lignin-based polyol were produced. Table 2 summarizes some of the data obtained for the lignin based RPU foams produced with 20/80/5 and 30/70/2 polyols. The properties of the RPU foams produced with the commercial polyol are also shown as a reference.

The produced lignin-based RPU foams (particularly those based on 20/80/5 polyols) exhibit lower mechanical properties and density to compare with reference foams (those obtained from the commercial polyol). Additionally, it was also observed that RPU foams based on Alcell and Indulin AT polyols showed higher mechanical properties and density values to compare with those produced with Sarkanda and Curan 27-11P polyols. In fact, RPU foams prepared with 20/80/5 Sarkanda based polyols were found to be brittle presenting quite large cells, as observed in SEM micrographs (Figures not shown). For Sarkanda lignin 30/70/2

polyol, the generated mixtures were so heterogeneous that the production of RPU foams was not possible, probably because of the complex rheological properties of this polyol.
Foams produced with 30/70/2 Curan 27-11P based polyol also showed some brittleness. For RPU foam samples including 100% (w/w) Curan 27-11P based polyol no defined cells were observed by SEM. For those including 50% (w/w) irregular size and deteriorated cells were observed. In conclusion, the studied Sarkanda based polyols and the 20/80/5 Curan 27-11P seems to be unsuitable for RPU formulations.

Table 2. Density, thermal conductivity and compressive modulus of lignin based RPU foams.

L/PO/C (w/v/(%w/w))	Lignin sample/ % Lignin polyol (w/w)	Density (Kg/m^3)	Conductivity (mW/mK)	Compressive Modulus (MPa)
30/70/2	Alcell/100	22.3	25.7	3.1
	Alcell/50	25.1	26.9	3.0
	Indulin AT/100	23.1	27.4	4.0
	Indulin AT/50	23.7	29.1	3.6
20/80/5	Alcell/100	20.9	26.7	2.5
	Alcell/50	23.9	30.5	3.3
	Indulin AT/100	19.2	26.8	2.6
	Indulin AT/50	22.4	32.9	2.4
	Curan 27-11P/100	18.4	28.5	2.3
	Curan 27-11P/50	19.4	31.3	2.7
Reference Foam (100% commercial polyol)		31.1	30.3	4.6

For thermal conductivity it was observed that RPU foams produced with 100% (w/w) lignin-based polyols present the lowest conductivity values. RPU foams prepared with 20/80/5 based formulations presented cells with an elongate hexagonal well defined shape and a quite homogeneous size distribution. For comparison, foams prepared with different lignin based polyols contents, are presented in Figure 1. The observed elongate form can explain the low density and compressive modulus obtained for these RPU foam formulations. As a consequence of lower density, mechanical properties are influenced (anisotropy effect) (Hawkins et al., 2005). In fact, SEM micrographs showed that with the increase of commercial polyol content, the cells tend to become smaller and less elongate, thus explaining the observed increase of density and compressive modulus. For the studied lignin-based RPU foams, cells with very large size are often detected thus contributing to less homogeneous structures. This heterogeneity can justify the reason why no relation was found between RPU foam lignin content and the conductivity. Nonetheless, compressive modulus and density were found to correlate relatively well.
Foams produced with 30/70/2 formulations presented cells with smaller size (approximately 370 µm instead of 550 µm obtained with 20/80/5 based RPU foams) and with a more pronounced spherical form comparatively to those produced with 20/80/5 based polyols (see Figure 2). This can explain the higher density and the improved thermal conductivity and mechanical properties of the latter formulations (20/80/5 lignin-based polyols). Also, this could be associated with higher hydroxyl number and lignin content and a decrease of KOH and homopolymer contents in the final 30/70/2 polyol mixture.

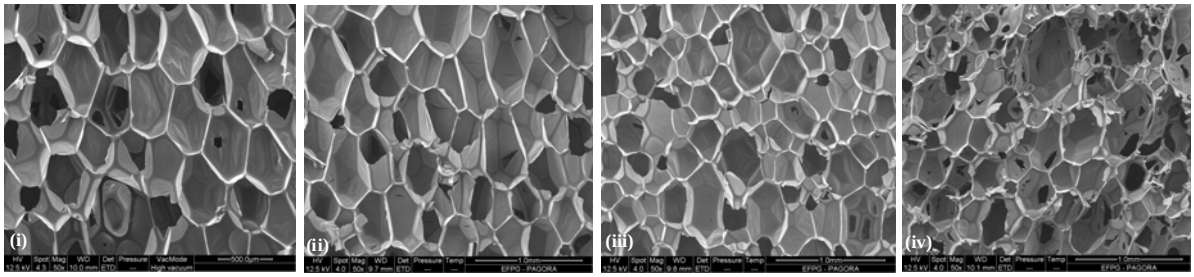

Figure 1 Scanning electron micrographs obtained for RPU foams containing 100% (w/w) for (i), (ii) 20/80/5 and (iii),(iv) 30/70/2 for Alcell and Indulin AT based polyol, respectively (free-rise direction).

3.2 Lignin-based elastomers polyurethanes

The obtained data showed that Alcell and Indulin AT produced elastomers with quite distinct properties. Figure 2 shows the effect of Alcell and Indulin AT content on the storage modulus (E´) and loss tangent (tan δ) with temperature. As can be observed for both Alcell and Indulin based elastomers, the maximum of tan δ shifts towards higher temperatures and the peak become broader as the lignin content increased. This trend was also confirmed by DSC analysis. Thus, glass transition temperature (Tg) increases with the increase of lignin content and the associated transition temperature range also increases with the increase of lignin content. Yoshida et al. (1990) pointed out that the increase of the transition temperature range may reflect structural heterogeneities in the network structure, e.g., a broad distribution of molecular weights between cross-linking points may exist. Also, the shift observed for Tg with the increase of lignin content must be due to an increasing of lignin incorporation. It is well know that increasing of cross-linking density introduces restrictions on the molecular motion thereby increasing the Tg value.

The dependence of storage modulus with temperature observed for lignin-based elastomers corresponded to that obtained for typical cross-linked polymers. For Alcell lignin elastomers the E´ in the rubbery region remained approximately constant with the increase of lignin content. Cross-linking density, determined from DMA data and soluble fraction also exhibit the same trend, i.e., the increase of lignin content did not yield significant modification neither concerning the cross-linking density nor that related to soluble fraction with. Soluble fraction and cross-linking density values were found to be approximately 0.085 and 0.28 × 10^{-3} mol/cm^3, respectively.

The E´ (rubbery region) of Indulin AT based elastomers increased with the lignin content until a value of 20% (w/w). Among the prepared materials incorporating 20 and 25% (w/w) no significant difference was noticed. The same trend was observed for cross-linking density, which increases from 0.6 × 10^{-3} to 1.0 × 10^{-3} mol/cm^3, as the lignin content increases. Regarding the soluble fraction a slight linear increment was observed from 4.4 to 7.5% (expressed in w/w %). Nevertheless, for a given lignin content the percentage of the soluble fraction was always lower than those obtained for Alcell based elastomers. This indicates that the incorporation of Indulin AT lignin in the polymer network was more effective than that of Alcell counterpart. The increase of cross-linking density and E´, for Indulin AT-based samples, can reflect more effective reactions between lignin hydroxyl groups and isocyanate functions. In fact, in comparison with Alcell, Indulin AT lignin presents higher hydroxyl group content, particularly, a higher aliphatic hydroxyl content (known to be more reactive with isocyanates to compare with phenolic ones). Also, Yoshida et al. (Yoshida et al., 1990) found that medium and high molecular lignin fractions act as cross-linking points, whereas low molecular weight fractions act more like a chain extender. This can also explain the different properties observed with Alcell and Indulin AT based elastomers since Alcell lignin has a weight average molar mass (M_W) much lower that that of Indulin AT homologue, i.e., 7281 and 13979 g/mol (determined from DMF/LiBr solutions using a GPC and based on polystyrene calibration), respectively.

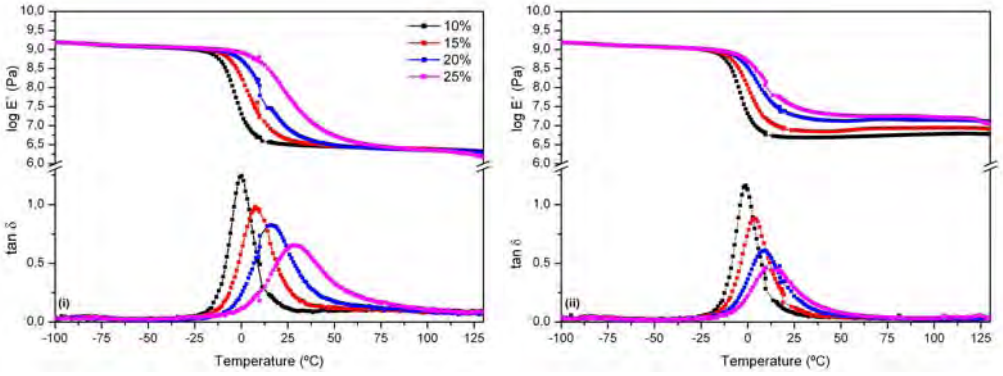

Figure 2 Storage modulus and tan δ as a function of temperature for elastomers containing 10, 15, 20 and 25% (w/w) of (i) Alcell and (ii) Indulin AT lignin.

4 Conclusions

This study provides irrefutable evidence about the possibility to incorporate lignin in polyurethane materials. A wide range of polyurethane materials presenting properties which depended on the lignin type and content introduced. Moreover, both approaches of using lignin (as such or after chemical modification, oxypropylation) yielded materials with very promising properties. In most cases, these materials exhibit properties similar to those of conventional ones, thus presenting a viable option to rationally valorise an abundant renewable industrial by- product.

Acknowledgements

The authors wish to thank Meadwestvaco, Borregaard LignoTech and Granite SA for kindly providing Indulin AT, Curan 27-11P and Sarkanda samples, respectively. Alcell lignin of Repap Enterprises Inc. was offered by Dr. Jairo Lora, to whom we are indebted. Financial support from the Portuguese Foundation for Science and Technology (grant SFRH/BD/18415/2004) and French-Portuguese Scientific Cooperation Programme (action F-32/08) are also acknowledged.

Keywords: Activated carbon, catalytic wet air oxidation, biodegradability enhancement, respirometry, biological treatment, inhibition and toxicity
Topic: Sustainable process-product development through green chemistry.

Abstract

This study examines the feasibility of coupling a Catalytic Wet Air Oxidation (CWAO), with activated carbon (AC) as catalyst, and an aerobic biological treatment to treat a high strength o-cresol wastewater. Two goals are pursued: a) To determine the effect of the main AC/CWAO intermediates on the activated sludge of a municipal WasteWater Treatment Plant (WWTP) and b) To demonstrate the feasibility of coupling the AC/CWAO effluent as a part of the influent of a municipal WWTP. Also, it is established the AC/CWAO intermediates distribution and the biodegradability enhancement. The main challenge in the coupling is to achieve the right balance between the oxidation deepness (economic cost) and the effluent biodegradability (distribution of oxidation products) after the oxidation step, which ensures the success of a subsequent biological treatment.

First of all, several CWAO tests were completed (140ºC-160ºC, 2-9 bar of oxygen partial pressure, at a space time of 0.12 h) for a high-strength o-cresol wastewater. All the experiments were done in a fixed bed reactor, operating in trickle flow regime, and using AC as catalyst. The results of this part (Suárez-Ojeda et al., 2007a) show that o-cresol disappearance, chemical oxygen demand (COD) removal and total organic carbon (TOC) abatement are very sensible to temperature change but almost independent of oxygen partial pressure.

Secondly, biological parameters were measured using respirometric tests that were completed before and after CWAO and independently, for each one of the identified intermediates (Suárez-Ojeda et al., 2007a). In the case of CWAO effluents, these tests have enabled the determination of the biodegradability, toxicity and inhibition over a non-acclimated activated sludge. Taking into account these results, it was possible to establish whether or not the CWAO effluents are suitable for a non adapted sludge and to develop suitable acclimatisation procedures to couple the CWAO step with a biological pilot plant.

Finally, the results of coupling the AC/CWAO effluent as a part of the influent of a municipal WWTP are presented (Suárez-Ojeda et al. 2007b). For instance, using 30%, as COD, of AC/CWAO effluent in the inlet to the pilot scale WWTP, the integrated AC/CWAO-biological treatment achieved a 98% of total COD removal and, particularly, a 91% of AC/CWAO effluent COD removal without any undesirable effect on the biomass.

The whole study shows a promising way for the development of efficient coupled processes for the treatment of wastewater containing toxic or biologically non-degradable compounds.

1 Introduction

Wastewater reduction and treatment is one of the challenges faced by our society. As an example, in the EU, 2700 tons/year of phenolic compounds in wastewater are released having both, toxic and bactericide effect (EPER, 2008). Several technologies have shown their potential for treating a wide variety of wastewater. Nearly all of them are based on the oxidation of the organic pollutants, which are converted into carbon dioxide and water or into harmless intermediate products, more suitable for a biological treatment (Bhargava et al., 2006). Therefore, Catalytic Wet Air Oxidation (CWAO), H_2O_2 promoted CWAO and Fenton process have become attractive techniques to efficiently treat organic wastewater that is either too concentrated or toxic to be biologically restored.

However, complete mineralisation of pollutants is extremely costly and the bactericide effect of some often found pollutants prevents industrial wastewater from being directly treated in a biological wastewater treatment plant (WWTP). Coupling of an initial oxidative step with a biological treatment can solve these pollution problems in a rational and less expensive way (Mantzavinos et al., 1999 and Patterson et al., 2002).

Hence, this study examines the feasibility of coupling a Catalytic Wet Air Oxidation (CWAO), with activated carbon (AC) as catalyst, and an aerobic biological treatment to deal with a high strength o-cresol wastewater. Two goals are pursued: a) To determine the effect of the main AC/CWAO intermediates on the activated sludge of a municipal WWTP and b) To demonstrate the feasibility of coupling the AC/CWAO effluent as a part of the influent of a municipal WWTP. Also, it is established the AC/CWAO intermediates distribution and the biodegradability enhancement. The main challenge in the coupling is to achieve the right balance between the oxidation deepness (economic cost) and the effluent biodegradability (distribution of oxidation products) after the oxidation step, which ensures the success of a subsequent biological treatment.

2. Experimental

2.1. Materials

Aldrich provided analytical grade o-cresol. Feed concentration was always 5 g l^{-1}. However, in terms of COD concentration, the initial concentration was 9.5 g COD l^{-1}. The AC used as catalyst was supplied by Merck (reference #102518) in the form of 2.5 mm pellets. Prior to use, AC was crushed and sieved. Then, the chosen particle size was in the range 0.7-0.3 mm in order to minimise mass transfer limitations according to Stüber et al. (2001). The characteristics of this AC, prior to use, can be found elsewhere (Suárez-Ojeda et al. 2005).

2.2. Experimental set-up and procedures for CWAO experiments

A complete scheme of the CWAO experimental apparatus as well as a more detailed description of the procedures can be found elsewhere (Suárez-Ojeda et al. 2005).

Several CWAO experiments were carried out (140ºC-160ºC, 2-9 bar of oxygen partial pressure, at a space time of 0.12 h) for a high-strength o-cresol wastewater. All the experiments were done in a fixed bed reactor, operating in trickle flow regime, and using AC as catalyst. Liquid samples were periodically withdrawn and analysed to determine target compound destruction (X), COD reduction (X_{COD}), TOC abatement (X_{TOC}), distribution of partial oxidation products, and biodegradability enhancement, measured as $\%COD_{RB}$.

2.3. Experimental set-up for respirometric experiments.

A complete scheme of the respirometric experiments as well as a more detailed description of the procedures can be found elsewhere (Suárez-Ojeda et al. 2007b). The respirometer used for the biodegradability screening tests corresponds to a LFS type, in which dissolved oxygen concentration (S_O) is measured in the liquid-phase (L), which is static (S) and continuously aerated (F). The pH was maintained at 7.5±0.5 and the temperature was set at 31±0.5ºC. The biomass used as seed culture came from a municipal biological WWTP (Tarragona, Catalonia, Spain). The biomass was starved overnight to ensure endogenous

conditions before each respirometric experiment. The presence of 20 mg l^{-1} of 1-allyl-2-thiourea (ATU) avoided nitrification interference. The average concentration of volatile suspended solids (VSS) in the respirometric tests was 3400±300 mg VSS l^{-1}.

To assess the biodegradability of the treated and non-treated effluents, a 20 mg COD l^{-1} (COD_{added}) pulse of either the CWAO effluent or o-cresol solution was added inside the respirometer. Then, the Oxygen Uptake Rate (OUR) profile and the Oxygen Consumption (OC) are obtained solving the S_O balance in the liquid phase of the respirometer. More information about the OUR and OC calculation can be found elsewhere (Spanjers et al., 1998).Once the OC is obtained from the respirometric tests, the readily biodegradable COD (COD_{RB}) can be calculated using the heterotrophic yield coefficient (YH) as follows:

$$COD_{RB} = \frac{OC}{1 - Y_H} \qquad \text{Equation 1}$$

The biological COD removal is a process where part of the substrate is directly used for new biomass growth and the rest is oxidized for energy production. In this context, Y_H represents the fraction of substrate used for production of new biomass. The COD_{RB} fraction of CWAO effluents is then calculated according to:

$$\%COD_{RB} = \frac{COD_{RB}}{COD_{added}} \cdot 100 \qquad \text{Equation 2}$$

2.4. Experimental set-up for the aerobic biological treatment

A pilot scale municipal WWTP was constructed by scaling down the Tarragona municipal WWTP. The bioreactor of the pilot plant is a 20 l aerated CSTR where the S_O is ranged from 2 to 5 mg l^{-1}. The bioreactor has S_O and pH probes that are connected to probe indicators-controllers. pH is left uncontrolled whereas S_O is controlled through manipulation of the pneumatic valve using an on/off control. The pilot plant was located inside a laboratory where the temperature was maintained at 25±1ºC through the air conditioning system.

The pilot plant was inoculated with sludge from the Tarragona municipal WWTP and its main operational parameters (a sludge retention time (SRT) of 8 d, an average organic loading rate (OLR) of 0.35 g COD g^{-1} VSS d^{-1} and VSS concentration of 4000 mg VSS l^{-1}) were maintained at similar values than those of the Tarragona WWTP.

The pilot plant began with an adaptation period to a synthetic municipal wastewater, which is similar to the original influent of the Tarragona WWTP. This period covered the first 10 d of operation. Later, the pilot plant behaviour in front of increasing loads of the o-cresol AC/CWAO effluent was studied. The parameters used to monitor the pilot plant were: COD effluent concentration, OLR, VSS concentration in the reactor and SVI. Analyses of TSS, VSS and COD were done as described in Standard Methods (APHA, 1999). The most relevant AC/CWAO intermediates were analysed using the methodology described in Suarez-Ojeda et al. (2007a).

3. Results and Discussion

The steady-state conversions (X, X_{COD} and X_{TOC}) and AC mass change (M_{AC}) are listed in Table 1. As expected, temperature has a strong influence on the conversions. For o-cresol, at 2 bar, X goes from 33% to 83%, X_{COD} from 15% to 53% and X_{TOC} from 14% to 47% as temperature increases from 140 to 160ºC. In turn, P_{O2} has a weaker effect on the overall conversions.

The M_{AC} was calculated as the relative difference between the final and the original mass of the loaded AC dried at 400ºC and serves to quantify if oxidative coupling or AC oxidation prevails, as oxidative coupling renders a gain in M_{AC} whereas AC oxidation/burning results in a decrease of M_{AC}. In the less severe CWAO conditions, the M_{AC} was always positive. But, for the most severe oxidative condition, 160ºC –and 9 bar, the M_{AC} was always negative.

Table 1. Final conversions for o-cresol and M_{AC} in CWAO tests.

		140ºC				160ºC			
Compound	P_{O2} (bar)	X (%)	X_{COD} (%)	X_{TOC} (%)	M_{AC}(%)	X (%)	X_{COD} (%)	X_{TOC} (%)	M_{AC}(%)
o-cresol	9 bar	97	42	40	19.3	90	64	46	-62.3
	2 bar	33	15	14	17.0	83	53	47	54.2

Regarding to the reaction intermediates, the theoretical chemical oxygen demand (COD_{Th}) of each effluent was calculated from the obtained HPLC concentrations. The partial oxidation products have been grouped into carboxylic acids, quinone-like products, condensation products, non-identified products and, remaining target compound. Later, the contribution of each group was compared to the total experimental COD analytically measured. The results are summarised in Figure 1.

For o-cresol, at 140-9 and 160-2, the products distribution are similar, indicating that these reaction conditions were severe enough to oxidize the o-cresol but not sufficient to yield significant changes in the selectivity towards carboxylic acids. At 140-2 bar, the reaction conditions were not sufficient to transform o-cresol into more suitable intermediates.

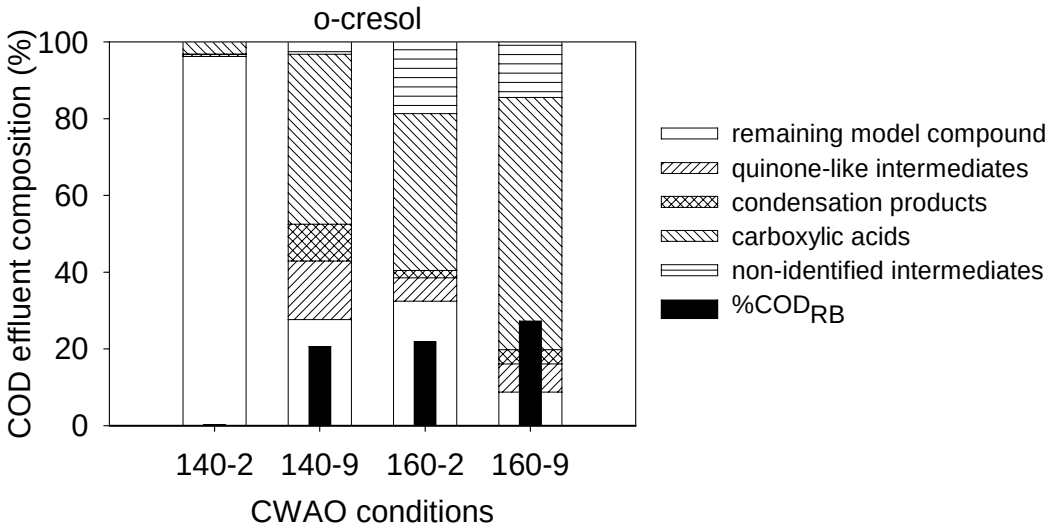

Figure 1. Intermediates distribution and $\%COD_{RB}$ obtained by respirometric test for each o-cresol CWAO effluent.

Figure 1 also shows the $\%COD_{RB}$ of each CWAO effluents for o-cresol. The measured $\%COD_{RB}$ of the initial o-cresol solution was 0%. There was no biodegradability at 140-2 because the remaining o-cresol concentration was the highest and the carboxylic acids concentration was almost negligible. For the rest of conditions, the $\%COD_{RB}$ was very similar, being 160-9 the condition which had the highest proportion of carboxylic acids and consequently the highest biodegradability, as reflected by the maximum $\%COD_{RB}$ (27%).

Three different features should be considered when selecting the most suitable CWAO condition: the maximum COD conversion obtained in the CWAO, the maximum $\%COD_{RB}$ and the catalyst preservation. In general, it could be concluded that the best CWAO condition for o-cresol is 160-2. At this condition, the X_{COD} was higher and the catalyst preservation was clearly better at 2 bar than at 9 bar of P_{O2}. Finally, the $\%COD_{RB}$ was 23% very similar to the obtained at 160-9 (27%).

The biological treatment study is divided into three periods according to the percentage of the total influent COD coming from the AC/CWAO effluent (5, 15 or 30%). Figure 2 shows the pilot plant evolution. Total influent and effluent COD concentrations and SVI were monitored during 125 d. Also, the TSS and VSS were measured during the study and the average values of biomass concentration and VSS/TSS ratio were 4400±300 mg VSS l^{-1} and 80±10% mg VSS l^{-1}, respectively.

Figure 2 shows that the total effluent COD concentration never surpassed the COD discharge limit fixed by the EU Directive, i.e. 125 mg COD l^{-1} (ECC, 1991), although the pilot scale WWTP worked in the range of the typical OLR for municipal WWTP (WEF, 1992). Moreover, the most relevant components of the effluents of periods 2 and 3 were analysed. This analysis showed that the COD of these effluents was basically in form of: phenol (13 mg COD l^{-1} in period 2 and 32 mg COD l^{-1} in period 3), o-cresol (9 and 18 mg COD l^{-1}) and malonic acid (2 and 7 mg COD l^{-1}). The rest of intermediates were completely biodegraded. The removal of COD in form of phenol was 48% in period 2 and 64% in period 3. The removal of COD in form of o-cresol was 87% in period 2 and 92% in period 3. The removal of both phenolic compounds was quite high and it was probably due to their co-metabolic biodegradation with readily biodegradable compounds. The increase in the removal of phenolic compounds between period 2 and 3 could be due to the progressive acclimatisation of the pilot plant sludge to phenolic compounds.

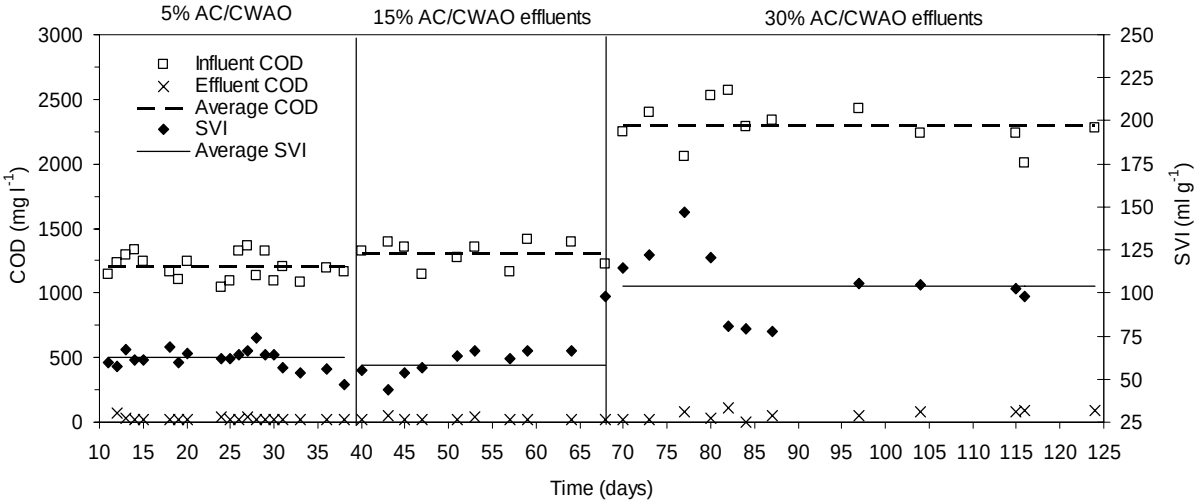

Figure 2. Evolution of pilot scale municipal WWTP parameters during the 125 days of continuous operation with o-cresol AC/CWAO effluent as a part of the total influent

Moreover, Figure 2 shows that the SVI was not affected by the presence of 5% (period 1) or 15% (period 2) of COD in form of AC/CWAO effluent in the influent of the pilot plant. After the increase of the COD coming from the AC/CWAO effluent to 30% (period 3), the SVI increased considerably. This increase could be due to some toxic effect on the biomass. Therefore the sludge purge was reduced 50% until the system recovered and returned to normal operation being the average SVI of 104 ml g^{-1}. In any case, the system never exceeded the SVI value of 150 ml g^{-1}, which is considered the threshold of poor settleability (WEF, 1992).

4. Conclusions

In the context of integrated management of high-strength o-cresol wastewater, for 30% of the total influent COD from the AC/CWAO effluent, the results show more than 99% in overall COD removal from the initial o-cresol: from 9500 mg l^{-1} to just only 64 mg l^{-1}. In terms of o-cresol removal, the integrated process is capable of passing from 5000 mg l^{-1} to only 7 mg l^{-1} that is 99.9% o-cresol removal (Figure 3).

Keywords: Cloud point extraction, polyethoxylated alcohols, metal or organic pollutants.

Abstract

Above a temperature called "cloud point" (T_c), the aqueous solutions of most polyethoxylated non-ionic surfactants separate into two equilibrium phases: a surfactant-rich one (coacervate) and a dilute one. Micellar solubilization allows two-aqueous phase extraction and concentration of hydrophobic or amphiphilic compounds into the small volume of coacervate. For electrolytes (*e.g.* heavy metal salts), the use of ionic/non-ionic mixed micelles makes a chelating agent unnecessary. Such a cloud point extraction may be applied to the decontamination of industrial effluents containing metal or organic compounds (soluble or dispersed pollution) or to the concentration or even the separation of high value-added substances. This is therefore a "Green Chemistry" process, *i.e.* environmentally-friendly and energy-saving. Cloud point extraction of metal ions (Ni^{2+}, Cd^{2+}, Pb^{2+}, Cr^{3+}) with mixed micelles of polyethoxylated alcohols (C_iE_j) and anionic surfactants (sodium dodecylsulfate "SDS" or dodecylbenzenesulfonates "SDBS") is achieved from model solutions of metal nitrates, possibly mixed with organics. The results are promising, due to extraction percentages lying between 50 and 90% and small volume fractions of coacervate, the best performances being obtained for Pb^{2+}, whose hydration enthalpy is the lowest. Moreover, the ability of those mixed micelles to extract both organic (phenol and 2,4-dimethylaniline) and heavy metal pollutants from model solutions is shown.

1. Introduction

The respect of environment is nowadays a worldwide requirement which implies the development of new curative processes and the design of intrinsically clean processes. Among others, these processes apply to wastewater treatment (water polluted by organics or heavy metals). The criteria of water quality (compliance with regulations) and economy are decisive; in order to take into account the physical and chemical specificities of the effluents, tests with real wastewaters are necessary.

Surfactant adsorption at interfaces makes them useful auxiliaries in several types of extraction processes. On the other hand, volatile organic solvents, commonly used in liquid-liquid extraction, are subject to more and more severe regulations, due to their toxicity and/or ecotoxicity. Since the phase diagrams of many polyethoxylated surfactant/water binary systems show a lower consolute point curve, the existence of the corresponding two-phase region can be turned to account to extract metal ions, small organic molecules or biological macromolecules from their dilute aqueous solutions. This operation, known as liquid-coacervate or cloud-point extraction (CPE), consists of two steps: (1) organic solute or metal-chelate complex solubilization into the extractant (aqueous solution of non-ionic surfactant) and (2) cloud-point phase separation of this solution into a dilute phase and a surfactant-rich one, called coacervate. Whether the dilute phase or the coacervate is of interest, two main

Corresponding author. Tel. 33 (0) 5 34 61 52 54. E-mail: JeanPaul.Canselier@ensiacet.fr

types of applications may be considered: removal of pollutants from aqueous effluents and concentration, recovery and, possibly, separation of high added-value substances [1-6].

Since the CPE technique has been proposed, a lot of applications in wastewater treatment have been published. However, previous studies on the removal of dissolved contaminants by CPE were mainly based on the use of single surfactant systems and restricted to some types of organic solutes [4-8]. Few studies have been conducted on the applications of mixed surfactants on the simultaneous removal of metal ions and organic solutes in a CPE process [9]. One of the most important properties of these organized structures is their good capacity to solubilise solutes of different character and nature. These solutes may interact with surfactant aggregates electrostatically, hydrophobically or by a combination of both effects.

This work involves the extraction of soluble electrolytes (Ni^{2+}, Cd^{2+}, Pb^{2+}, Cr^{3+}), from model solutions with polyethoxylated alcohols (C_iE_j) mixed with anionic surfactants (sodium dodecylsulfate "SDS" or dodecylbenzenesulfonates "SDBS"). The non-ionic surfactant, along with its cloud point property, is responsible for phase separation; the anionic species plays the role of a complexing agent. The CPE technique thus offers a convenient alternative to conventional liquid-liquid extraction that uses organic solvents, with another major interest: the absence of classical but expensive chelating agents for metal ions.

2. Experimental

Materials

The two anionic surfactants used were sodium dodecylsulfate (SDS 98,5% purity, Aldrich) and sodium dodecylbenzenesulfonates (SDBS 97,5% purity, kindly supplied by Rhodia France). The non-ionic surfactant was an oxo-alcohol (Oxo-$C_{10}E_3$). About 20% of the oxo-alcohol chains are branched. This sample was kindly supplied by SEPPIC (Castres, France). The Oxo-$C_{10}E_3$ sample was freed from residual polyols by washing with water at 95°C. The inorganic salts used were: $Pb(NO_3)_2.4H_2O$ (99%, Aldrich), $Cd(NO_3)_2.4H_2O$ (99%, Aldrich), $Ni(NO_3)_2.6H_2O$ (99%, Aldrich) and $Cr(NO_3)_3.9H_2O$ (99%, Aldrich). Reagent grade phenol, C_6H_5OH, and 2,4-Dimethylaniline, $(CH_3)_2C_6H_3NH_2$, from Aldrich, were used as received. The water was distilled and deionised.

Procedure

The concentrations of phenol and 2,4-dimethylaniline were measured by a reversed-phase HPLC system consisting of one SpectraSystem P-1000-XR pump, an AS-1000-XR auto injector, a RP18 (ODS) column, and a SpectraSystem UV-2000. The conditions used for the determination of aromatic solute concentrations were as follows: column temperature, 25°C; pressure, 80 bar; flow rate 1 mL/min of 67/37 (v/v) of H_2O/CH_3CN eluant. Phenol and 2,4-dimethylaniline concentrations were obtained from data processed with the Chromquest 3.0 software.

Inductively coupled plasma - ICP (Jobin Yvon – Ultima 2R) was used to measure the concentration of metal ions in the following conditions: plasma temperature, 8000 °C; air flow rate 20 mL/min; nebulizer pressure, 3.10 bar. The concentration of heavy metal was measured by UV absorption at the relevant wavelength (λ, nm): λ_{Pb} = 220.353; λ_{Cd} = 228.802; λ_{Ni} = 221.647; λ_{Cr} = 283.563.

The polluted aqueous phase and the surfactant solution were mixed together and separated at room temperature or after heating, according to the cloud point curve of the surfactant [10].

3. Results and discussion

Figure 1 represents the ratio, E%, of metal ions (Ni^{2+}, Cd^{2+}, Pb^{2+}, Cr^{3+}) extracted as a function of anionic surfactant (SDS and SDBS) concentration. From zero for pure non-ionic micelles, this ratio increases with anionic surfactant concentration. Only for Cr^{3+} is the

Corresponding author. Tel. 33 (0) 5 34 61 52 54. E-mail: JeanPaul.Canselier@ensiacet.fr

variation linear in the concentration range studied. The incorporation of an anionic surfactant into non-ionic micelles involves Coulombic interactions with metal ions. In other words, the negatively charged micelles cause the cations to bind or adsorb onto the micelle surface, however, the coacervate volume fraction, ϕ_C, increases with surfactant concentration. The main issue is to obtain the best compromise between E% (maximum) and ϕ_C (minimum).

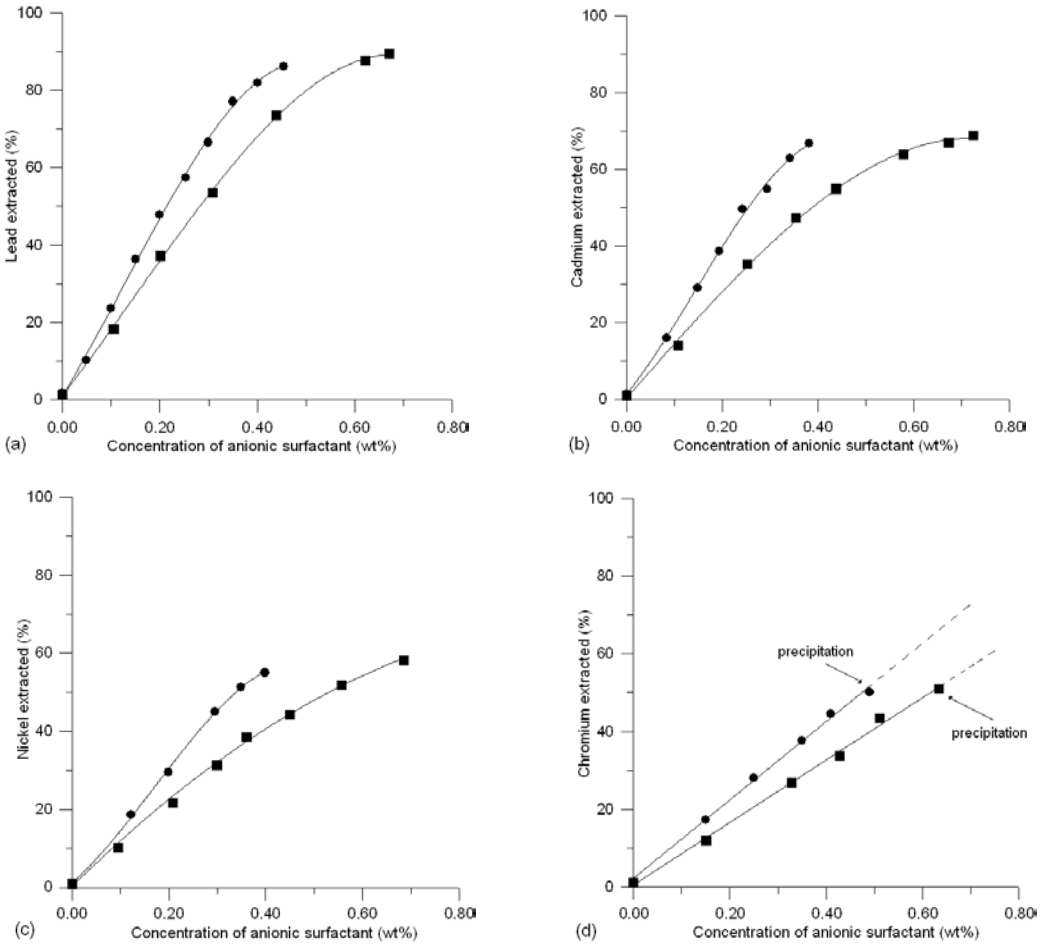

Figure 1. Effect of anionic surfactant concentration on heavy metal pollutants recovery.
(•) SDS, (■) SDBS ; oxo-$C_{10}E_3$ = 2,0% ; $[M^{n+}]$ = 1,5 g/L ; t = 45°C
(a) Pb^{2+}, (b) Cd^{2+}, (c) Ni^{2+}, (d) Cr^{3+}

The maximum extraction ratios are summarized in Table 1. Extraction efficiency increases in the following order: $E\%_{Pb} > E\%_{Cd} > E\%_{Ni} > E\%_{Cr}$. This order seems to be correlated with those of ionic radii, RI_M ($RI_{Pb} > RI_{Cd} > RI_{Ni} > RI_{Cr}$), hydration enthalpies, Δ_hH_M and hydration radii, RH_M ($\Delta_hH_{Pb} < \Delta_hH_{Cd} < \Delta_hH_{Ni} < \Delta_hH_{Cr}$; $RH_{Pb} < RH_{Cd} < RH_{Ni} < RH_{Cr}$).

Table 1. E% maximum for the metal ions.

Anionic surfactant	E% (M^{n+})			
	Pb^{2+}	Cd^{2+}	Ni^{2+}	Cr^{3+}
SDS	86	68	55	49
SDBS	90	70	59	51

The case of Cr^{3+}, a trivalent cation, is slightly different from those of the other three metal cations and it makes sense that, although the attraction of Cr^{+3} ions towards the micelle surface is strong, for a given density of micellar charge, Cr^{+3} extraction is less efficient, probably due to the reduction of the charged micelle binding sites for Cr^{+3} to be adsorbed

Corresponding author. Tel. 33 (0) 5 34 61 52 54. E-mail: JeanPaul.Canselier@ensiacet.fr

onto the micelle surface. So, to obtain the same performance as with the divalent cations, it is likely that a mixed micelle richer in anionic species should be required. In fact, at least with Oxo-$C_{10}E_3$, the use of higher ratios of anionic surfactant comes up against the precipitation of chromium dodecylsulfate or dodecylbenzenesulfonates.

Figure 2 shows that the recoveries of phenol and 2,4-dimethylaniline are strongly improved when the non-ionic surfactant (Oxo-$C_{10}E_3$) concentration increases. Thus, in a 8 wt.% Oxo-$C_{10}E_3$ solution, the extents of phenol and 2,4-dimethylaniline recovery are about 90% and 86%, respectively. However, for lead, the effect of the non-ionic surfactant concentration is relatively insignificant. The recovery of lead is about 80% in a 4 wt.% surfactant solution.

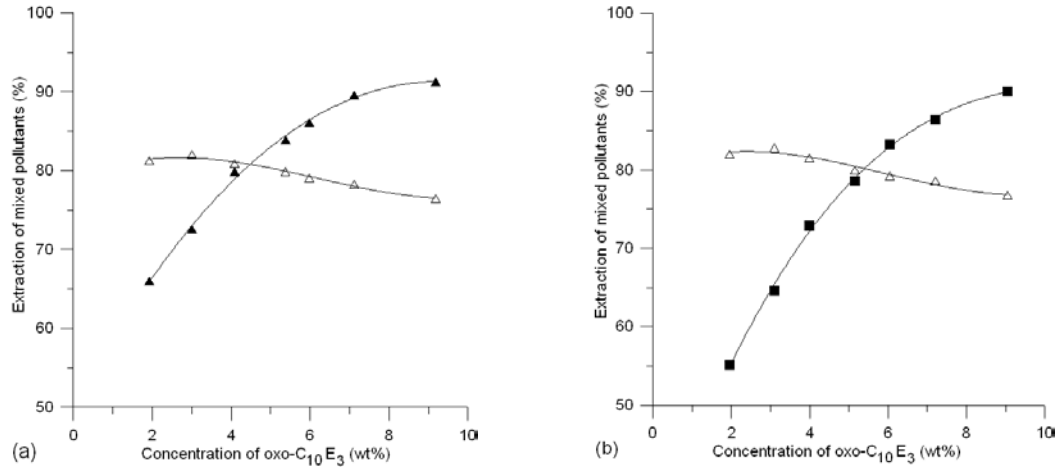

Figure 2. Effect of surfactant concentration on organic and heavy metal pollutants recovery. SDS = 0,38 %, SDBS = 0,60 %, [Pb^{2+}] = 1,5 g/L, [Ph] = 2,0 g/L, [DMA] = 1,3 g/L, T = 45°C
(▲) Phenol, (■) DMA, (∆) lead,
(a) SDS, (b) SDBS

These results suggest that mixed micelles can form hydrogen bonds between hydroxyl or amino groups and the most available ether oxygen atoms of the polyoxyethylene chain (reducing surfactant solubility)[11]. The rate of recovery in such systems can be correlated to the log P (octanol/H_2O partition coefficient) of the aromatic solutes but not to their aqueous solubility [12]. On the other hand, metal ions bind to the negatively charged surface of anionic surfactant micelles by Coulombic interactions. In summary, metal ions bind or adsorb on the surface of oppositely charged micelles, while organic solutes are solubilised within the micelles.

4. Conclusions

A new possibility for the application of CPE involves the use of mixed surfactants as extractants. The combination of the surfactant capacity to solubilise different species can be applied to the extraction of organic and heavy metal pollutants from model solutions. The results are promising, due to extraction percentages lying between 50 and 90%, the best performances being obtained for Pb^{2+}, whose hydration enthalpy is the lowest. Moreover, the ability of those mixed micelles to extract both organic (*e.g.* phenol and 2,4-dimethylaniline) and heavy metal pollutants from model solutions is shown. Further studies on the extraction of metals under anionic form or both cationic and anionic forms are currently in progress, affording encouraging results. A compromise is always to be found between E% (maximum) and coacervate volume fraction (minimum). These results let predict a possible treatment of more complex media. In addition, CPE offers the benefit of low cost, easy handling and reduced toxic effects. Finally, a continuous, multi-stage process should be developed rather soon.

Keywords: Zeolite, Chromium, Biosorption, Mordenite
Topic: Integration of Life Sciences and Engineering.

Abstract

This work reports the usage of a combined zeolite-biosorbent system for the removal and recovery of aqueous Cr^{VI}. The biosorption system consisted of a bacterium, *Arthrobacter viscosus*, supported on two mordenite (MOR) type zeolites with different Si/Al ratio, HMOR (Si/Al = 10) and NaMOR (Si/Al = 6.5). The results show that the biofilm of *A. viscosus* supported on MOR zeolite is able to recover chromium from dilute solutions. For both biosorption-MOR systems, the maximum removal was obtained for initial concentration of 20 mg_{Cr}/L. However, the best results were obtained for HMOR-system with a removal of 52.1 % for the diluted concentration and the best uptake, 3.3 $mg_{Cr^{VI}}/g_{zeolite}$, was achieved for the initial concentration of 100 mg_{Cr}/L. The Langmuir isotherm model was applied with good fitting to the experimental data.

1 Introduction

The emission of organic and inorganic pollutants from industrial sources into the environment is a well known risk factor. Pollution of the aquatic environment is mainly caused by the discharge of industrial effluents. The contamination with heavy metals is of great concern, where industries such as tanneries, electroplating and mining are found present. The continuous increase in emission of heavy metals into the environment poses a threat to human health, as the ingestion of several metals beyond admissible concentrations causes chronic disorders (Demir et al., 2007). Chromium is a metal of widespread industrial usage and is a common pollutant found in wastewaters. It is considered carcinogenic to humans in its Cr^{VI} oxidation state, whereas the Cr^{III} oxidation state is considered less dangerous.

From the different technologies available for the remediation of wastewaters containing heavy metals, biosorption has received considerable attention. The usage of microbial biomass for the removal of metals has been widely studied in recent years (Gavrilescu, 2004). Some studies refer that biosorbents require an adequate support to enhance good performance (Kratochvil et al., 1998). The employment of zeolites as supports for biosorbents has been reported (Figueiredo et al., 2006 and Tavares et al., 2006). Zeolites are widely known to be versatile materials, having found industrial application in various fields such as catalysis, adsorption, molecular sieving and ion exchange. In pollution control, the adsorption and ion exchange capacities have been exploited in the treatment of industrial effluents. The use of zeolites for the removal of heavy metals found in wastewaters has been proposed as a low-cost technique (Babel et al., 2003). However, zeolites can only be used as ionic exchangers for the removal of cationic species, due to the proprieties of the negatively charged aluminosilicate framework. While most metal species in water are cationic, aqueous Cr^{VI} is found in the anion form as chromate or dichromate ions. The repulsion between these ions and the zeolite framework avoids direct removal of Cr^{VI} by zeolite.

* Corresponding author. Tel +(351)-253604400. E-mail: hsfigueiredo@deb.uminho.pt

The different method for the removal of Cr^{VI} from effluents proposed (Figueiredo et al., 2006; Tavares et al., 2006 and Silva et al., 2008) combines the biosorption capabilities of the *A. viscosus* bacteria with a robust support of faujasite (FAU) zeolite. The bacterium reduces Cr^{VI} to the cationic Cr^{III} species which are exchanged by the charge-balancing cations in the zeolite structure. The combined technology enables Cr recovery from contaminated effluents in a solid matrix that can be easily recovered from solution and reused as catalysts for several reactions. The oxidation of 1,2-dichlorobenzene in gas phase with Cr containing NaY and NaX zeolites recovered from biosorption essays was reported by Figueiredo et al. (2006).

As there are various zeolitic structures available, it is possible to draw a series of catalysts with recovered metals by simply changing the support for biosorption. The present work reports the usage of mordenite (MOR) type zeolites as supports for the *A. viscosus* bacteria. MOR zeolite differs from FAU zeolite as its structure has channels in a single axis orientation, whereas FAU zeolite has channels in all three axes (Čejka et al., 2005). FAU zeolite also has large supercages, unlike the tubular structure of MOR. Both zeolites present large 12-ring pore opening. MOR zeolites have been studied as catalysts for several reactions and it is common to find them associated to different transition metals. Yim et al. (2000) studied the oxidation of perchloroethylene over chromium supported on mordenite in gas phase, while catalysis in liquid phase reactions was also studied with these zeolites, as described by Kostrab et al. (2006).

This work presents the usage of a different zeolitic structure, mordenite type zeolite as support for the biosorption of Cr^{VI}. Two MOR zeolites, H-form (HMOR) and Na-form (NaMOR) were tested as supports for the biosorption of aqueous Cr^{VI} species.

2 Materials and Methods

a) *Preparation of the zeolitic supports*

Powder samples of HMOR (CBV 21A, Si/Al = 10, surface area of 500 m^2/g) and NaMOR (CBV 10A, Si/Al = 6.5, surface area of 425 m^2/g) were obtained from Zeolyst International and were previously calcined at 500 ºC during 8 h under dry air flow prior to use.

b) *Preparation of the A. viscosus*

A. viscosus was obtained from the Spanish Type-Culture Collection of the University of Valencia. The culture medium is composed by glucose (10 g/L), peptone (5 g/L), yeast extract (3 g/L) and malt extract (3 g/L). The medium is sterilized at 121 ºC, cooled to room temperature, inoculated with the bacteria and it is grown for 24 h at 28 ºC in an incubator prior to use in the Cr^{VI} removal essays.

c) *Cr^{VI} removal essays*

The removal of Cr^{VI} from aqueous solutions was performed in batch conditions: 1 g of either NaMOR or HMOR zeolite was transferred to 250 mL Erlenmeyer flasks, where 15 mL of the grown culture medium and 150 mL of each chromium solution were added. A total of 6 different Cr solutions were tested, with initial concentrations ranging from 20 to 120 mg_{Cr}/L, and were prepared by dilution of $K_2Cr_2O_7$ (Panreac. p.a.) in deionized water. All concentrations were tested in triplicate. The flasks were kept in an incubator at 28 ºC with moderate agitation for 8 days, for both zeolites. Samples were taken at a daily basis, centrifuged and the supernatant was analyzed for Cr^{VI} using the 1,5-diphenylcarbazide colorimetric method (Eaton et al., 1995).

3 Results

Cr^{VI} removal was observed for both NaMOR and HMOR based biosorption systems. Figure 1 presents the Cr^{VI} removal for both supports and the results are detailed in table 1:

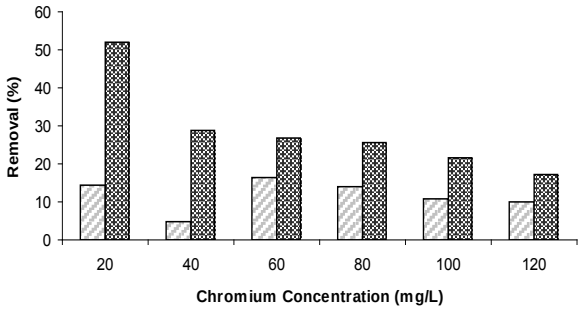

Figure 1: Cr^{VI} removal for NaMOR (light grey) and HMOR (dark grey), for the different chromium concentrations.

Table 1: Cr^{VI} removal and uptakes for both systems tested.

Support	NaMOR		HMOR	
Initial Cr^{VI} concentration (mg/L)	Removal (%)	Uptake ($mg_{Cr^{VI}}/g_{zeolite}$)	Removal (%)	Uptake ($mg_{Cr^{VI}}/g_{zeolite}$)
20	14.6	0.4	52.1	1.5
40	4.7	0.3	28.9	1.6
60	16.3	1.5	26.7	2.4
80	13.9	1.7	25.5	3.1
100	10.9	1.7	21.5	3.3
120	10.1	1.8	17.3	3.1

The best performance in terms of Cr^{VI} removal and uptake was achieved with the HMOR-*A. viscosus* system in all tested solutions with different Cr^{VI} concentrations. With this system, the best removal was obtained for diluted solutions and the uptake increased steadily up to the initial concentration of 80 mg_{Cr}/L and remained stable for the more concentrated solutions. For the NaMOR-based system, the removal appears to be better at the intermediate concentration solutions (40 to 60 mg_{Cr}/L), although the uptake progressed similarly to the HMOR-based system.

The efficiency of Cr^{VI} removal is related to the reduction performed by the *A. viscosus* bacterium (Silva et al., 2008). The ability of several bacteria to bio-reduce Cr^{VI} has been thoroughly studied. Namely, several *Arthrobacter* species are known to perform the reduction of Cr^{VI} (Tsibakhashvili et al., 2004. and Lin et al., 2006) and the reaction takes place in the electron-donor functional groups present in the polysaccharide chains. This reaction is pH-sensitive, as reported in the studies of Cr^{VI} removal by microbial biomass by Park et al. (2005, 2008), which suggest that acidic conditions favor the reduction of Cr^{VI}. Higher pH values limit the reduction capacity and the removal of Cr^{VI} species is performed by retention in the surface of the biomass. The pH values of the solutions were measured at the initial and final experimental time and the results are presented in table 2:

Table 2: Measured pH values for the different solutions

Solution	Initial Cr^{VI} solution	HMOR		NaMOR	
		Initial	Final	Initial	Final
20	5.21	3.60	3.35	7.03	7.85
40	5.20	3.52	3.27	6.31	8.19
60	4.30	3.53	3.21	6.22	7.83
80	5.02	3.29	3.10	6.08	5.41
100	4.83	3.39	3.11	6.12	5.18
120	4.72	3.31	3.07	6.09	5.34

The initial shift in the pH is related to the rapid ion exchange between the zeolite and the residual protons and potassium ions present in the aqueous media (K^+ originates from the chromium salt employed). For the biosorption-NaMOR, the system increases pH at the initial stages, with this effect being more notorious in the lower Cr^{VI} concentration solutions which have a lower K^+ concentration. In fact, this support has 6.5 % of Na_2O and most likely protons co-exchanged with Na^+ ions from the zeolite. For the biosorption-HMOR system the behavior is different. The principal charge balancing cation in its framework is the proton due to the absence of sodium (Na_2O = 0.05%). Charge compensation by co-exchange of protons and potassium leads to some residual acidity in the zeolite, so the shift in the pH of the solutions is towards a more acidic region. Therefore, the biosorption-HMOR system is more adequate to the reduction of Cr^{VI} by the *A. viscosus* bacterium and the differences in the uptake are related to this fact. It is expected that the HMOR zeolite recovered from solution will present a higher Cr loading when compared to the NaMOR.

The Langmuir adsorption isotherm model was applied to the experimental data obtained for the biosorption-MOR systems. The data was plotted (figure 2) and the parameter values were calculated and are presented in table 3:

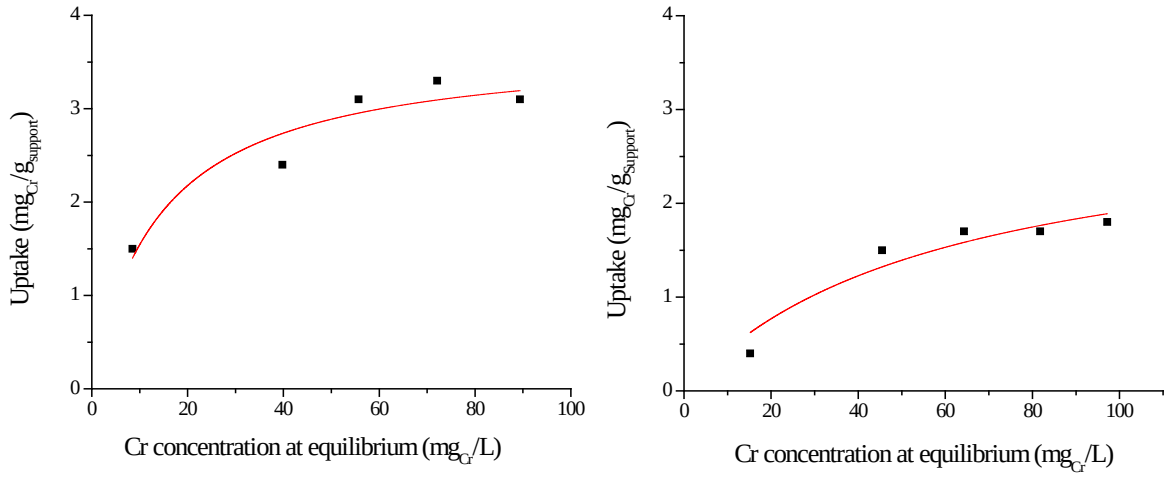

Figure 2: Uptake vs. equilibrium concentration for HMOR – bacteria (left) and NaMOR – bacteria (right), with plotted Langmuir fitting to experimental data for both systems.

Table 3: Langmuir model parameters

System	Parameters	
HMOR	q_{max}	3.5 $mg_{Cr}/g_{support}$
	b	0.37 $mg^{-1}.L$
NaMOR	q_{max}	2.0 $mg_{Cr}/g_{support}$
	b	0.33 $mg^{-1}.L$

The Langmuir adsorption model presented good fitting to experimental data for both systems, indicating that the Cr^{VI} removal performed by both systems is similar to an adsorption process. The calculated maximum uptakes (q_{max}) are similar to the obtained experimentally.

4 Conclusions

Both biosorption HMOR and NaMOR systems were able to recover Cr^{VI} from solution, with the biosorption-HMOR system being more efficient for all tested chromium solutions. The removal is higher for the lower concentration solutions. The pH regulation performed by the HMOR support increases the amount of Cr^{VI} reduced by the *A. viscosus* bacterium, whereas the pH shift into higher values performed by the NaMOR support hinders the reduction and therefore limits Cr^{VI} removal and uptake.

The Langmuir adsorption model was successfully applied to the experimental data making possible the modeling of the Cr^{VI} removal process by the combined *A. viscosus* - mordenite zeolite.

Keywords: Crystallization, Phosphorus recovery, Struvite, Airlift reactor.

Topic: Sustainable process-product development through green chemistry

Abstract

Crystallization of struvite in an airlift reactor was achieved with different phosphorus or magnesium sources. Struvite was precipitated from either a secondary treated industrial wastewater from the frozen seafood sector, or from a synthetic wastewater with high phosphate concentration. Seawater and a magnesium chloride solution were used as magnesium source for struvite precipitation. Struvite precipitation was not influenced by either the nature of the phosphorus or magnesium source used. The main parameter that could affect the phosphorus removal was pH. The treated effluent with the lower phosphorus concentration was obtained when pH was above 8.5 and close to 9.

Amorphous calcium precipitation was also observed during the period in which seawater was used as magnesium source. The formation of calcium phosphate had two different effects, one positive as acts as glue that promotes the agglomeration of the struvite crystals, and one negative as some fraction of this phosphate was washed out with the effluent. Seawater was found to be a reliable and inexpensive magnesium source for MAP crystallization, especially for those facilities located near the seashore.

1 Introduction

Phosphorus removal from wastewaters is currently achieved by precipitation with Fe and Al salts or lime. These precipitation processes are widely used for removing phosphorus during the treatment of wastewater from diluted wastewaters. However the precipitation could be disadvantageous when the concentration of phosphorus is very high as occurs for some industrial wastewaters. For these wastewaters a high amount of precipitates are generated and the cost of the chemicals required could be a drawback that could made uneconomic the precipitation of phosphates. Additionally considering sustainability, the phosphorus recovery process from these precipitates is very difficult and expensive. Due to the above mentioned drawbacks, the precipitation of phosphate by crystallization of struvite (magnesium ammonium phosphate, MAP, $NH_4MgPO_4 \cdot 6H_20$) could be an alternative for the sustainable and economical recovery of this compound from concentrated wastewaters.

Struvite is a white, crystalline substance of distinctive orthorhombic crystal structure (Abbona et al., 1984). Its density is 1710 kg/m^3. The crystallization of struvite represents an interesting technique to recover this element from wastewater. The product recovered, struvite, is easy to hand and free of sludge-handling problems. Struvite crystallization has been demonstrated to be an economical way to remove phosphorous of wastewater effluents, especially at high phosphorous concentrations. Additionally, struvite has a commercial value as a fertiliser, so is supposed to be really beneficial in all senses for

nutrient recovery (Ghosh et al 1996). Struvite usually precipitates as stable white orthorhombic crystals in a 1:1:1 molar ratio according to equation 1:

$$Mg^{2+} + NH_4^+ + H_nPO_4^{n-3} + 6H_2O \leftrightarrow MgNH_4PO_4{\cdot}6H_2O + nH^+ \quad (1)$$

Struvite has a solubility product, Ksp, around $5.37 \cdot 10^{-14}$ (Ohlinger 1998). As suggested by equation 1, struvite solubility is conditioned by the pH of the solution. It is highly soluble at acid pH and highly insoluble at alkaline pH environment. Thus, its precipitation could be controlled by pH adjustment, as well as by alteration of the concentration of the ions indicated in equation 1. The pH range within which struvite may precipitate is between 7 and 11. This is closely related to the decrease in struvite's solubility when pH increases (Battistoni et al., 1997; Matynia et al., 2002).

Struvite crystallization may be achieved with different plant configurations: Complete Stirred Tank Reactors (Regy et al. 2001) and either Two-phase (Bhuiyan et al. 2008) or Three-phase Fluidized bed reactors (Battistoni et al. 1997; Matsumiya et al. 2000). The main aim of this research was to study the performance of a three-phase airlift reactor for recovering MAP from industrial wastewaters with a high phosphorus concentration. Wastewaters were generated in a frozen seafood factory located near the seashore. Magnesium concentration in the wastewater is low, and thus should be externally added in order to precipitate struvite in the reactor.

2 Materials and methods.

A 2.7 L volume airlift reactor with a three-phase separator at the top of the system was used during the experiments of MAP crystallization (Figure 1). An external settler was coupled in series to the airlift reactor in order to avoid the outflow of fine particles with the effluent. Two different influents were fed to the reacto to study and compare the efficiency of the MAP crystallization with either a synthetic solution or with the real wastewater in the airlift system:

i.- A synthetic wastewater with a phosphate concentration similar to that observed in the industrial wastewater (average 630 mg P-PO_4^{3-}/L), that was prepared by diluting sodium phosphate in tap water.

ii.- An industrial wastewater, generated in a frozen seafood factory located in Galicia (NW Spain) with very high phosphate concentration was used. This wastewater was previously secondary treated in an aerobic biological pilot plant in order to reduce the COD concentration and hydrolyse organic P and polyphosphates present in the raw influent.

Additionally, the precipitation of struvite was assayed by using two different magnesium sources: a concentrated magnesium chloride solution and seawater. The seawater used was collected near the industrial facility and contained around 1250 mg/L of Mg and 400 mg/L Ca. The reactor was operated during 128 days and the operation could be divided in three different stages:

Stage I: Days 0 to 34, Start up period: The Airlift reactor was fed continuously during 6 hours per day, feeding it with the synthetic medium. Ammonium chloride and magnesium chloride solutions were used Mg and NH_4^+ sources. During the operation the "Hydraulic Retention Time" (HRT) of the reactor was fixed in 6 h.

Stage II: Days 43 to 91, Operation with industrial wastewaters: During this period the reactor was operated continuously. The secondary treated industrial wastewater was fed to the reactor and the two concentrated media with ammonia and magnesium salts. HRT ranged between 1.1 and 6 h.

Stage III: Days 103 to 128, Synthetic wastewater and the concentrated ammonia media were fed continuously again. Nevertheless, in this case, seawater was used as magnesium source. HRT was maintained in 1.1 h.

The determination of orthophosphate and ammonium concentrations Most of the analyses were done accordingly to the Standard Methods. Phosphate and ammonia concentration, Suspended solids, Conductivity, alkalinity, TOC, IC and were measured in the influent and effluent from the reactor. Mg and Ca were punctually determined in the effluent. Suspended solids concentration, temperature and pH were determined in the reactor. X-ray fluorescence and ICP-OES were used for determine the elemental composition of the precipitates and the effluent, respectively. Samples of struvite crystals were taken in the reactor or the settler for observation by using SEM with Energy Dispersive X-ray analysis (SEM-EDS) and to identify the nature of the crystals by using X-ray diffraction (XRD).

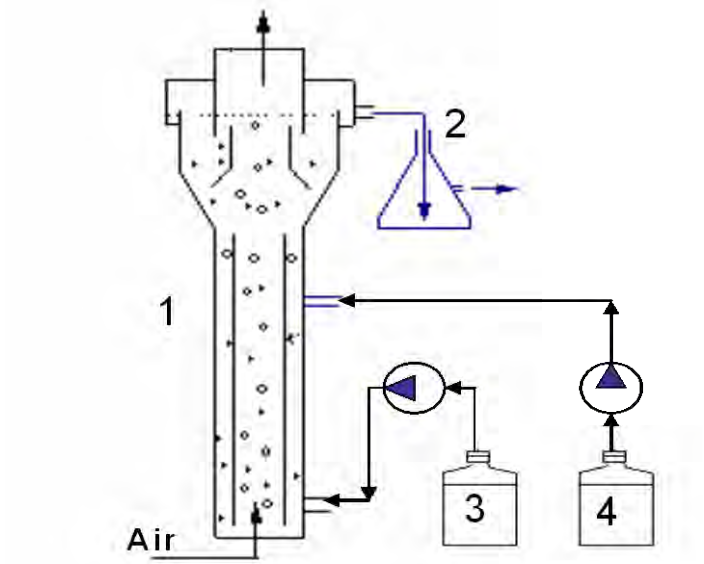

Figure 1. Schematic diagram of the Lab-scale airlift reactor for struvite crystallization. **(1)** Airlift reactor; **(2)** Secondary settler; **(3)** wastewater **(4)** Magnesium source.

3 Results and discussion

Figure 5 shows pH evolution all over the operation time. Reactor pH was controlled by using a NaOH solution, in order to maintain it above 7.5. The efficiency of the reactor depended on the pH of operation; in fact the best results in terms of low fine particles outflow and phosphate concentration in the effluent were achieved when pH values were between 8.5 and 9.0, independently of either the magnesium or phosphate source. This pH was achieved either by adding NaOH into the reactor. Other authors referred optimum pH for MAP crystallization of 9.0 (Wang et al. 2006) or even at 10 if seawater is used as magnesium source (Lee et al. 2003). Stripping of a fraction of the inorganic carbon present in the influent was observed. This was especially observed during period II in which the secondary treated wastewater was fed.

Struvite formation can be inhibited by the interaction of calcium and magnesium, depending on their relative concentrations (Battistoni et al., 1997). It has been concluded that the precipitation of the calcium phosphate apatite occurs at pH values above 9.5 whereas struvite precipitation takes place at pH values of 8 and above. In fact, when

seawater was employed as magnesium source, the calcium forms an amorphous precipitate of $Ca_3(PO_4)_2$, at pH values below 8,5 (Figures 4A and 4B).

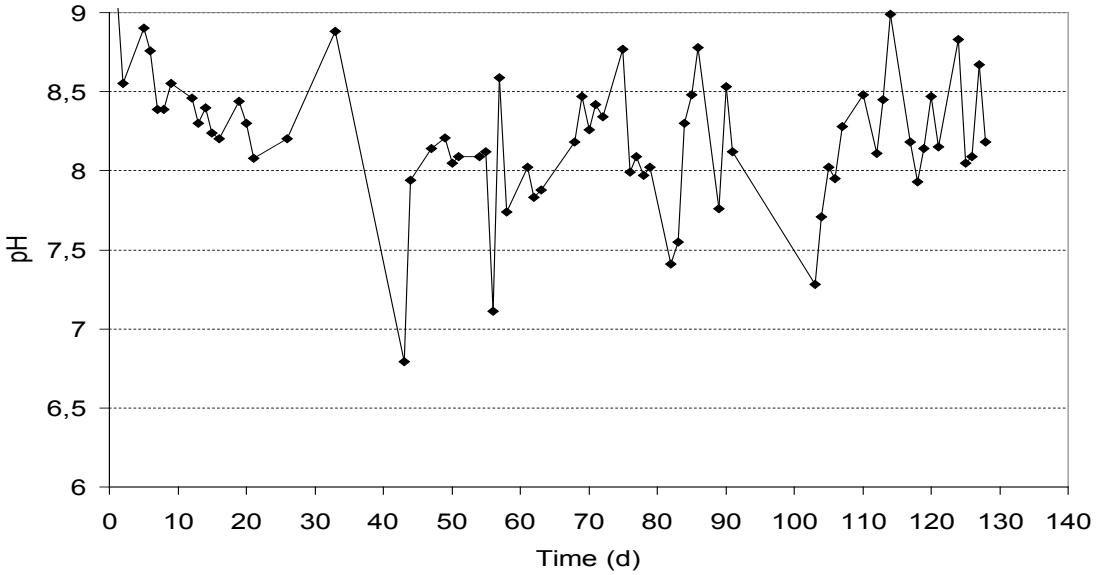

Figure 2. pH evolution in the airlift reactor during the experiments.

Phosphorus recovery, through struvite precipitation, from either synthetic or real wastewater was achieved during the three experimental periods in which the reactor was fed with different sources of phosphate and magnesium. Primary nucleation (crystal birth) was induced during the first experimental of the stage I, by raising the pH of the reactor, and later secondary nucleation (crystal growth) was observed. MAP crystals concentration in the reactor ranged from 20 to 90 g/L during the operation.

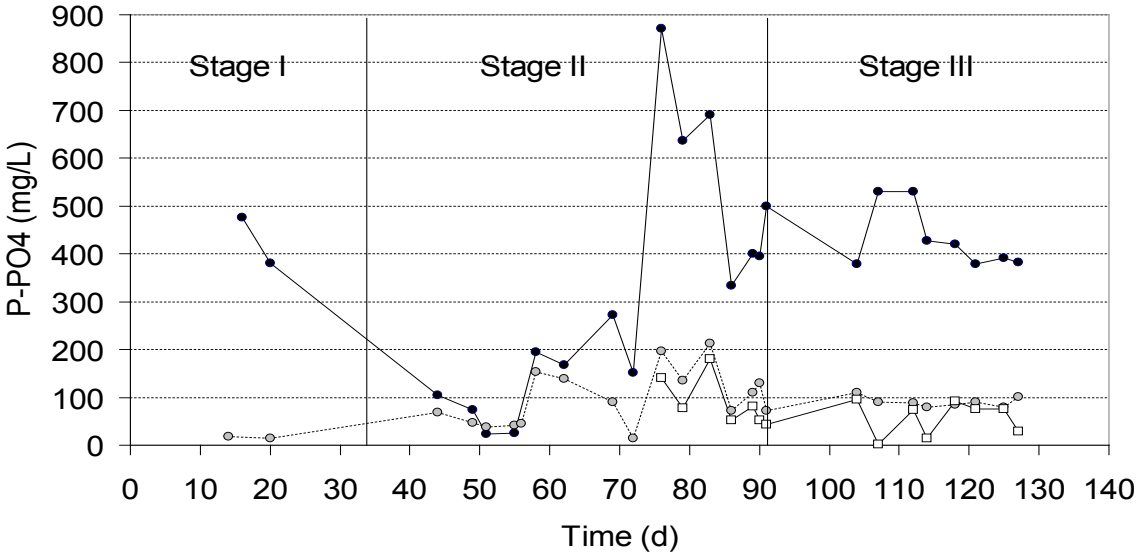

Figure 3. Evolution of orthophosphate concentration in the influent (●), soluble orthophosphate in the effluent (□) and total phosphate in the effluent (●) of the airlift reactor.

Microscopical observations of precipitates using SEM showed different kinds of precipitates depending on the period of operation (Figure 4). Obviously, the best results

were obtained during the first operating period, with HRT of 6 h. Nevertheless, a high phosphate separation was also achieved under different feeding conditions, even with HRT of 1.1 h, by maintaining an adequate range of pH. Recovery efficiency (Phosphate precipitates that were retained into the reactor) was above 80%.

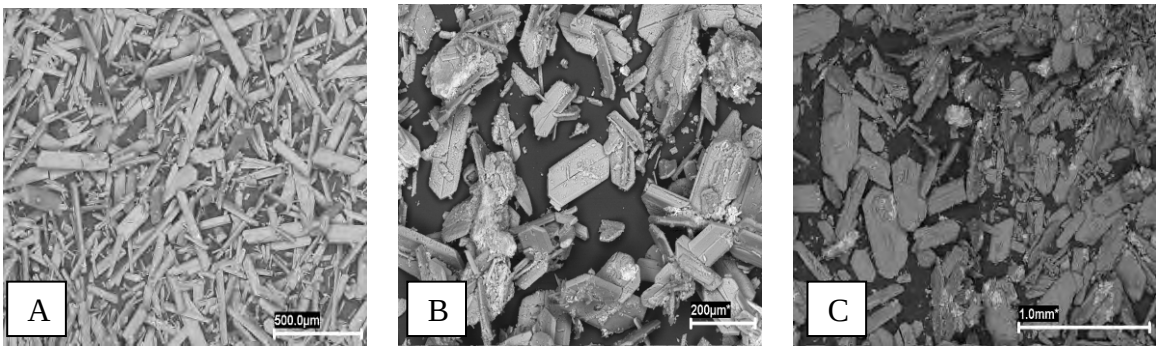

Figure 4. Microphotography of the struvite crystals on stages 1 (A), 2, (B) and 3 (C).

During the first operation period (feeding synthetic wastewater), small amounts of fine particles was detected in the effluent. Needle-form struvite crystals grew as monocrystrals, not agglomerated. Kinetics studies demonstrated that during this period magnesium excess was not a key factor in the formation of struvite, as the P efficiency was similar at molar ratios higher than 1:1 of Mg and P.

The precipitation of a amorphous calcium phosphate was also observed, during the third operation periods in which seawater was used as magnesium source. Used seawater contained around 400 mg/L Ca. XRD analysis demonstrated the amorphous nature of this precipitate. Calcium phosphate [$Ca_3(PO_4)_2$] also acts like a glue for the struvite crystals, The presence of agglomerates of struvite with amorphous calcium was observed by using XRD and SEM-EDS. Le Corre el al. (2005) also observed an increase of the struvite particle size formed, that was caused by the addition of Ca during batch assays. In this sense Ca had a positive effect, as promote the growth of aggregates and promotes the P precipitation. Nevertheless, the addition of seawater also had a negative effect on P efficiency.

The main inconvenient observed during the operation with seawater was the increment of fines that was observed in the effluent. These fines caused a certain loss on the phosphate efficiency of the system and were principally composed by amorphous precipitates of $Ca_3(PO_4)_2$ on stage 3 (Figure 5B).

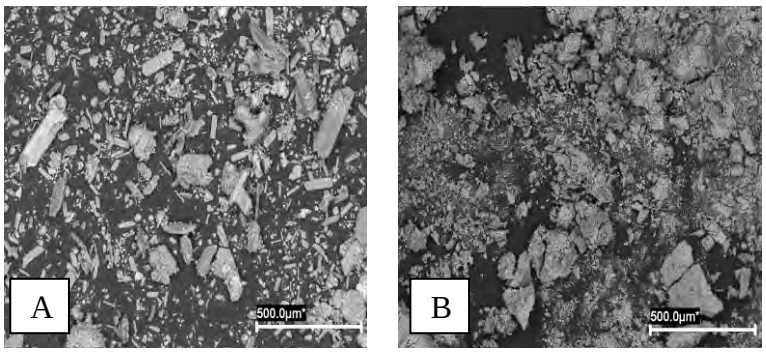

Figure 5. Microphotography of the particle fines washed out from the reactor with the effluent but retained in the secondary settler during operating stages 2 (A) and 3 (B).

Phosphate concentration in the effluent was influenced more by the operation pH than for the magnesium source. In this sense, seawater provides inexhaustible and inexpensive source for MAP precipitation in facilities near the seashore. In this sense, the cost of adding a magnesium salts could be a major economic constrain to application of MAP crystallization for nutrient recovery.

4 Conclusions

Crystallization of struvite was observed during the three periods studied and was not influenced by either the nature of the phosphorus or magnesium source used. The main parameter that could affect the phosphorus removal was pH. pH also affected the formation of fine particles that were washed out of the airlift reactor. Regardless of the feed synthetic or real wastewater, best periods of operation took place when pH is above 8.5 and close to 9. pH may be controlled by adding NaOH or other suitable alkali.

Amorphous calcium formation was observed during the period in which seawater is used as magnesium source. The formation of calcium phosphate had two different effects, one positive as acts as glue that promotes the agglomeration of struvite crystals, and one negative as some fraction of this phosphate was washed out with the effluent. Seawater, for those facilities located near the seashore, is a reliable and inexpensive magnesium source for MAP crystallization.

Topic: Sustainable process – product development through green chemistry.

Abstract

The ecodesign of a product implies that different potential environmental problems of diverse nature must be considered, apart from the general design criteria. In this sense, an ecodesign tool integrating the criteria provided by three environmental evaluation methodologies, i.e., Ecological Footprint (EF), Life Cycle Assessment (LCA) and Environmental Risk Assessment (ERA), has been constructed on the basis of fuzzy logic reasoning and features. This idea enabled the decision making at process level taking into account the values of the different indicators at a time. The relative importance of each of them has been established through the definition of membership functions as inputs to the fuzzy inference reasoning procedure in the case of a specific product. As a result, a Fuzzy EcoDesign Index (FEcoDI) was obtained. A well known case study was used to test the tool. Different packaging materials for a beverage bottle were considered to identify the most environmentally friendly option.

1 Introduction

Ecodesign may be defined as the systematic introduction of environmental concerns during product design and development (AENOR, 2003). This means to bear in mind the environmental impacts at all stages of the product life cycle from the designing and development phases. The identification and valorization of the environmental burdens requires the application of evaluation tools. There are different options when deciding which supporting tools to use. Some traditional tools used in ecodesign are qualitative and subjective like the Life Cycle Design Strategies (LiDS) Wheel, or semi-quantitative like the Materials Energy Toxicity (MET) Matrix. On the other side, the more developed ones, like the Ecoindicators or the Life Cycle Assessment (LCA), include objective criteria and quantitative evaluation of the environmental impact (Rieradevall and Vinyets, 1999).

The different kinds of tools can highlight different potential environmental problems (Byggeth and Hochschorner, 2006). Consequently, none of them can be believed to offer a totally comprehensive evaluation. In some cases the limitations stem from the application of a single approach can be assumed, but in other situations an integrative proposal needs to be considered. Ecological Footprint (EF), Life Cycle Assessment (LCA) and Environmental Risk Assessment (ERA) are considered as examples of objective and quantitative ecodesign tools. Besides, they provide complementary information about environmental performance of processes and products. The EF gives valuable information about the degree of sustainability of a particular process since this indicator especially accounts for resources and energy consumption, as well as for waste generation. However, some limitations were

* Corresponding author. Tel + 34-981-563100 Ext. 16800. E-mail: marta.herva@usc.es

acknowledged for this methodology (Kitzes et al, 2007), and for this reason it results interesting to complement EF studies through a simplified LCA (Herva et al, 2008a). In addition to using LCA to assess aspects excluded from EF estimates (e.g. emissions different from CO_2 or hazardous wastes), its application was proposed when a more in depth analysis was required for a particular functional unit, thus helping to identify more sustainable solutions or best available technologies (Azapagic, 1999). The existence of a relation between EF and LCA has been identified by Huijbregts et al (2007) when the Ecoindicator 99 was employed. Regarding CO_2 emissions, another concept becoming popular because of its relation with the Kyoto Protocol is the Carbon Footprint (CF). This indicator, which is part of the total EF estimate, is employed to measure the total greenhouse emissions.

Although LCA is claimed to offer an integrative assessment of a process, the information provided regarding human and ecosystem toxicity, for example, is more incomplete than desirable. This means that it has a limited capacity to predict toxicity effects. ERA provides an established methodology based on the assessment of different scenarios, exposure pathways, duration and frequency that allows for a more rigorous and exhaustive evaluation. Therefore, LCA and ERA are complementary tools (Leet and Geibig, 2006) that can be integrated (Huijbregts et al, 2000). ERA is used to estimate a risk index associated to certain hazardous substances that raw materials may contain (organic compounds, heavy metals…) and that would affect the final consumers or factory employees (Franco et al, 2007).

In the present work, a framework based on the integration of EF, LCA and ERA is proposed. This approach was built on the basis of Fuzzy Logic (FL) reasoning and features. The usefulness of FL based methods to address uncertainty and subjectivity in environmental problems has already been stated (Carrasco et al, 2002). The established objective was to obtain a final Fuzzy EcoDesign Index that could help to distinguish the best option from an environmental point of view. To test the tool, different packaging materials for a beverage bottle were considered to identify the most environmentally friendly option.

2 Materials and methods

2.1. Case study

A 2 litre bottle of drinking water has been studied. Two kind of plastic materials were proposed: PET and PVC. Based on the life cycle inventory of these products (Feijoo and Roca, 2005), EF and complementary LCA were estimated. For ERA, particular acknowledged risk problems were taken into account, like the migration of bisphenol A and aldehydes in PET (Le et al, 2008; Dabrowska et al, 2003), or vinyl chloride monomer in PVC (Fayad et al, 1997).

2.2 Ecodesign tools methodologies

The methodology employed for the EF assessment was based on the fundamentals of yield and equivalence factors stated by the creators of this concept (Monfreda et al, 2004). In particular, EF estimates were done with the adaptation carried out by Herva et al (2008b) to assess the sustainability of a production process. This indicator was employed to evaluate the energy and materials consumption in the production process of the product.

Emissions released during the manufacture were evaluated via LCA. In this case, the methodology established in the ISO 14040 standards was used. During the life cycle impact assessment, only the compulsory characterization phase was carried out. However, normalization phase was also conducted in order to obtain environmental impacts prioritization criteria. Characterization and normalization factors from the Dutch Institute of Environmental Sciences (CML, 2000) were applied in equations [1] and [2], respectively. Global Warming Potential (GWP) and Acidification Potential (AP) impact categories were incorporated to the EF estimate using absorption factors (Herva et al, 2008a). In the GWP case, this would constitute the Carbon Footprint (CF).

$$C_j = \sum_i C_{ij} = \sum_i A_i \cdot W_{ij} \qquad [1] \qquad C_{j,N} = C_j / N_j \qquad [2]$$

where A_i is the amount of emission *i* released, W_{ij} is the characterization factor for the emission *i* within the category *j*, C_{ij} is the contribution of the emission *i* to the category *j*, C_j is the characterized value of the category *j*, N_j is the normalization factor of the category *j* and $C_{j,N}$ is the category *j* normalized. C_j units depend on the category considered, whereas $C_{j,N}$ is dimensionless.

For the environmental risk estimates, migration rates from bottle to water and final concentrations in water for the compounds considered (bisphenol A, vinyl chloride monomer and aldehydes) were found in the literature (Table 1).

Table 1. Data used for the risk characterization.

Compound	Material	Migration rate / Concentration in water			RfDs[(a)] (mg kg^{-1} day^{-1})	SF[(a)] (kg day mg^{-1})
		Value	Units	Source		
Bisphenol A	PET	0.19±0.13	ng/h[(b)]	Le et al, 2008	$5.00 \cdot 10^{-2}$	-
Vinyl monomer	PVC	0.6	µg/l	Fayad et al, 1997	$3.00 \cdot 10^{-3}$	1.50
Acetaldehyde	PET	60.0±6.0	µg/l	Dabrowska, 2003	-	-
Formaldehyde	PET	78.1±7.8	µg/l	Dabrowska, 2003	$2.00 \cdot 10^{-1}$	-

[(a)] US-EPA, 2007 [(b)] A six-month storage period considered.

The concentration of these compounds in water stored depended mainly on initial concentrations in the bottle material, as well as in temperature and time of storage. Thus, estimations were made under the worst case scenario conditions. Final concentrations achieved in the beverage were multiplied by a human water intake factor of $2.5 \cdot 10^{-2}$ l/(kg·d) (Clark et al, 2003) during the exposition evaluation phase. Thus, only the oral pathway was considered. For the risk characterization, reference doses (RfDs) for non carcinogenic effects, and slope factors (SF) for carcinogenic effects, were used in order to calculate the Hazard Quotient (HQ) and the Cancer Risk factor (CR) as stated in equations [3] and [4].

$$HQ = Dose / RfDs \qquad [3] \qquad CR = Dose \cdot SF \qquad [4]$$

HQ and CR values calculated for the different compounds must be summed up for each material. The result must keep under maximum acceptable levels of 1 and 10^{-4}, respectively.

2.3. Fuzzy logic structure

The use of FL techniques allows us to mesh a quantitative approach using a qualitative representation (Carrasco et al, 2002). Membership functions were defined for each methodology as inputs to a fuzzy inference reasoning procedure in the case of a specific product, a 2 litre water bottle. Since in this case the most important LCA environmental impacts were GWP and AP (obtained in the normalization phase), and they could be integrated in the EF value, membership functions were defined for CR, HQ and EF. The EF contribution to the ecodesign indicator was measured in terms of EF variation (ΔEF) in relation to a base case; that is to say, the higher the decrease in the EF value, the better.

As output to the inference engine, a Fuzzy EcoDesign Index (FEcoDI) was obtained, which collected the different criteria given by the tools used. Thus, each considered alternative was evaluated and the FEcoDI obtained. The Matlab® Fuzzy Logic Toolbox was used and the Mamdani inference system selected. The best option, from an overall environmental point of view, will be the one with the highest FEcoDI (Figure 1).

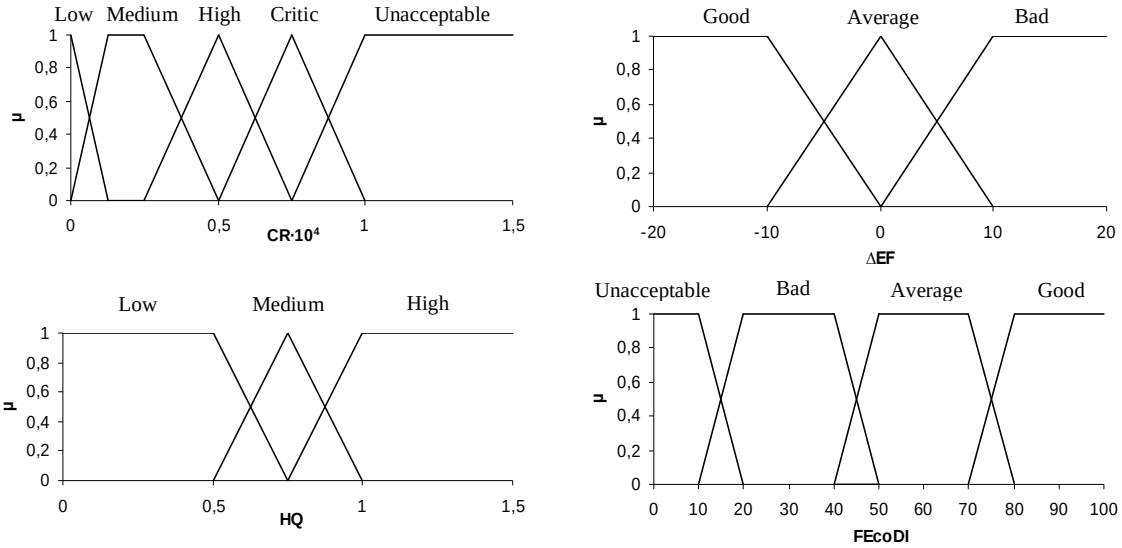

Figure 1. Membership functions for input variables (CR, HQ, EF) and for the output FEcoDI.

3 Results and discussion

On the basis of the inventoried data for the manufacture of a 2 litre bottle of these materials, the EF and ACV were calculated, the former accounting for materials and energy consumption, and the latter for atmospheric and aquatic emissions. LCA results for the characterization and normalization phase are shown in Table 2 and Figure 2, respectively. Observing the major influence of GWP and AP categories, the other ones were discarded from the study. After the integration of these two into EF estimates, the total amount of productive land required resulted in 2.27 m^2/bottle for PVC and 2.43 m^2/bottle for PET. Since in the fuzzy structure EF is measured in terms of variance with respect to a base case, the lowest value of the two (the correspondent to PVC) was taken as reference level. Consequently, the input for the PET bottle would correspond to a 7% increase in relation to the PVC bottle EF.

Table 2. Characterization phase for PVC and PET bottle.

Impact category	Units	PVC	PET
GWP	g CO_2	61.5	55.0
AP	g SO_2	0.75	0.90
ODP	g CFC	$1.44 \cdot 10^{-5}$	$2.16 \cdot 10^{-5}$
EP	g PO_4	$6.96 \cdot 10^{-2}$	$6.60 \cdot 10^{-2}$

GWP = Global Warming Potential AP = Acidification Potential
ODP = Ozone Depletion Potential EP = Eutrophization Potential

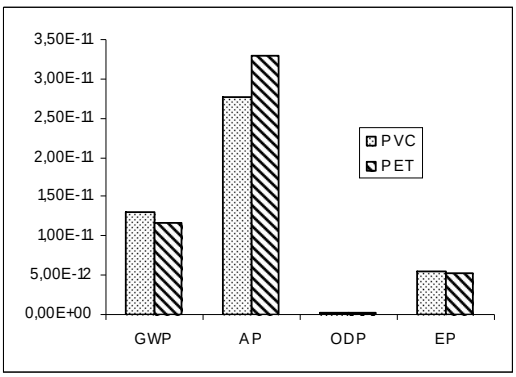

Figure 2. Normalization phase for PVC and PET bottle.

Results from ERA are collected in Table 3. Although acetaldehyde and formaldehyde have the R40 risk phrase associated (ESIS, 2008), what means that there is limited evidence of a carcinogenic effect (they are catalogue as carcinogenic type 3), at the moment there is no slope factor available recognised by and international organisation for these substances. Furthermore, acetaldehyde has neither RfDs nor SF; thus, it was not possible to assess the potential environmental risk contribution of this compound. The HQ and CR are below the safety limits stated by the US-EPA in all cases. It must be noticed that in the case of PET the risk contribution of two compounds was considered, while for the PVC only the potential risk

derived from the vinyl monomer migration was assessed. This was made according to main risk problems acknowledged in literature, and taking into account that the purpose of the analysis was to test the tool, not to present definite results on the evaluation of the two materials.

The results obtained with each methodology were introduced in the ecodesign tool. As a result, a FEcoDI of 30.0 for the PVC bottle was obtained, while a value of 66.6 was estimated for the PET bottle. Consequently, this would lead to select the PET bottle as the best option from an environmental point of view.

Table 3. Results for the Environmental Risk Assessment.

Material	Compound	HQ	CR
PET	Bisphenol A	$2.05 \cdot 10^{-4}$	-
	Formaldehyde	$9.76 \cdot 10^{-3}$	-
	Total	$9.97 \cdot 10^{-3}$	-
PVC	Vinyl monomer	$5.00 \cdot 10^{-3}$	$2.25 \cdot 10^{-5}$

The main difference between the two materials studied was the existence of a carcinogenic slope factor for the vinyl monomer. In the definition of membership functions, the universe of discourse for CR was divided into more categories than for the other variables. The CR has a probabilistic nature; this means that if it has a value different from zero, a risk of someone suffering from cancer will exist. However, in the case of HQ there will be effects on exposed population only if the reference dose is exceeded. As a result, fewer precautions were taken for HQ values lower than 1, while for the CR a more strict characterization was considered necessary. The tool seemed to be sensitive to changes in the EF only when CR and HQ were low enough. This may be because of the way the decision tree was constructed, first evaluating the CR and then the HQ, and only allowing the EF appraisal of those products that had passed the first barriers. Therefore, materials that may cause carcinogenic effects will receive a bad evaluation from the tool. In this case, the PET bottle obtained a better FEcoDI in spite of having a higher EF and HQ. The revision of this imbalanced weight for the input variables may lead to variations in the structure of the decision tree in the fuzzy reasoning. Besides, it was observed in this case study that even if different HQ values were calculated for the two materials evaluated, no changes in the FEcoDI were obtained.

4 Conclusions

A first approach of a tool based on EF, LCA and ERA was built on the basis of fuzzy logic reasoning and features. The output obtained was a Fuzzy EcoDesign Indicator (FEcoDI) that could range between 0 and 100, and that collected the criteria offered by the different environmental evaluation methods. In general terms, the constructed tool seemed to work properly. However, when testing it with real cases some limitations were detected and further development is proposed. The following steps may be considered: a.- Integration of more LCA impact categories that may be significant in the evaluation of other products; b.- A refinement of the decision tree in the fuzzy reasoning; and c.- A revision in the number of categories defined in the universe of discourse of HQ.

Keywords: Process design, Sustainability metrics, Mass and Energy Indicators, Safety indices
Topic: Systematic methods and tools for managing the complexity

Abstract

In this paper presents a methodology able to generate, screen and then identify sustainable alternatives in any chemical process by locating the operational, environmental, economical and safety related bottlenecks in the process. New alternatives were identified through a set of indicators and then evaluated through performance criteria, which includes a set of Sustainability Metrics and Safety indices. The methodology was already described for continuous processes and has now been extended to handle also batch operations. The methodology is described for both continuous and batch processes highlighting the differences among them. The main features/advantages of the software called SustainPro, which includes the indicator-based methodology, is presented. Through a batch case study (Insulin Process) the important features of the methodology and its application for sustainable process design are highlight through the use of SustainPro.

Introduction

Nowadays the concerns about the human future are growing everyday and consequently the need for improving the industrial plant operation and design is also increasing. The use of green compounds and the operability at sustainable conditions are two factors among many others that should be taken into account in the retrofitting of the already existing processes. Important questions to ask in this respect are - How should we improve an existing process (that is generate retrofit alternatives) without too much effort? What should be done in order to make the process more sustainable? Which are the process points that are going to significantly improve the plant performance? In order to address all the previous issues, it is useful to develop systematic methods and tools, which enable the generation of more sustainable alternatives and also improve the ability to adapt to the future needs.

Many methodologies have been proposed in order to determine new design alternatives of a chemical process with respect to improvement of the process. The indicator-based methodology proposed by Uerdigen et al., (2003) is considered in this paper. This methodology is based on mass and energy indicators, which are able to identify and screen processes operating in the continuous mode, however in this methodology there is no performance evaluation between the new design alternative for a given process with the "reference" design. Jensen et al., (2003) further extended this methodology where the previously defined indicators were retained but the choice of the best alternative was obtained using new parameters related to economic, safety and environmental factors.

Recently, Carvalho et al., (2007) presented a new generic and systematic methodology, which combines the previous versions, incorporates new features, as well as extend the application range to a while spectrum of chemical process. This was achieved through improvements in the flowsheet decomposition technique combine with flow-path identification, selection of target indicators as well as generation of new feasible alternatives. Recently the methodology has also been extended to batch processes.

Some work has also being developed in the batch process improvements. Houghton et al.

(1996) presented a hierarchical design procedure with potential strategies for reducing waste generation in a batch plant. This was done by listing a series of heuristic solutions that is directed at each decision level of the hierarchical design procedure. Halim and Srinivasan, (2006) presented an intelligent system to guide the non-expert in waste minimization assessment of batch processes (BATCHENVOP*Expert*).
In this paper a methodology to screen and identify the critical points in a batch process will be presented. As done for the continuous processes an evaluation in terms of economical, environmental and safety will be performed for the batch process. A batch case study will be described step by step in order to illustrate the methodology.

Methodology

The methodology has been developed for the continuous processes (Carvalho *et al*., 2007) and now it has been extended to batch processes. The following figure shows a diagram with the methodology description.

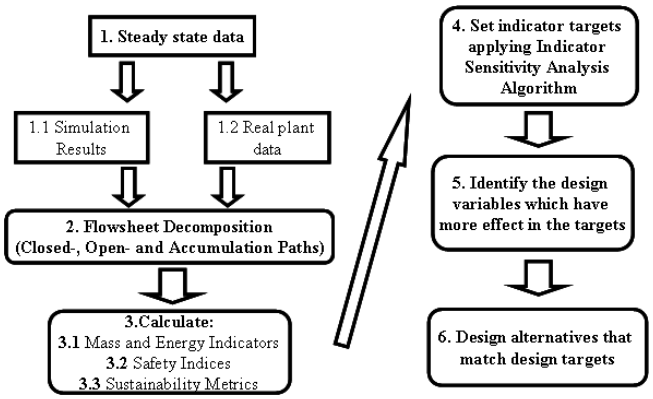

Figure 1: Flow-diagram of the indicator-based methodology

A brief description about both approaches is given below.

Step 1: Collect the steady state data
Process data needed to apply the methodology is collected. In the continuous processes, steady state data related to the mass and the energy balance is needed. In the batch processes the information required is the time of each operation, the equipment volume, the initial and the final mass for each compound in each operation and the energy used in each operation. The purchase and sale prices for each compound as well as the treatment costs are also included in the initial data. This data can be provided from the real plant data or through model-based simulations.

Step 2: Flowsheet decomposition
The flowsheet decomposition for continuous processes is performed to identify all the open- and closed-paths for each compound in the process flowsheet. In the batch processes, although the same decomposition takes place, in this case the accumulation paths (AP) are also determined. These paths (AP) correspond to the accumulation in a given operation.
It is important to mention the difference between the flowsheets for the continuous and batch modes. In the continuous processes the flowsheet is represented as a sequence of equipments, however in the batch processes the flowsheet is represented as a sequence of operations. Initially the flowsheet decomposition is performed in the same way for both continuous and batch processes, the only difference is the addition of accumulation paths for the batch processes.

Step 3: Calculate the indicators, the sustainability and the safety parameters
There is a set of 5 mass indicators and 3 energy indicators, which were defined for the

continuous processes analysis but that, can also be applied to batch processes. In this step the entire mass and energy indicators are calculated for all open- and closed-paths determined in step 2 for both batch and continuous processes. Two new set of indicators for batch processes have been developed: The Operation Indicator (compares the operation performance) and the Compound Indicator (indicate for each operation which compound is most likely to cause operational problems). These two set of indicators are applied to the batch processes analysis.
Operation Indicators were already described in Carvalho et. al, 2008. In table 1 a summary of the Compound Indicators is presented.

Table 1- Summary of compound indicators expressions

Indicator	Description	Operation	Definition
FVF	Free Volume Fraction	All	$FVF = \frac{V_{equi} - \sum_{i}^{I} \frac{F_{AP}^{i}}{\rho^{i}(t)}}{V_{equi}}$
TF	Time Factor	Mixer	$TF_{j,i} = \frac{1}{\frac{F_{AP}^{i}}{\sum_{AP}^{CO} F_{AP}^{i-1}}} \times \frac{t_j}{t_{total}}$
		Reactor	$TF_{j,i} = x\left(\frac{1}{\frac{F_{AP}^{i}}{\rho^{i}}} \times \frac{t_j}{t_{total}}\right) + (1-x)\left((1-z)\frac{1}{\frac{F_{AP}^{i}}{\rho^{i}}} \times \frac{t_j}{t_{total}}\right)$
		Heat Exchanger	$TF_{j,i} = \frac{F_{AP}^{i} \times cp^{i}}{\sum_{AP}^{CO} F_{AP}^{i-1} \times cp^{i-1}} \times \frac{t_j}{t_{total}}$
		Separation	$TF_{j,i} = \frac{F_{AP}^{i}}{\lvert Property^{c} - Property^{c} \rvert} \times \frac{t_j}{t_{total}}$
EF	Energy Factor	Mixer	$EF_{j,i} = \frac{F_{AP}^{i} \sum_{k}^{n} \Delta p_k^{i}}{\sum_{AP}^{n} F_{AP}^{i} \sum_{k}^{n} \Delta p_k^{i}} \times \frac{E_j}{\sum_j E_j}$
		Reactor	$EF_{j,i} = F_{AP}^{i} \times \Delta H_f \left[y \times \left(x \times \frac{\Delta H_f}{\sum_{AP}^{CO} \Delta H_f^{i-1}} + (1-x)\left(1 - \frac{\Delta H_f}{\sum_{AP}^{CO} \Delta H_f^{i-1}}\right)\right) + (1-y)\left(x \times \frac{\Delta H_f}{\sum_{AP}^{CO} \Delta H_f^{i-1}} \left(1 - \frac{\Delta H_f}{\sum_{AP}^{CO} \Delta H_f^{i-1}}\right) + (1-x)\frac{\Delta H_f}{\sum_{AP}^{CO} \Delta H_f^{i-1}}\right)\right] \times \frac{E_j}{\sum_j E_j}$
		Heat Exchanger	$EF_{j,i} = \frac{F_{AP}^{i} \times cp^{i}}{\sum_{AP}^{CO} F_{AP}^{i-1} \times cp^{i-1}} \times \frac{E_j}{\sum_j E_j}$
		Separation	$EF_{j,i} = \frac{F_{AP}^{i} \times Property^{i}}{\sum_{AP}^{CO} F_{AP}^{i-1} \times Property^{i-1}} \times \frac{E_j}{\sum_j E_j}$

In the previous table V_{equi} is the volume of the equipment, F_{AP} is the accumulation-path flowrate, ρ is the density, t is the time, υ is the stoichiometric coefficient, c_p is the heat capacity, E is the energy consumed and ΔHf is the heat of formation. The entire set of indicators show high potential for improvement when they present high values. The indicators values show the compounds responsible for the high energy consumption, the time used in a given operation or the volume occupancy. Summarizing, once this indicators are applied to each compound, those presenting high values compared with the others should be reduced in order to improve the process performance.
Through the values obtained for all indicators it is possible to identify the locations within the process where the mass/energy “paths” face “barriers” with respect to costs, benefits, or accumulation problems. These critical points “indicate” high potential for process improvements. The process impact analysis is carried out through the calculation of a set of sustainability metrics and/or the LCA analysis. The safety of the process is measured by the use of a set of safety indices. These two set of metrics are used in the evaluation of the new alternative when compared to the “base” process.

Step 4: Indicator Sensitivity Analysis (ISA) algorithm
In this step the target indicators are determined using the ISA algorithm. To apply this algorithm the indicators having the highest potential for process improvement with respect to sustainability and other criteria are first identified. Then an objective function such as gross-profit or process total cost is specified. Through a sensitive analysis the indicators that allow the best improvements in the objective function among the selected indicators are determined. The ones with the best improvements will be the design targets for the new

process design alternative.

Step 5: Process Sensitivity Analysis
A process sensitivity analysis with respect to the operational (parameters) variables, which influence the target indicators, is performed. The analysis identifies the operational variables that need to be changed to improve the process in the desired direction.

Step 6: Generation of new design alternatives
New alternatives are generated using a systematic analysis where a collection of synthesis algorithm can be used. This collection combines three different algorithms for process-product synthesis Jaksland and Gani, (1996), Harper, (2000) and D'Anterroches and Gani, (2005) into one integrated method.

Sustain-Pro
Based on the above methodology, a software (Sustain-Pro) has been developed to allow an easy application of the methodology for generation of more sustainable design alternatives. The inputs for Sustain-Pro are the mass and the energy balance data as well as the prices of the compounds present in the process. Sustain-Pro follows all the steps of the methodology, allowing thereby, the creation/evaluation of new alternatives strategy to any chemical process.

Insulin Production-Case Study
The insulin process is divided into four sections: 1) Fermentation, 2) Primary Recovery, 3) Reactions, and 4) Final Purification. In this paper the process analysis will be done exclusively to the fermentation part in order to illustrate the methodology potential. The flowsheet for the fermentation section is presented in the following figure.

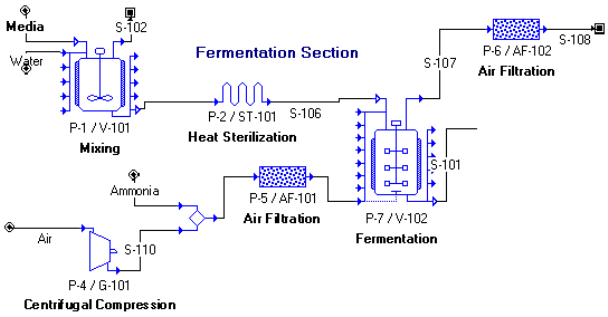

Figure 2: Fermentation section flowsheet

Step 1: Collect the steady state data
A *SuperPro Designer* simulation model of insulin synthesis plant was used as an example of the batch methodology's extension. The flowsheet of the process can be found in case studies provided by *SuperPro Designer* software package. The prices and costs are also specified by the *SuperPro Designer*.

Step 2: Flowsheet decomposition
The process involves 21 streams, 14 operations and 8 compounds. The flowsheet for the sequence of operations is represented in the following figure.

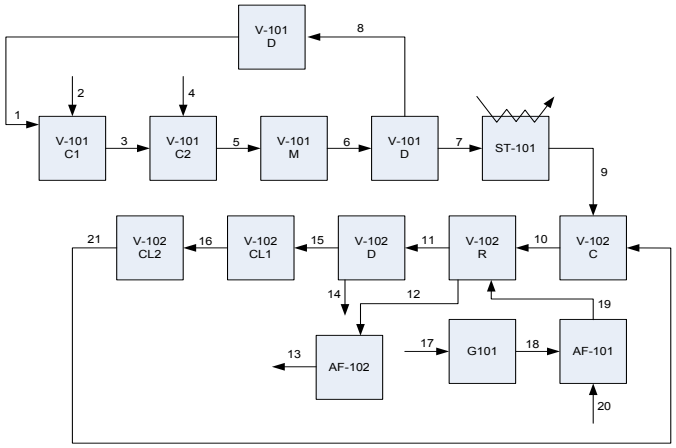

Figure 3: Insulin operations diagram

For this case study the operations diagram decomposition generated 16 closed-paths, 27 open-paths having flowrates greater than zero and 80 accumulation-paths (Sustain-Pro).

Step 3: Calculate the indicators, the sustainability and the safety metrics
For the entire set of flow-paths, the full-set of indicators were calculated and only the most sensitive indicators were selected. The sustainability metrics as well as the safety index were also calculated. For this case study the most sensitive indicators were the MVA – Material Value Added, for OP 7 and OP10 (see table 2). They presented very negative values, which mean that a lot of money was being spent with the entrance and the exit of glucose and salts respectively. The value of the target indicators should be increased. Regarding the batch indicators, TF in AP51 for Glucose was the most sensitive indicator and its value should be reduced in order to have a lower operational time.

Table 2- MVA values for the insulin process

Open Path	Compound	MVA (10^3\$/y)
OP7	Glucose	-7233
OP10	Salts	-1757

Step 4: Indicator Sensitivity Analysis (ISA) algorithm
Through the ISA algorithm it was found out that among the two selected indicators the MVA indicator related with OP7 was the most sensitive and consequently the one that should be primarily improved.

Step 5: Process sensitivity Analysis
Making a sensitivity analysis to the operational parameters influencing the target indicators it was verified that the most significant parameter was the reduction of the flowrate for OP7.

Step 6: Generation of new design alternatives
To reduce the OP7 flowrate, the recycle of the glucose needs to be considered. To recycle glucose a separation needs to be inserted in order to separate/recover the raw material. Through the use of the synthesis method to identify new separation processes, Jaksland and Gani, (1996), it was verified that a filter and an evaporation unit need to be inserted in order to recover the glucose.
Regarding the compound indicators for the batch operations, the TF presented some problems in the reaction operation for the glucose, once its value was higher than the other values. This means that the glucose was limiting the rate of the reaction. Consequently, it would be better to operate with a greater excess of glucose.
Summarizing, the new design alternative consisted of recycling the glucose. With this new alternative the profit increased 1.04%, the water and the energy metrics per value added

improved by 1.03% and finally the material metrics improved by 2.55% and 3.26 respectively per kg of final product and per value added. All the other parameters remained constant. The target indicators improved by 100%.

Conclusions and Future Work

The development of a systematic and generic indicator-based methodology for continuous and batch process analysis and for generating sustainable processes improvements has been presented and highlighted. With the development of corresponding software (Sustain-Pro), the application of the methodology to continuous processes has become easier and wide. This methodology has been applied to a number of case studies involving well known processes such as the HDA-process, MTBE, VCM, ammonia production, natural gas purification plant and many more (details of these case studies can be obtained from the authors). Current and future work will further develop the methodology to incorporate more features to handle various types of batch and continuous processes as well as the corresponding software (Sustain-Pro). There will be also collaboration with the Institute of Chemical and Engineering Sciences to join two softwares, SustainPro and ENVOPExpert, (Halim and Srinivasan, 2002) in order to generate a more powerful tool, which generates optimal sustainable new design alternatives.

Topic: Catalysis and reaction engineering

Abstract

The anaerobic decolourisation of azo dye Orange II (O-II) was studied in a continuous upflow stirred packed-bed reactor (USPBR) filled with biological activated carbon (BAC). A model was developed involving both heterogeneous catalysis and biological decolourisation. First-order, autocatalytic and Michaelis–Menten kinetics were found to describe the decolourisation process rather well at lower initial dye concentration. O-II showed significant inhibition effect to biomass beyond inlet dye concentrations of 300 mg L^{-1}. Expanding Michaelis–Menten kinetics by a substrate inhibition factor resulted in a model giving good fitting to experimental points, independently on the initial colourant concentration. Processing at very low hydraulic residence time together with higher initial dye concentration resulted in toxicity to bacteria.

1 Introduction

A typical drawback of azo dye colouration – mainly occuring in textile industry – is that large amounts of the dyestuff are directly spilt to wastewater. Discharging dyes into the hydrosphere can cause environmental damage as they give water undesirable color and reduce sunlight penetration (Al-Degs et al., 2008), with some dyes and their degradation products also being toxic or carcinogenic. Considering both the volume generated and the effluent composition, textile industry wastewater is rated as the most polluting amongst all industrial sectors (Sandhya and Swaminathan, 2006). Relevant factories have deficiencies of treating efficiently these effluents on industrial scale, particularly at higher dye concentrations and at lower energy consumptions.

Bioremediation-based technologies for treating azo dye wastewater have attracted interest since they are both economic and environmentally friendly. One possible strategy for efficient biomineralisation of these azo compounds is a sequential anaerobic–aerobic process (Kalyuzhnyi and Sklyar, 2000). However, the unspecific anaerobic reduction of many azo dyes usually proceeds rather slowly. To overcome this problem, by using redox mediators, such as quinoid compounds (Rau et al., 2002) during the reduction, anaerobic biodegradation can be enhanced resulting much higher removal rates. By immobilizing the electron mediator in the bioreactor, the problem of continuous dosing of the redox compound can be avoided resulting lower process costs. Activated carbon as a possible solid redox mediator containing surface quinonic structures, was reported to be enable to accelerate azo dye reduction (Van der Zee et al., 2003; Mezohegyi et al., 2007a).

To our knowledge, packed bed-type reactors using biological activated carbon (BAC) system have never been applied for anaerobic azo dye decolourisation by other authors. In our previous study (Mezohegyi et al., 2007a) the results cleared that comparing to other continuous and biological processes treating azo dyes, continuous

* Corresponding author. Tel + 34-977-559643. E-mail:afabrega@urv.cat

upflow packed-bed reactor (UPBR) with BAC seemed to be one of the most effective systems for anaerobic azo dye biodegradation. It was also found (Mezohegyi et al., 2007b) that the application of special stirring in the carbon bed resulted in an increase of azo dye bioconversion compared to unstirred reactor system with ensuring high dye degradation rates at very short space times/hydraulic residence times. In recent study, the anaerobic decolourisation of an acid azo dye in continuous upflow stirred packed-bed reactor (USPBR) was investigated. Different decolourisation models were compared and the effects of initial dye concentration on biodegradation were discussed.

2 Materials and methods

2.1 Chemicals

The azo dye Orange II (O-II) sodium salt (dye content 99%, Sigma, ref. O8126) was selected as the model colourant. Sodium acetate (99%, Aldrich, ref. 11019-1) was used as co-substrate being both the carbon source for sludge and electron donor for azo reduction. Activated carbon (Merck, granules of 2.5 mm, ref. 1.02518.1000) was used as catalytic support material in the upflow stirred packed-bed reactor. Activated carbon was crushed and granules of 25-50 mesh size were separated, washed with distilled water, dried at 104°C for 15 h and stored under normal conditions. The basal media containing microelements accorded with the one used in our previous study (Mezohegyi et al., 2007a).

2.2 Upflow stirred packed-bed reactor setup

Figure 1 shows schematically the continuous and anaerobic experimental system. The upflow stirred packed-bed reactor has a diameter of 15 mm with a volume of 10 mL. It is filled with the mixture of 10 g of carborundum granules as inert and 250 mg of activated carbon (AC) with size of 25-50 mesh. The packed-bed porosity is about 0.3. Two filters were placed into the top and bottom of the reactor to prevent washing out of AC. The temperature was kept constant at 35°C. The entering feed was 100 mg L^{-1} azo dye solution containing 200 mg L^{-1} sodium acetate and the basal media. The flow rate of the feed was varied between 25 and 350 mL h^{-1} and was ensured by a micro pump (Bio-chem Valve Inc., ref. 120SP2420-4TV). The anaerobic condition in the feeding bottle (5 L) was maintained by both cooling of the solution (at 5°C) and bubbling of helium. The redox potential was continuously monitored (measured where the outlet immediately left the USPBR) and remained below -500 mV (referred to Ag^{+}/AgCl electrode). The reactor was built together with a stirring system that makes possible to apply a very fine and slow agitation (1 revolution per hour) in the biological activated carbon bed that was established in the same way as described in (Mezohegyi et al., 2007a).

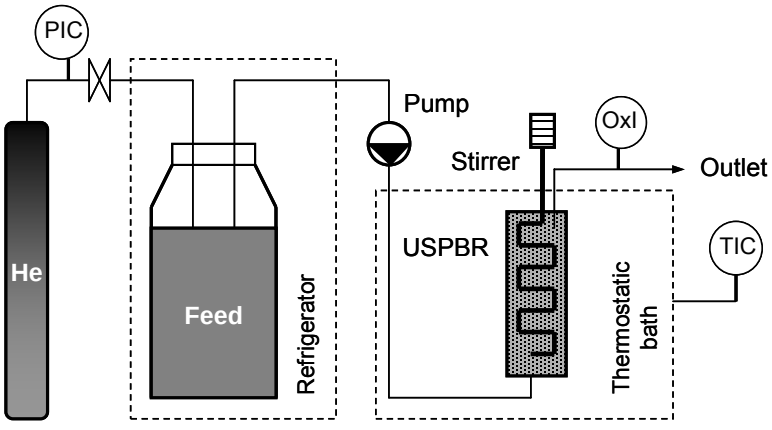

Figure 1. Anaerobic upflow stirred packed-bed reactor setup.

2.3 Analytical methods

Quantitative determination of Orange II and acetate in the outlets was done by HPLC on a C_{18} Hypersil ODS column in a gradient of methanol–water mobile phase with a flow rate of 1 mL min^{-1}. O-II was determined at 487 nm and acetate at 210 nm.

3 Results and discussion

3.1 Modeling O-II anaerobic biodegradation in USPBR

3.1.1 Determination of reaction rate

Kinetic models with a specified reaction rate were developed involving both heterogeneous catalysis and biological decolourisation in the reactor. The mole balance for the packed-bed reactor is given by (eq. 1):

$$\frac{dF_{AZO}}{dm_C} = -r'_{AZO} = \frac{d(c_{AZO} \cdot F_V)}{d(\tau \cdot F_V \cdot \rho)} \quad (1)$$

where F_{AZO} (mmol min^{-1}) is the molar flow of azo dye solution, m_C (g) is the mass of catalyst in the reactor, r'_{AZO} (mmol min^{-1} g^{-1}) is the rate of the reaction, c_{AZO} (mmol L^{-1}) is the dye concentration, F_V (L min^{-1}) is the volumetric flow, τ (min) is the space time and ρ (g L^{-1}) is the density of solution. If the flow rate of azo dye solution is kept constant and the density difference between the dye solution and water is neglected, the reaction rate r_{AZO} (mmol min^{-1} L^{-1}) will finally be (eq. 2):

$$\frac{dc_{AZO}}{d\tau} = -r_{AZO} \quad (2)$$

3.1.2 Kinetic models

The upflow stirred packed-bed reactor provided reproducible data to make kinetic modeling of O-II biodegradation possible. More than one kinetic model was found to describe rather well Orange II anaerobic biodegradation, namely, first-order model, Michaelis–Menten (MM) model and a second-order autocatalytic model (Van der Zee et al., 2000). Table 1 shows the kinetic parameters encountered for these models. The simple first-order model and the second-order autocatalytic model fit well the experimental points (data not shown). Latter one can be proved by the autocatalytic nature of 1-amino-2-naphthol, being one of the anaerobic degradation products of Orange II. On the other hand, Michaelis–Menten model is expected to describe O-II biodecolourisation since it is a biological process and, also, the amount of consumed acetate by bacteria – providing the electrons to azo reduction – is directly proportional to dye conversion. Indeed, MM kinetics seems to be applicable for modeling Orange II degradation in our reactor system (Fig. 2). According to the very good fitting of all models, the reaction rate predicted by all then should be similar. This is accomplished when comparing the first-order and autocatalytic model, since the first-order constants are similar and the second part of the autocatalytic model gives relatively small values because of the second-power function of the small dye concentration used. The reaction rates of the first-order and MM model are similar as well, since the first-order constants are similar and the Michaelis-constant is rather big relatively to the outlet dye concentrations, thus MM reduces to first-order model in this case.

One of the most frequent models having been found to describe dye biodegradation in different reactor systems are Monod-types and some further include dye adsorption onto biologically activated carbon (Walker and Weatherley, 1997). On the other hand,

many azo dyes may have strong adsorption affinity to activated carbons depending on the surface chemistry of the carbon (Pereira et al., 2003). It can be interesting to mention that the so-called Langmuir–Hinshelwood equation – describing the rate law for surface catalysed reactions where the overall reaction rate is proportional to the surface coverage of the substrate over the catalyst – is analogous with the MM model and differences only are between the kinetic constants. Hereby, the former equation may also be used to describe our system suggesting that strong adsorption capacity of the carbon for O-II can play an important role during this complex biological decolourisation process.

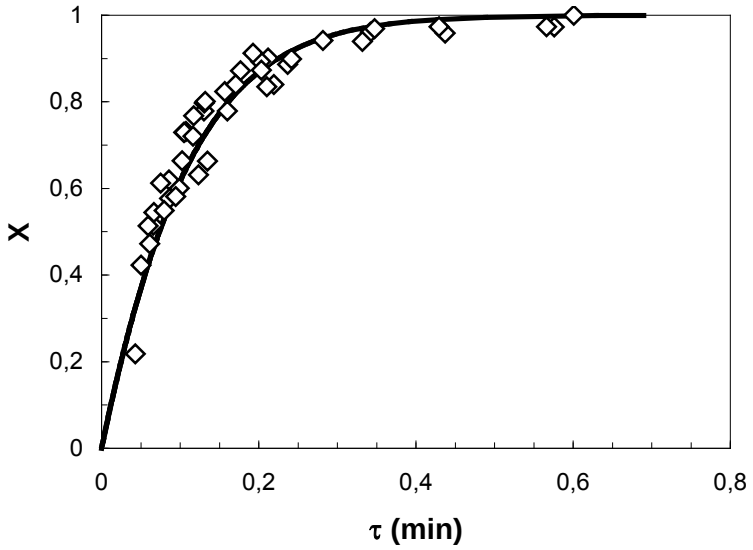

Figure 2. Kinetic modeling of Orange II anaerobic biodegradation in upflow stirred packed-bed reactor: Orange II conversion (X) in the function of space time (τ, min); line shows the fitting to Michaelis–Menten model.

3.2 Substrate inhibition and toxicity effects

50 days after measuring experimental points in USPBR, the reproducibility of the reactor system was checked by measuring O-II conversions again, at certain space times. The previously determined Michaelis–Menten model fitted still well the newly measured points. After that, the inlet dye concentration was increased from 100 mg L^{-1} to 300 mg L^{-1} to check if higher O-II concentrations may have inhibition or toxicity effects to the biomass. Figure 3 shows that the MM model set before shows significant deviation from experimental points at initial concentration of 300 mg L^{-1}. This suggests that O-II possesses concentration-dependent inhibition effects for bacteria in the reactor. For this, MM model was expanded by an inhibition factor and this model with 3 kinetic constants describes well the degradation process, independently on the initial dye concentrations (Fig. 3). The substrate inhibition was found to be significant since the value of the constant ratio k_i/k_2 is less than 10. Table 1 also shows the standard deviation value associated to experimental points involving both initial dye concentrations of 100 and 300 mg L^{-1}. However, the recalculated kinetic constants – including both inlet concentrations – differ from the former ones. This can be explained by having not only inhibition but also toxicity effects to the biomass at higher inlet dye concentrations. Indeed, using very high flow rate in the reactor at 300 mg L^{-1} of initial dye concentration resulted toxicity, i.e. the redox potential was increased from -485 mV up to -180 mV in 3 hours after changing the flow of solution from 150 to 260 mL h^{-1}. Then, to avoid the irreversible deactivation of microbes, the flow was set back to 55 mL h^{-1} and, in addition, after 2 days the initial O-II concentration was changed back to 100 mg L^{-1}. After 5 more days, the redox potential decreased back to -486 mV and O-II conversion nearly returned to the value as it was before the toxicity to biomass (Fig. 3).

Table 1
Kinetic data of models used for anaerobic Orange II degradation

model type	model equation	kinetic constants	SD[a]
first-order	$r_{AO7} = -k \cdot c_{AO7}$	$k = 10.1\ min^{-1}$	0.048
autocatalytic	$r_{AO7} = -k_1 \cdot c_{AO7} - k_2 \cdot c_{AO7} \cdot (c_0 - c_{AO7})$	$k_1 = 10.8\ min^{-1}$ $k_2 = 1.05\ L\ mmol^{-1}\ min^{-1}$	0.047
Michaelis–Menten	$r_{AO7} = -\frac{k_1 \cdot c_{AO7}}{k_2 + c_{AO7}}$	$k_1 = 10.8\ mmol\ L^{-1}\ min^{-1}$ $k_2 = 0.94\ mmol\ L^{-1}$	0.054
Michaelis–Menten with substrate inhibition	$r_{AO7} = -\frac{k_1 \cdot c_{AO7}}{k_2 + c_{AO7} + \frac{{c_{AO7}}^2}{k_i}}$	$k_1 = 11.7\ mmol\ L^{-1}\ min^{-1}$ $k_2 = 1.15\ mmol\ L^{-1}$ $k_i = 4.38\ mmol\ L^{-1}$	0.048
		$k_1' = 6.18\ mmol\ L^{-1}\ min^{-1}$ $k_2' = 0.55\ mmol\ L^{-1}$ $k_i' = 0.09\ mmol\ L^{-1}$	0.056[b]

[a] Standard deviation associated to the model fitting: $SD = \sqrt{\Sigma\left(X - X^{MOD}\right)^2 / (n-1)}$ where n is the number of experimental points.

[b] Standard deviation associated to k' values calculated from experimental points involving both initial dye concentrations of 0.286 and 0.857 mmol L^{-1} (100 and 300 mg L^{-1}, respectively).

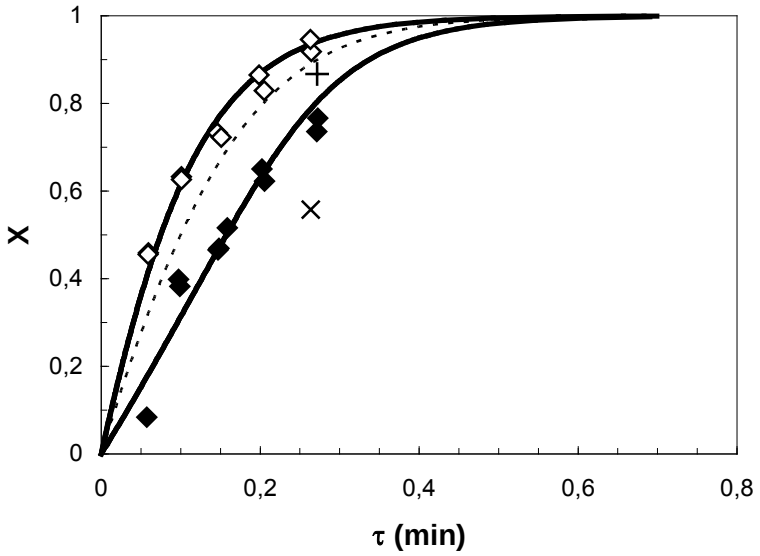

Figure 3. Substrate inhibition and toxicity effects during Orange II decolourisation in upflow stirred packed-bed reactor: (◇) shows repeated experimental points with initial O-II concentration of 100 mg L^{-1}; (◆) shows experimental points with initial O-II concentration of 300 mg L^{-1}; (×) shows O-II conversion, 1 day after biomass toxicity; (+) shows O-II conversion, 6 days after biomass toxicity; dotted line represents the Michaelis–Menten model at initial Orange II concentration of 300 mg L^{-1} supposing no substrate inhibition; continuous lines show the fitting to Michaelis–Menten model with substrate inhibition at initial O-II concentrations of 100 and 300 mg L^{-1}.

4 Conclusions

To the best of our knowledge, a continuous upflow stirred packed-bed reactor with biological activated carbon was applied for the first time for anaerobic azo dye decolourisation. The USPBR provided reproducible data to make kinetic modeling of O-II biodegradation possible. First-order, autocatalytic and Michaelis–Menten models were all found to give good fittings to experimental points of dye conversion at lower inlet dye concentration. On the other hand, O-II showed significant inhibition effects to

the biomass at higher initial concentration and, also, processing at very low hydraulic residence times together with high initial dye concentration resulted in toxicity to bacteria. It can be assumed that a general model, describing the anaerobic biodegradation of diverse azo dyes in USPBR-BAC system, will be made up of the combination of dye inhibition and possible autocatalytic effects together with Michaelis–Menten kinetics.

Abstract

In the present paper it is compared the performance of most of the commercially available photocatalysts (based on titanium dioxide), as well as synthesized new ones (TiO_2 encapsulated in adsorbents), on photooxidizing NO. Commercial samples are also tested when incorporated in a water-base paint coating. Lower NO conversions achieved with the encapsulated photocatalytic TiO_2 materials (TiO_2 content about 1 wt.% except for zeolite Y with two exchanges steps) than with the commercial ones suggest the possible influence of the intrinsic characteristics of the encapsulated materials on the photo-activity. It is observed a strong synergetic effect between the adsorbent, such as zeolite Y, and the TiO_2, in mechanical mixtures. In fact, a film produced from mixtures of P25 and zeolite Y, with only 15 wt.% in P25, originated approximately the same values of NO conversion (55 %) and ionic selectivity (35 %) than a film with 100 wt.% of P25. It is also concluded that by using a paint with a pigment volume concentration (PVC) above the critical value, hosting 10 wt.% of photocatalyst, it is possible to photo oxidize approximately 50 % of NO with approximately 30 % of ionic selectivity, in operating conditions close to those suggested in standard ISO 22197-1:2007(E).

1. Introduction

NOx is a precursor for urban smog and tropospheric ozone formation that are related with healthy damages (EPA, 1998). Therefore, improvements in de-NOx technologies are needed.

Photocatalysis has been tested at lab scale in the NOx abatement and photocatalytic construction materials, such as paints, have been pointed as a possible solution to help in the de-NOx of the environment (e.g. Strini *et al*., 2005). However, for successful application of this technology it is important to protect the constituents of these construction materials towards the photocatalytic process occurring in its matrix. In this line some studies have been performed and basically two strategies can be identified in the literature: i) decrease the amount of incorporated photocatalytic TiO_2 and select constituents with higher chemical stability (Motohashi and Inukai, 2007); and ii) use of encapsulated TiO_2 particles (Cosa *et al.*, 2002). Encapsulating TiO_2's particles shows other attractive advantages, such as concentrate the target compounds to abate, over the product ones, by adsorption, increasing therefore the reaction rate (Corma and García, 2004).

At our lab, it is aimed to produce a photocatalytic paint with chemical stability towards

* Corresponding author. Tel + 351-225-081-695. E-mail:mendes@fe.up.pt

photooxidation and obeying to the parameters of the paint industry regarding its properties. With this and the above-mentioned issues in mind, TiO_2 was incorporated inside the porous structure of zeolites Y and USY (*zeolyst Inc*.) and montmorillonite K-10 (*Sigma-Aldrich*). The photo-activity of these composite materials was tested in powder pressed films and discussed taking into account some of their intrinsic characteristics. Comparison was made with the photo-activity of commercial photocatalytic TiO_2 samples. These commercial materials were also tested when incorporated in an exterior high quality paint above the critical Pigment Volume Concentration (CPVC).

2. Experimental procedure

2.1. Encapsulated photocatalysts, synthesis and characterization

The experiments described below aim at testing the photo-activity of encapsulated TiO_2 on various adsorbent materials (hereafter named as encapsulated "photocatalytic" TiO_2) and compare their performance with that of commercial photocatalytic TiO_2, which are plain, mostly anatase, TiO_2 particles. The encapsulated photocatalytic materials were produced by ion exchange using $(Ti{=}O)K_2(C_2O_4)\cdot H_2O$ as TiO_2 precursor, as described by Cosa *et al*. (2002). The adsorbents used as support were montmorillonite k-10 (mK-10) from *Sigma-Aldrich* and Zeolites Y and USY from *Zeolyst Inc*. These materials were exchanged once or twice. The first exchange was performed with a 0.2 M solution in TiO_2 precursor and the second with a 0.6 M solution. The encapsulated photocatalyic TiO_2 obtained by one or two ion exchanges were denoted as TiO_2@support and $(TiO_2)_2$@support, respectively, with "support" being USY, Y or mk-10. "(P25+Y)_15 wt.% TiO_2" refers to the material produced from the mechanical mixture of zeolite Y and P25 TiO_2 (15 wt.% in P25).

Elemental analysis was performed by ICP using a Varian 715-ES instrument. The surface area and porosity was studied by nitrogen adsorption at 77 K using a Micromeritics ASAP 2010. RAMAN analyses were performed with a Renishaw instrument in order to investigate the anatase and rutile-related bands. Diffuse reflectance UV-Vis spectroscopy (Varian Cary 5) was also performed targeting to evaluate the light absorption spectrum and to measure the related optical band-gap.

Commercial photocatalytic TiO_2 here used for comparison are the following: P25, from *Degussa;* PC500, from *Millennium;* VLP7000, from *Kronos;* UV100, from *Sachtleben; and* AMT100, from *Tayca.*

2.2. Photocatalytic films application

Powder pressed films and paint films were tested in the setup described below. Powder pressed films were produced by pressing the powder to the base of the reactor, applying 20 bar for 7 min. Two film sizes were used, 10 x 5 cm^2 and 6 x 5 cm^2, depending on the available amount of sample. The name of the experimental run indicates the area used (see section 3.2). Paint films were produced using a draw down bar. It was used an exterior water-base paint above CPVC and produced accordingly to the formulation kindly supplied by CIN, S.A. The original formulation was modified by replacing a portion of the TiO_2 used for opacity (which it is not photoactive), by the photocatalytic one, in order to produce a photocatalytic paint with ca. 10 wt.% of photocatalytic TiO_2.

2.3. Setup and photocatalytic experiments

The operating conditions and construction of the setup were inspired on standard ISO 22197-1:2007(E). Basically it comprehends a thermostatic cabinet where the reactor and the feed system are assembled. In the rectangular base of the reactor it is applied the photocatalytic film to be tested. A photoluminescent NO and NO_2 analyser (*Thermoelectron*

42C) is used to read the concentration of these species. The irradiance, relative humidity (RH), NO concentration at the inlet of the reactor (NO_{in}) and temperature were set to 10 $W \cdot m^{-2}$ (UV BLB lamp 365 nm – *Vilbert Lourmat*), 50 %, 1 ppmv (in ArK), and 25 ºC, respectively. Total gas flow rate used was 0.7 $L_N \cdot min^{-1}$.

3. Results and discussion

Photocatalysis of NOx can proceed as reduction and/or as oxidation. However, photo-reduction is not probable to occur in the presence of water and oxygen. Also, it is not referred the formation of N_2O in similar systems (Devahasdin *et al.*, 2003). NO photooxidation should then proceed to NO_2 and then to NO_2^- or NO_3^-. NO conversion (X_{NO}) and selectivity towards NO_2^- and NO_3^- (hereafter referred as ionic selectivity - S_{ionic}) were calculated using the following equations:

$$X_{NO} = \left(\frac{NO_{in} - NO_{out}}{NO_{in}} \right) \times 100 \qquad S_{ionic} = \left(\frac{(NO_{in} - NO_{out}) - NO_{2_{out}}}{NO_{in} - NO_{out}} \right) \times 100$$

where NO_{in} stands for the concentration of NO at the inlet of the reactor and NO_{out} and $NO_{2,out}$ to the NO and NO_2 outlet concentrations, respectively.

3.1. Characterization of the photocatalysts

Raman studies were performed in order to identify the typical rutile or anatase structures of TiO_2. However, typical peaks, as detected for P25, were not observed for the encapsulated materials. X-ray diffraction also did not allow the identification of typical peaks of crystal structures of TiO_2. Such fact does not mean that a crystalline structure does not exist; actually, a photocatalytic activity was detected, as shown later on. The analysis of the diffractogram of zeolite Y with one and two exchanges (Fig. 1a) reveals complete loss of crystallinity. Diffuse reflectance was performed and has also shown the light absorption characteristic of TiO_2. However, due to a low signal to noise ratio it was impossible to calculate the band-gap.

Table 1 presents the weight percentage of Ti in each sample, and the BET surface area, obtained by ICP and nitrogen adsorption isotherms performed at 77 K, respectively. Results of $(TiO_2)_2$@Y show a very large amount of incorporated Ti, which can be the cause of the loss of crystallinity shown in Fig. 1a. Such loss produces a strong decrease in the BET surface area of zeolite Y from the first to the second ion exchange steps (Table 1 and Fig. 1b). A decrease was also noticed in the other supports tested, however much less pronounced than with zeolite Y.

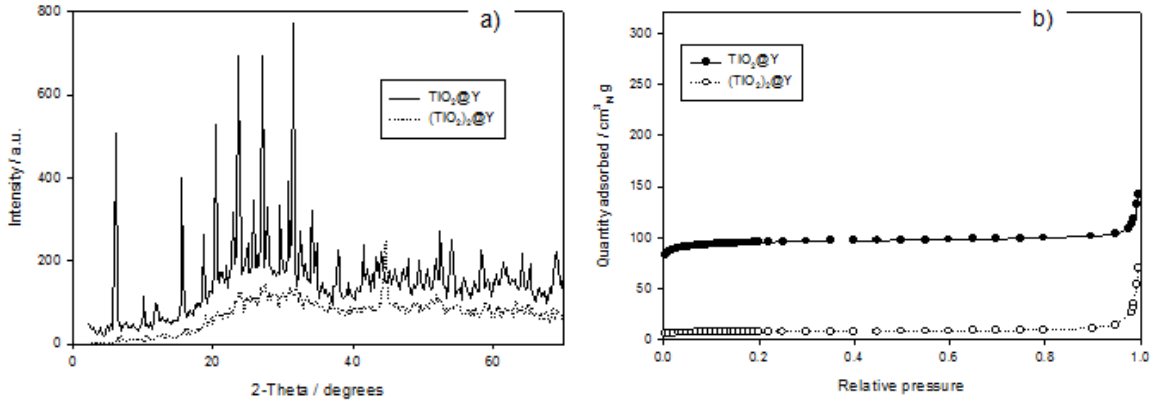

Figure 1 – X-ray diffraction patterns (a) and nitrogen adsorption isotherms performed at 77 K (b) for the encapsulated photocatalysts into zeolite Y.

Table 1 – Results of elemental analysis performed by ICP, and BET surface areas obtained by nitrogen adsorption isotherms performed at 77 K.

	TiO_2@Y	$(TiO_2)_2$@Y	USY	$(TiO_2)_2$@USY	mK-10	TiO_2@mK-10	$(TiO_2)_2$@mK-10
Ti (wt.%)	0.96	10.68	0.07	1.12	0.28	0.60	0.89
BET surface area (m^2 g^{-1})	311	25	558	519	269	264	259

3.2. Photocatalytic experiments

Table 2 presents the mass of each photocatalytic material used. The names of the experiments code the material tested and the area of the film. For example, the first test in Table 2 was made with PC500 titania in a film of 10 x 5 cm^2. In the case of the photocatalyst P25, three replicates were performed with different masses ("P25_10x5_exp1" and two following experiments). The masses of TiO_2 employed in powder pressed films were obtained by direct weighting, in the case of commercial photocatalysts, and were estimated, taking into account the amount of Ti exchanged, in the case of the encapsulated materials.

Figure 2 summarizes the NO conversions and ionic selectivities (taken at steady state). Experiments with paint films are denoted with the suffix "paint".

From Table 2 one can see that there is a relatively large variation in the photocatalytic masses from experiment to experiment, due to the associated difficulties on its control. However, experiments "P25_10x5_exp1", "P25_10x5_exp2" and "P25_10x5_exp3" show that for the mass range used this variable has little influence on the performance of the photocatalyst (cf. Fig. 2). Actually, the mass increments on these tests were achieved by increasing the thickness of the same film, meaning that there is a critical photocatalytic thickness beyond which no further improvements are achievable. The photocatalyst film effective area is, on the other hand, a very important variable. Figure 2 highlights this issue by comparison of experiments "P25_10x5_exp1" with "P25_6x5", which films have the same thickness but different areas; the later shows a NO conversion of 50 % vs. 80 % in the first one. Figure 2 puts into evidence that commercial titania samples provide, when used alone (pressed powder films) NO conversions above 50 %, except for the P25_6x5 film, due to the reasons just mentioned (smaller area). It is thus worth of noting that although the film area is the same as in the experiment where it is mechanically mixed with zeolite Y - "(P25 + Y)_15 wt.% TiO_2_6x5" (Table 2), the latter exhibits a similar NO conversion (Fig. 2), in spite of its much lower photocatalyst surface that is possibly exposed to radiation (as a consequence of a TiO_2 load of only 15 wt.%). This indicates that the adsorbent is playing a significant role on the photoactivity, an issue that needs however to be further investigated.

Regarding encapsulated materials, it is possible to see that the increase in the number of ion exchange cycles leads to better performances (Fig. 2). This can be related with either the increase in the Ti content of the samples (Table 1) or with the TiO_2 particles size (thus decreasing the so-called quantum size effect – blue shift) (Corma and García, 2004). Indeed, for zeolite Y only after a second exchange step some activity is noticed, which can be ascribed to the particle diameter increase leading to absorption of radiation in the wavelength range of the UV lamp used (> 300 nm), and being responsible for the structure destruction above-mentioned (Fig 1a). However, further investigation must be performed in order to confirm such fact. In general, performances reached with the encapsulated materials are quite low. Even so, it must be noticed the lower masses of TiO_2 per surface area of film when compared with the powder pressed films of commercial TiO_2 (Table 2). Comparing with the performance of paint films (with commercial TiO_2) it is possible to see that either the environment of the TiO_2 and/or the photocatalytic particle properties play an important role. Nevertheless, encapsulated materials are promising as long as one can still increase the Ti content (case of the mK-10 support) and the radiation absorption spectra by means of

sensitizing/doping.

Table 2 – Photocatalytic materials and estimated TiO_2's mass in each experiment.

		Powder pressed films		Paint films
	Experiment	**Mass of powder pressed (g)**	**Estimated mass of TiO_2 (g cm^{-2})**	**Estimated mass of TiO_2 (g cm^{-2})**
Commercial TiO_2	PC500_10x5	3.02	0.0604	0.0012
	UV100_10x5	3.29	0.0658	0.0012
	VLP7000_10x5	2.89	0.0578	0.0017
	AMT100_10x5	3.35	0.0670	0.0013
	P25_10x5_exp1	0.67	0.0134	0.0012
	P25_10x5_exp2	0.92	0.0184	n.p.
	P25_10x5_exp3	1.18	0.0236	n.p.

	TiO_2@Y_6x5	1.61	0.0010	n.p.
	$(TiO_2)_2$@USY_6x5	1.32	0.0010	n.p.
	$(TiO_2)_2$@mK-10_6x5	1.23	0.0007	n.p.
	TiO_2@mK-10_6x5	1.78	0.0007	n.p.

(n.p. – not-performed)

Paint films have lower photocatalytic activity than the corresponding powder films (Fig. 2). However it must be noticed the lower mass of TiO_2 per surface area exposed to the light. NO conversions were approximately 45-55 % and ionic selectivities around 40 % (with exception for paint films loaded with VLP7000 and AMT100, which originate ionic selectivities of only ca. 20 %). The performances reached with most paint films are worth mentioning, being thus promising for further studies.

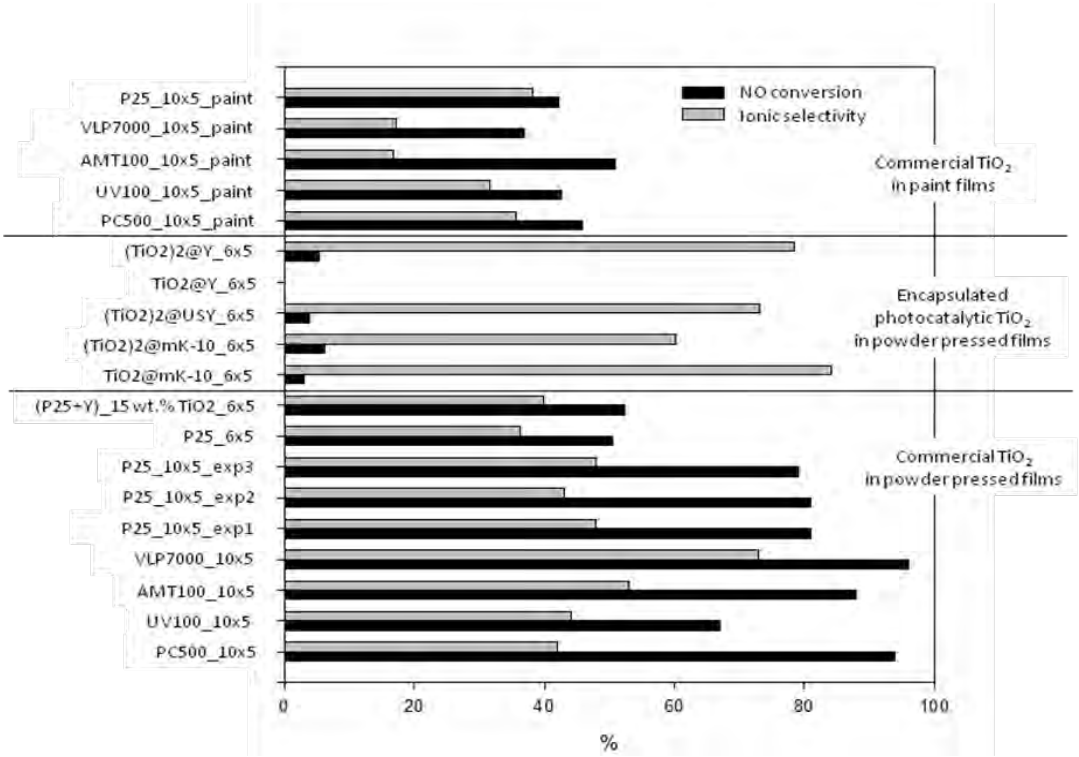

Figure 2 – NO conversion and ionic selectivity at steady state for all tested films of Table 2.

4. Conclusions

Among all the experiments performed, best NO conversions were obtained with powder pressed films of commercial TiO_2. The highest performance was achieved with VLP7000 from *Kronos* (96 %). Mixtures of commercial P25 with zeolite Y showed the same performance of a film with only P25, revealing the importance of the surroundings of the TiO_2 photocatalyst in its activity.

The mass content of TiO_2 in adsorbents, among other properties, seem to play an important role on the photo-activity. In this way, in future works efforts must be directed to analyse these properties and their correlation with the photo-activity.

Paint films produce a NO conversion of approximately 45 %, which is higher than the performance obtained with the encapsulated materials in powder pressed films.

Keywords: Simulated Moving Bed, Chromatography, Adsorption, Sustainable technology, Separations, Equipment development and Process intensification
Topic: Sustainable process-product development through green chemistry

Introduction

Nowadays, it is widely accepted that process innovation should be based not only on the challenges, problems, and needs but also on the social, political, and cultural conditions prevailing in the prospective market. Concepts such as Sustainability or Sustainable Development (Brundtland report [1]), the problematic of resources depletion and eco-efficient techniques have to be taken into account. The reduction or renouncement of organic solvents represents not only the trend of the so-called green chemistry but also a sustainable and environmentally friendly production of chemical products that accounts for the economical as security (social) aspects.

The use of continuous chromatographic counter current operation modes maximizes the mass transfer driving force, providing a better utilization of the adsorbent as solvent consumption than the traditional batch mode. Nevertheless, in this counter current operation (so-called TMB-True Moving Bed), it is necessary to circulate not only the fluid phase but also the solid. The solid motion has some disadvantages (attrition, lack of efficiency, fluid velocity limited by fluidization phenomena, etc.) and from a technical point of view, is not easy to implement. The solution to this major problem was first proposed through an inventive way by Broughton and Gerhold (1961) [2]; using simple fixed bed columns the solid movement is simulated by a synchronous shift of all inlet and outlet ports in the direction of the fluid flow. This simulated solid motion lead to the Simulated Moving Bed (SMB) concept firstly implemented by the UOP Inc, Figure 1.

Figure 1 - Schematic representation of a 4 columns SMB unit operating over a complete cycle, from 0 to $4t_s$ (with t_s representing the ports switch time); (a) period of the first switch; (b) period of the second switch and an equivalent 4 "columns length" TMB unit (c).

Until the 90s the major implementation of the SMB technology continued to be in the petrochemical separation field with more than 100 industrial plants. Nevertheless, the application of the SMB concept to HPLC chromatographic separations in the earlier 90s, led to the second "boom" on the SMB technology applied now to the fine chemistry separations [3].

This late demand on the SMB technique has been the cause and consequence of an also emergent interest in the study and research on this particular matter, leading to the formulation of quite singular/different operation modes since the original patent. Non conventional strategies as the introduction of non synchronous inlet/outlet shifts (the Varicol process [4,5]) or the variable flux with/or variable composition in the inlet/outlet streams (the PowerFeed process [6,7]) and Modicon ([8,9]), as well as the utilization of multiple feed or distributed feed (the Two Feeds SMB in [10,11]) and the Outlet Streams Swing (OSS) [11], have increased the potential of this technique for a vast range on binary the separation field.

The practical application of the so-called "non conventional modes of operation" in Simulated Moving Bed (SMB) units is per itself a challenge. Generally an SMB unit, industrial, pilot of laboratory-scale, is limited to one or two modes of operation and to implement a new operating mode is necessary to contact the supplier, do adjustments, even to reformulate the entire unit if not to acquire a new one. Therefore, flexibility is seen as one of the more relevant qualities for this kind of equipment [12], principally for laboratory-scale usage in technology demonstration stage, as for the separation low quantities in the fine chemical area, Figure 2.

Figure 2 – Positioning of the FlexSMB-LSRE® unit as pilot/lab scale unit in the "R&D flow sheet".

This aspect was the main reason that led to the design and construction of a 6 columns unit at LSRE, the FlexSMB-LSRE®, here by presented.

FlexSMB-LSRE – from theory to practice

As mentioned before, there is a considerable number of different operation techniques related with SMB, namely the asynchronous SMB, Modicon, Powerfeed, Multifeed, OSS, Pseudo SMB etc… Classified by: binary or multicomponent separation; the number of zones and number of rings etc… However, with the assemblage of new units the classification takes into account the number and type of valves and pumps, dead volumes fraction and principally its flexibility, i.e., its capacity of operating different modes with the same unit, and therefore to extend its own performance and operability.

In the FlexSMB-LSRE® unit it was chosen to operate with two SD (dead end slow path) valves per stream in the extract and raffinate current and one SD per stream in the feed and eluent/desorbent currents and a two way valve per column, Figure 3.

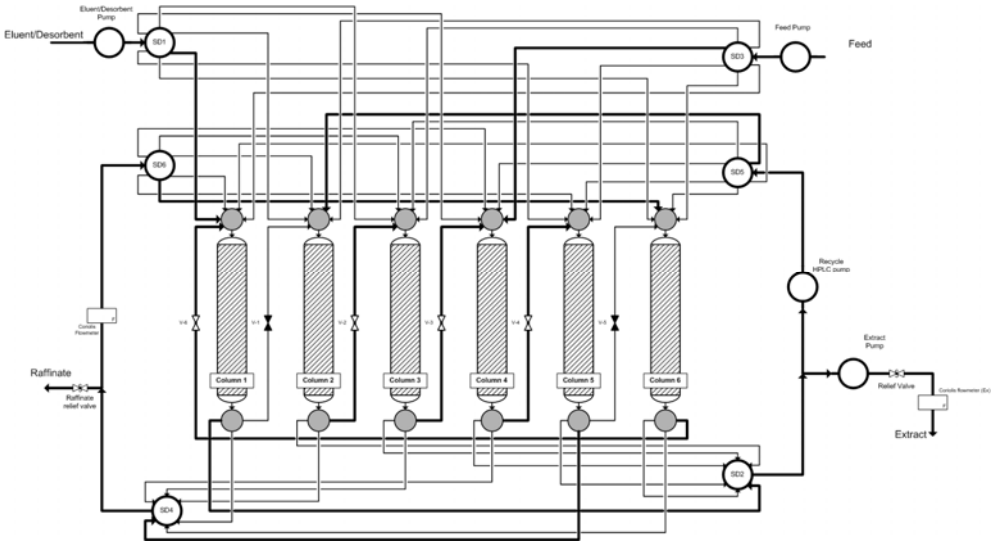

Figure 3 - Flexible SMB valves Scheme, during the first step, 6 columns operating a [1 2 2 1] classic SMB, bold lines the active connections, thick lines stagnated volumes.

It is possible to operate most of the different SMB modes, with simple adjustments and columns re-configuration. From Figure 3, it can be observed that stream from the zone I exit, in this case, from column 1, is fully withdrawn by valve SD2. Part of this stream leaves as the extract and the remaining is pumped to valve SD5 which returns the stream to the inlet of column 2. Similarly, valve SD4 withdraws the complete stream from column 5, splits part of it into the raffinate outlet and pumps the remaining to valve SD6 which returns the stream to the inlet of column 6. The inlet flows to column 1 by means of SD3 valve and the eluent/desorbent current with valve SD1. Each valve, each HPLC pump and flowmeter are computer controlled, and fully automated. The LabView platform was chosen for the automation and control of the FlexSMB-LSRE® unit, Figure 4.

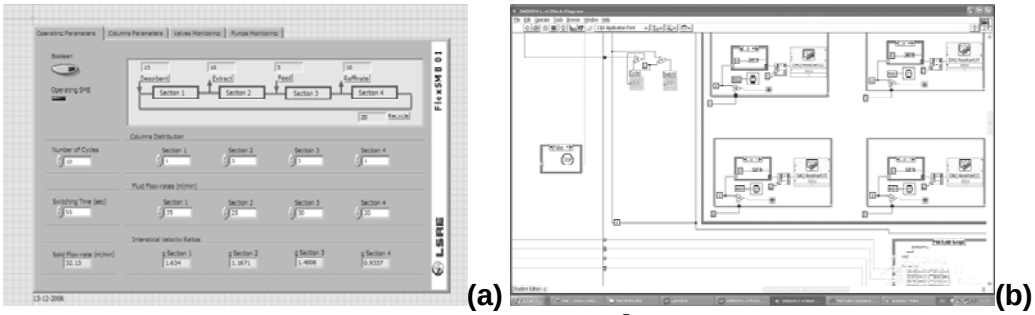

Figure 4 – LabView front Panel of the FlexSMB-LSRE® automation routines, (a) Operation Parameters, and (b) code.

The LabView automation routines are user friendly and also allow to acquire pressure as flow rate measurements for different streams in the SMB unit.

Test and Operation

An SMB unit is usually assembled with similar columns, and packing material, as the ones used in the batch systems. In this unit, 6 columns with 10.0 cm of length and diameter of 2.0 cm, in stainless steel were used. For each column a slurry of approx. 18.5 g of Chiral AD 20 μm in approx. 36 ml of 2-propanol was prepared (pure 2-propanol was chosen as slurry solvent taking into account its physical proprieties, namely its viscosity), and packed by means of an Analytical Slurry Packer from Alltech Associates Inc.

In the case of SMB operation, the main consequences associated with columns packing fluctuations remain in the heterogeneity of the retention factors and asymmetrical pressure drops. The columns should present similar retention factors for a given species. Therefore,

one Column (0) was tested for HETP (Height Equivalent to the Theoretical Plate) numbers, Figure 5, and for comparison, tracer experiments were performed to the remaining columns, Figure 6.

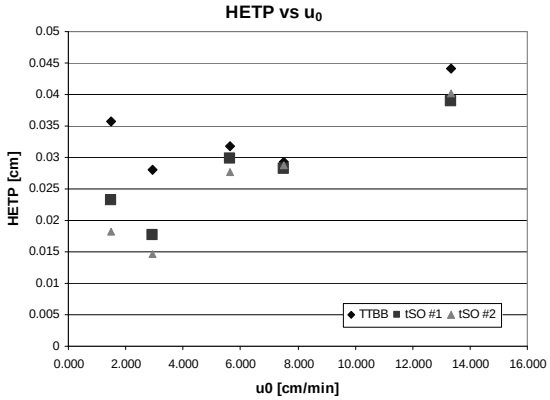

Figure 5 – HETP experiences for Column 0, (TTBB: 1,3,5 – TriTert ButyBenzol; TSO: Trans – Stilbene Oxide).

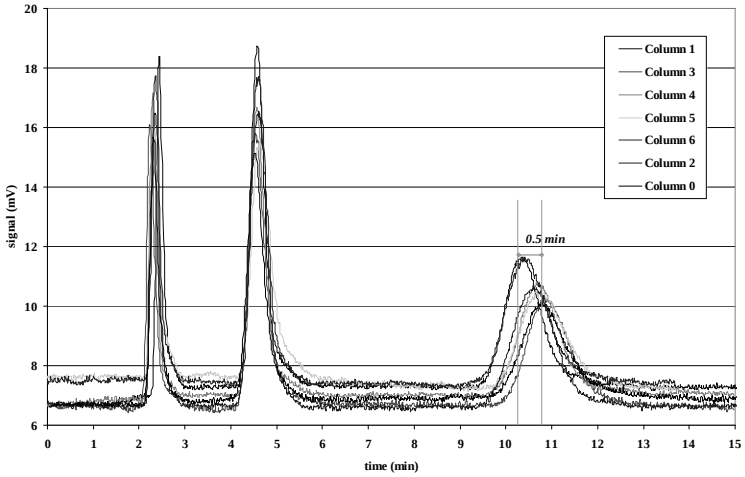

Figure 6 – Tracer experiences for the 7 columns, first peak TTBB, second and third the racemic mixture of TSO.

Then a first experiment was performed for the separation of a racemic mixture, (R,S)-α-Tetralol ((S,R)-(±)-1,2,3,4 Tetrahydro-1-naphthol) studied before by Zabka and Rodrigues [13-14], racemate concentration of 1.0 $g.l^{-1}$ in a heptane-2propanol solvent (95 %+5 % volumic fraccion, respectively), and the operating conditions as mentioned in Table 1.

Table 3 – FlexSMB-LSRE® operanting parameters.

SMB Operating Conditions	
C_R^F=0.50 $g.l^{-1}$;	C_S^F=0.5 $g.l^{-1}$
t_c=3.05 min;	
Q_{Eluent}=6.0 $ml.min^{-1}$;	$Q_{Extract}$=4.3 $ml.min^{-1}$;
Q_{Feed}=1.0 $ml.min^{-1}$;	$Q_{Raffinate}$=2.7 $ml.min^{-1}$;
Q_{IV}^*=23.0 $ml.min^{-1}$	

In the cyclic steady state (cycle 27) it was possible to obtain the following concentration profiles within the column, Figure 7.

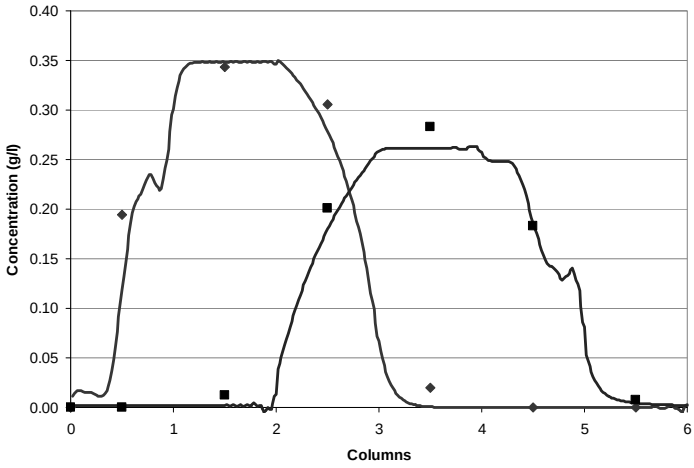

Figure 7 – Concentration profiles obtained from cycle 24 to 28, diamonds R tetralol and squares the S tetralol, lines the theoretical profiles obtained from a dead volumes approach.

And the concentration of each enantiomers in the respective outlet current, as shown in Figure 8.

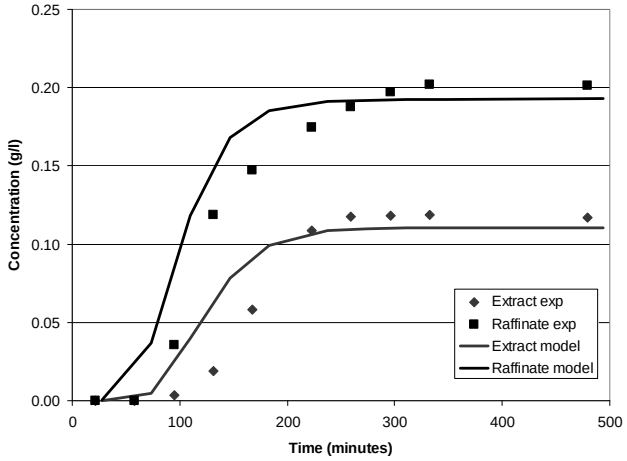

Figure 8 – History of the average concentration on more retained product on the extract and the less retained species in the raffinate current over a cycle, namely, cycle: 2; 4; 6; 8; 10; 13; 15; 17; 19; 27, each pure, diamonds R tetralol and squares the S tetralol, lines the theoretical profiles obtained from a dead volumes approach.

Taking into account of the major objectives of this unit, its flexibility, it was developed the asynchronous SMB mode of operation for the inner columns, i.e., section 2 and 3 with variable number of columns per switch. This routine has been tested and will soon be implemented for a racemic mixture separation.

Conclusion

Throughout the years LSRE developed a considerable know how related with design, simulation and optimization of Simulated Moving Bed units for petrochemical, and specially, fine chemical separation and reaction fields. These skills were now complemented with the full design and construction of a flexible SMB unit, able to operate most of the non conventional SMB modes. Years of intangible assets can now be put into practice.

This unit was already tested for a classic SMB separation for a racemic mixture of (R,S)-α-Tetralol, in columns packed with Chiral AD 20 μm, and operated for asynchronous SMB. The tests to different separations will now continue demonstrating all the potential of this Flexible Unit.

Keywords: Advanced control; anaerobic digestion; cascade control; multi-objective control.
Topic: Systematic methods and tools for managing the complexity — Process control & operations.

Abstract

A new multi-objective control strategy based on volatile fatty acids (VFA) and methane flow rate (Q_{CH4}) is derived for an Upflow Sludge Bed-Filter (USBF) reactor, which is used for the anaerobic treatment of industrial wine distillery wastewater. The approach presented here is novel in the sense that (i) considers two operational objectives, the control on the effluent quality and the control on the maximum production rate of methane; (ii) takes advantage of the difference between the dynamics of the liquid and gas phase, using variables of both phases. The control system includes a cascade controller with a reference signal for methane flow rate. The control system computes the feed flow rate for adjusting the organic load applied to the reactor. The performance of the proposed control scheme is illustrated via numerical simulations and parameter optimization with the Anaerobic Digestion Model no.1 (ADM1) respect of influent perturbations.

1 Introduction

Anaerobic digestion processes consist of a set of conversions of organic matter into methane and carbon dioxide, occurring in absence of oxygen. The use of methane as an energy source, the low growth of sludge and its ability to treating wastewater with medium to high organic loads are some of the reasons that contributed to increase the popularity of anaerobic wastewater treatment (AWT) in the last few decades. However, the AWT has classically been regarded as a difficult process to be controlled and managed. In this sense, the ideal control system must fulfill different characteristics for assuring altogether: (a) high quality of effluent; (b) maximum methane production; (c) general stability criterion; and (d) applicability to different types of wastewaters.

In the literature different process variables and promising controllers have been proposed using different control schemes and techniques. In this sense, the advances in the development and increasing availability of the on-line sensors (Vanrolleghem & Lee, 2003; Spanjers & van Lier, 2006) together with a better knowledge of involved biological phenomena (Batstone et al., 2002) allowed to design new controllers in the last years. Recently, in the European project TELEMAC (Bernard, 2005) a number of controllers for anaerobic wastewater treatment were developed. However, they only consider effluent quality as an operational criterion. Other controllers (Steyer et al., 1999; Liu et al., 2004) were designed to achieve the maximum organic loading rate and the greater production of methane.

In this contribution, a new robust multi-objective controller is derived for an Upflow Sludge Bed-Filter (USBF) reactor. The approach is novel in the sense that considers the main operational criteria in the same control structure. Moreover, this controller takes advantage of

* Corresponding author. Tel +34 981-563100 Ext.: 16742. E-mail:carlos.garcia.dieguez@usc.es

the difference in the dynamics of the liquid phase and the gas phase through a cascade structure with a reference signal.

2 Model description and problem statement

2.1. *IWA Anaerobic Digestion Model no. 1 (ADM1)*

ADM1 (Batstone et al., 2002) is a complex model of the multistep anaerobic process transformations. This tool is adequate for predictions of enough accuracy to be useful in process development, optimization, and control. It is a standard benchmark for developing operational strategies and evaluating controllers (Batstone & Steyer, 2007). ADM1 incorporates processes such as hydrolysis of particulates, acidogenesis, acetogenesis, and methanogenesis, and it includes 26 dynamic state concentration variables, 19 biochemical kinetic processes, 3 gas-liquid transfer kinetic processes, and 8 implicit algebraic variables per liquid vessel. A modified version of the ADM1 incorporating ethanol degradation pathways and calibrated for a USBF reactor (Ruiz-Filippi et al., 2004) was used. In the modified version used, an additional group of ethanol degraders was included as well as a new state variable for ethanol. The extension for ethanol not only considers the hydrogen and acetate pathways but also takes into account other controller design volatile fatty acids (VFA) pathways (propionate and butyrate) by means of the stoichiometry. Thus, VFAs are suitably predicted, including overloads or transitions between steady states.

2.2. *Controller Objectives*

Many authors had used Haldane kinetic model for describing the behavior of the anaerobic digesters (Bastin & Dochain, 1990). In this case, Haldane model supplies a simple way to explain the controller objectives as well. Haldane kinetics has an obvious wash-out equilibrium point and two operational equilibrium points that have different dynamical properties in terms of stability. The latter two equilibrium points enable to distinguish two regions, a stable region and an unstable region (Figure 1). A controller always must keep the AWT system in the stable region; this is the main objective of any controller for AWT plants. Additionally other objectives can be established. In general, the biological wastewater treatment attempts decompose the organic compounds contained into the wastewater and fulfill with the environmental regulations. However, in the case of AWT other objective could be the maximum recovery of energy in methane form.

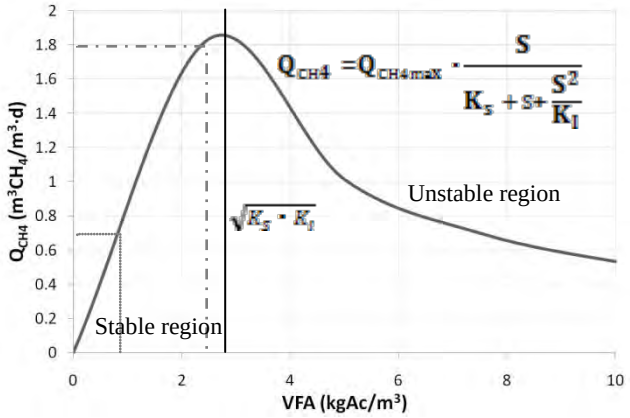

Figure 1. Haldane kinetic for an anaerobic digester. (- - -) Operational point with objective methane flow rate. (.....) Operational point with objective fulfill environmental regulation.

Therefore, the development of a controller able to integrate both objectives and provide a robust regulation of the process in a same single structure is of great interest for such wastewater treatment systems. Different control structures could be considered for this task, however a cascade framework was preferred in this case.

3 Controller design

3.1. *Selection of control variables*

Different combinations of variables were studied for establishing the most appropriate combination of them that permit the best control regulation in a cascade structure. When two variables for process state identifications are considered for winery wastewater, there are several combinations of pairs of these variables that accomplish complete classification of states (Castellano et al., 2007). A similar behavior had been observed with other types of wastewaters using experimental data and the same statistical technique. Variables in the liquid phase are supposed to present higher response times than the gas phase variables. Therefore, with this criterion an inner control loop with a secondary variable in the liquid phase doesn't seem to be the most appropriate. In addition with the same criterion, a combination between variables in the gas and in the liquid phase will allow us take advantage of the difference between the dynamics of both phases. Taking into account the above, a variable of the liquid phase, due to its slower response, should be used as a control variable in the external loop, and against a variable in the gas phase, which has a rapid response, should be used as a control variable in the inner loop. From the point of view of technical, economical and dynamical criteria, we decided flow rate of methane (Q_{CH4}) as inner-loop variable because a combination between this variable together with volatile fatty acids (VFA) allow us to detect a situation of imbalance in the AWT process. Furthermore; Q_{CH4} has a better relationship with the objective of maximize the methane production and the VFA with the environmental regulations. Currently, VFA can be determined by means of titrimetric methods to relatively low cost, per example with the AnaSense® analyzer (Ruiz-Filippi et al., 2005). In addition, accumulation of VFA can be very dangerous for the biological and structural stability to long-term of the anaerobic sludge.

3.2. *Methane productivity – Inner control loop*

The scheme of methane productivity control mode is depicted in Figure 2. This is an auto-setting controller system, having a methane reference signal (Q_{CH4} reference). Note that Q_{CH4} reference provides the set-point to the inner controller. The inner controller was implemented as PID controller. After a parameter adjustment, the conclusion is that integral and derivative terms are negligible. Therefore the equation of this controller can be expressed as: $Q(t) = Q_0 + K_p\ \Delta Q_{CH4}(t)$, where Q is the feed flow rate of the reactor or controller output, Q_0 is the controller output bias, K_P is the proportional gain, and ΔQ_{CH4} is the error between the Q_{CH4} actual value and the reference signal. We considered sampling interval of 15 min for the methane flowrate (Q_{CH4}) and the same interval of time for controller actions. This time is appropriate taking into account the scale of industrial anaerobic bioreactors and the slow dynamic of this process.

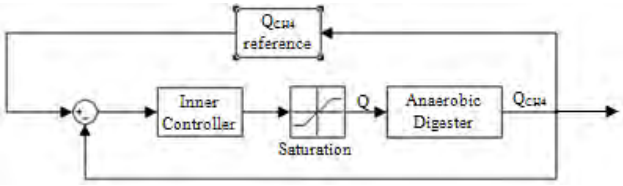

Figure 2. Block diagram of the methane productivity controller (inner-loop).

The controller operating in this mode was designed to maintain the process near to the maximum methane production ($Q_{CH4\ max}$) and push the system to higher OLR values, still avoiding overload and unstable operations.

3.3. *Tracking methane reference*

The methane reference signal (Q_{CH4} reference) is established in function of the chemical oxygen demand in the influent (COD_{in}) through an empirical correlation. The correlation is different for each control objective. It is obtained in this case by means of simulations. In the case of cascade controller, the simulations consist in optimize in pseudo steady-state the methane feed flow rate for different concentrations of COD_{in} that accomplished the

requirement of spillage (150 mg Ac/l). And in the case of inner loop controller, the simulation consist in obtain the maximum methane flow rate vs COD_{in}.

For a future closep-loop implementation in a pilot plant, a neuro-fuzzy system, that combines the advantages of artificial neural networks (ANN) and fuzzy inference system (FIS), was development in order to estimate COD_{in} (not measured in the plant). Any other technique of observation could be implemented for obtain this variable. Normally, COD_{in} presents high frequency noise, therefore in closep-loop implementation could be very useful the use of dead bands.

3.4. *Effluent quality control – cascade scheme*

A single-loop provides good performance when the dynamics are fast, the fraction dead time is small and disturbances are small and slow, like in the case of methane productivity controller. However, a single-loop for controlling VFA is insufficient because it lacks the characteristics described before. In this case a control cascade structure presents itself as an alternative. The cascade structure proposed for this task is shown in Figure 3.

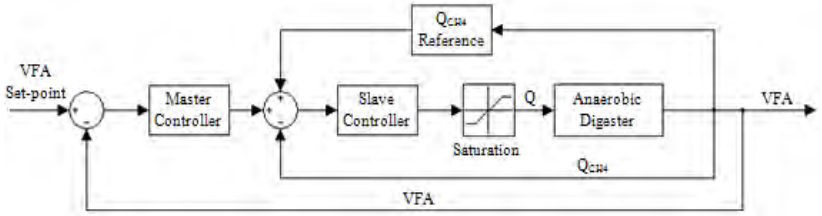

Figure 3. Block diagram of the cascade controller. Note that QCH4 reference signal provides the set-point to the inner controller and modifies this one in the cascade scheme.

Some considerations must be taken into account on this controller:

Assumption 1. The process behavior is linear in a range of values close to the set-point. This is more or less true while not occur inhibition episodes.

Assumption 2. The inlet compositions are piecewise constant, bounded and uncertain functions (organic load disturbances).

Assumption 3. The feed flow rate (Q) is constrained by a saturation function (according to physical restrictions on manipulated variable). Clearly, the minimum feed flow rate ($\underline{Q}$) is zero and the maximum feed flow rate ($\overline{Q}$) was established using the criterion of minimum hydraulic retention time (HRT) of 9 hours for prevent undesired wash-out of biomass.

$$sat(Q) = \begin{cases} \overline{Q}, & Q \geq \overline{Q} \\ Q, & \underline{Q} < Q < \overline{Q} \\ \underline{Q}, & \leq \underline{Q} \end{cases}$$

Furthermore, the speed with which increases or decreases the feed flow rate (ΔQ) was limited to 0.5 l/h each 15 minutes.

4 Results and discussion

4.1. *Optimization of the parameters*

In order to improve the controller settings, a tuning by means parameter optimization was computed using ADM1. The optimization of the controller parameters was made using a multiobjective optimization function “fminimax” in Matlab®. This function uses a sequential quadratic programming (SQP) method.

The parameters turned out to be very similar for the range of concentration studied, from 7 to 16 g/l in the CODin. This range is characteristic of this type of wastewater (wastewater containing ethanol).

Parameters	Slave	Master
K_c	0.0172	0,38
K_I	$7.2 \cdot 10^{-7}$	0
K_d	0,0006	0

Table 1. Parameters of the controllers

4.1. *Validation using ADM1*

The developed cascade controller system was tested using data generated by simulation with the modified ADM1, previously commented, under different operational situations: automatic restart-up, after short stops; organic overloads and organic underloads. In the Figure 4 the different simulations are shown. The initial conditions for the simulations were obtained for a medium value of OLR during a large period of time in order to ensure that a steady state was reached.

Restart-up of AWT plants after a short stop is often carried out in industrial applications. Automatic control systems can help to minimize the period for restarting the AWT plants. The cascade controller (see Figure 4a) restart-up the AWT plant in 3 days with a very small initial value for feed flow rate (5 l/h) and a COD_{in} of 10 g/l. However, the wished set-point was achieved in only two days.

As it can be seen in Figure 4b, the controller was able to maintaining stable the process after of a severe increment of COD_{in}, from 10 g/l to 15 g/l (50% of increment in the organic load). In a similar way, the controller responds to a decrease of a 30% in the organic load increasing the feed flow rate and handles accurately the organic underload. These perturbations without automatic control would cause a failure in the treatment system. In these cases a minimum variation of the volatile fatty acids was detected. In all the cases, the pH was kept stable near a neutral value and the IA/TA ratio was lower than 0.2, an adequate value lower than the 0.3 recommended limit value (results not shown here).

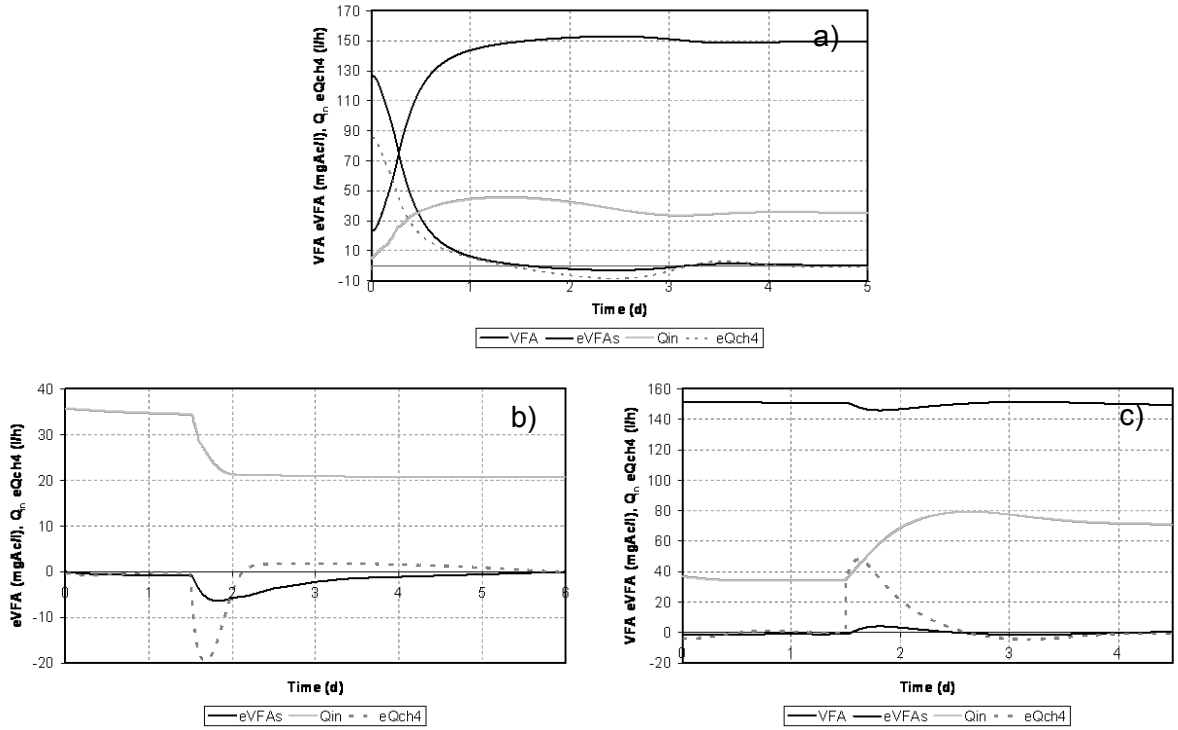

Figure 4. Simulations with ADM1. a) Restart-up, b) Organic overload, c) Organic underload.

Other few authors have successfully used cascade configurations for controlling anaerobic digesters. Alvarez-Ramirez et al. (2002) have shown that direct feedback control using linear controllers in a cascade configuration has potential application for optimal operation of AWT

plants. However, these authors used VFA and COD as process variables, both variables belong to the liquid phase which would delay the response of the controller system. Another interesting application in cascade for the monitoring of pH and biogas flow rate was developed by Liu et al. (2004). In this case good control performances were achieved in closed-loop during operation in a lab scale digester. Nevertheless, the quality of the effluent was not taking into account. Moreover, we consider that the pH in the inner loop is not a variable that allows us to act with fast enough, if there is not a good control on the addition of alkalinity especially in a full scale reactor.

5 Conclusions

In this paper, a new multi-objective cascade control for regulating anaerobic wastewater treatment was developed, optimized and validated by simulations carry out with an ADM1 virtual plant. This controller provided good performance against severe perturbations, supplying an adequate control action to achieve the desired set point as well as to manage sudden changes in the influent, and it is able to restart-up the AWT plant in a short period of time.

The relatively low cost of the measurement devices required, makes this controller very interesting for industrial application. Further closed-loop tests in a pilot plant are needed to assure the controller robustness in an industrial environment.

Topic: Advancing the chemical engineering fundamentals — Catalysis & reaction Engineering.

Abstract

The Fenton process is an adequate oxidation treatment for the partial-abatement of industrial effluents contaminated with organic pollutants, such as phenol, which are refractory towards biological treatments. The efficiency of the Fenton process depends on the wastewater composition as well as on the oxidation conditions, but also on the presence of other compounds, e.g. surfactants, that can interfere the oxidation. In this study, the effect of the oxidation conditions (catalyst and oxidant concentrations) is presented for phenolic wastewater in presence of an anionic surfactant. The results show that, selecting the appropriate amounts of catalyst and oxidant (40 mg/L and 12500 mg/L, respectively), the process is able to almost totally degrade phenol and phenol+anionic surfactant (sodium dodecylsulfate) solutions. The study also demonstrates that, when dealing with phenol+surfactant solutions, the efficiency of the process is decreased at low catalyst concentration. In addition, an increase of the surfactant concentration up to its critical micelar concentration causes a decrease of the phenol conversion. However, a further surfactant concentration increase does not change the phenol elimination achieved. It is believed that the morphology of the surfactant present in the polluted solutions has a crucial role on the degradation of phenol as it hosts phenol molecules in the interior of the micelles, worsening the interactions between the OH• radicals produced in the bulk phase by the Fenton's reaction and the phenol molecules, thus decreasing the degradation obtained.

1 Introduction

Chemical process industry produces large amounts of polluted waters which need to be treated before being released to the nature or re-used. Typically, biological treatments are preferred as they achieve adequate abatement of organic compounds at low cost. Nevertheless, many organic contaminants, such as phenol, are refractory to biological treatments. Thus, phenolic effluents cannot be directly treated in a conventional municipal wastewater treatment plant. In such a case, an effective pre-treatment step has to be applied prior to the biological treatment. Anyway, it is not appropriated to totally destroy the biorefractory organic contaminants because the associated cost would be unacceptably high. Hence, an effluent needs to be treated just for providing enough biodegradability to allow the subsequent biological treatment to successfully perform.

Physical methods, such as adsorption (Mukherjee et al., 2007), nanofiltration (Van der Bruggen et al., 1999), emulsion liquid membranes (Park et al., 2006) among many others can be employed as effective pre-treatments for removing phenol from wastewaters.

* Corresponding author. Tel + 34 977559646. E-mail:jose.font@urv.cat

However, physical methods only transfer the organic contaminant from one effluent to a secondary liquid or solid waste. In addition, physical methods often need regeneration or cleaning cycles. Thus, the environmental problem still remains after the physical methods.

Chemical pre-treatments, such as oxidation processes, are being designed for achieving a partial mineralisation of phenolic compounds. The biodegradability of the partially-treated effluent can be controlled as the formed oxidation intermediates and their concentrations depend on the operating conditions. Thus, the pair oxidation-biological treatment is an attractive and feasible option for dealing with phenolic effluents (Suárez-Ojeda et al., 2007).

Advanced Oxidation Processes (AOP's) are a group of chemical pre-treatments whose common characteristic is that a very powerful and non-selective radical, the hydroxyl radical (OH•), is formed. Among them, Fenton process is able to effectively degrade phenolic compounds at room temperature and atmospheric pressure (Chamarro et al., 2001) using the well-known Fenton liquor, i.e. ferrous ions (soluble salts) and hydrogen peroxide. The fast interaction between these two species leads to the formation of hydroxyl radicals, which then attack organic contaminants at different extent.

The Fenton process has also been used for the partial treatment of other organic pollutants such as dyes (Lodha and Chaudhari, 2007), chelating agents (Ghiselli et al., 2004), pharmaceuticals (Esplugas et al., 2007) and so on. However, no attention has been paid in the effect of the presence of a secondary organic product on the degradation efficiency of an easy-to-degrade organic contaminant, such as phenol.

The aim of this work is to study the effect of an anionic surfactant (sodium dodecylsulfate, SDS) on the degradation of phenol by the Fenton process. In all the tests, carried out in a batch reactor, the initial concentration of phenol was 2500 mg/L and the solution pH was not adjusted. The effect of the catalyst and the oxidant concentration on the degradation of phenol was explored in both absence and presence of SDS. As surfactants are molecules having a hydrophobic head and a hydrophilic tail, they group forming micelles above its critical micelar concentration (cmc). All the experiments showing the effect of the catalyst and the oxidant concentration in presence of SDS were performed at a SDS concentration equal to its cmc. On the other hand, to test the effect of the morphology of the SDS (micelar or monomeric form), experiments at several SDS concentrations (from 577 to 3170 mg/L) were also conducted.

2 Materials and methods

The oxidation experiments were conducted in batch mode in a 500-mL jacketed glass reactor. The reactor was stirred at 300 rpm with a magnetic stirrer (Selecta, model Agimatic REV-S). All the experiments were performed at 30 ºC, controlled by means of a thermostatic bath (Haake S, model Fisous). A typical experiment started by placing in the reactor 250 mL of solution containing phenol (phenol crystallised; Panreac, purity 99%) and iron sulfate (iron sulfate heptahydrate (Riedel de-Haën, purity 99%) at the desired concentration. In the experiments where the effect of the presence of SDS on the phenol conversion had to be tested, SDS (sodium dodecylsulfate; Fluka, purity 96%) was also dissolved in the solution together with the phenol and iron sulfate. After this, 10-mL sample were withdrawn and kept in the fridge for further iron analysis (Atomic absorption spectrometry; Perkin Elmer, model 3110) and phenol (HPLC; Agilent Technologies, model 1100). The details of the used HPLC method can be found elsewhere (Suárez-Ojeda et al., 2005). Then, the stirring and the thermostatic bath were switched on and when the reactor temperature was 30 ºC, the desired amount of hydrogen peroxide (hydrogen peroxide 30% w./v.; Panreac) was added. At this point, the Fenton's reaction started. Several samples (5 mL each) were periodically withdrawn from the reactor and stored in glass vials containing 100 μL of NaOH 6N. The basification of the samples was done in order to instantaneously stop the Fenton's reaction in the vials. The samples were stored in the fridge for at least 24 h. Then, samples were

centrifuged (Ortodiresa, model Digicen 20) at 10000 rpm for 10 min. Phenol was analysed as the initial solution.

3 Results

3.1 Hydrogen peroxide concentration and SDS presence effects

In this section, the effect of the oxidant (hydrogen peroxide) and catalyst (iron sulfate) concentrations on the phenol conversion is presented. The initial concentrations of phenol and SDS (when present) were 2500 mg/L and 2307 mg/L (equal to cmc), respectively. The catalyst concentration was constant and equal to 7.0 mg/L in this set of experiments. The hydrogen peroxide concentration ranged between 2500 and 15000 mg/L. These hydrogen peroxide concentrations represent 0.2 and 1.2 times the theoretical stoichiometric amount of hydrogen peroxide needed to totally mineralize 2500 mg/L of phenol. Figure 1 shows the effect of the oxidant concentration on the phenol conversion both in absence and presence of SDS.

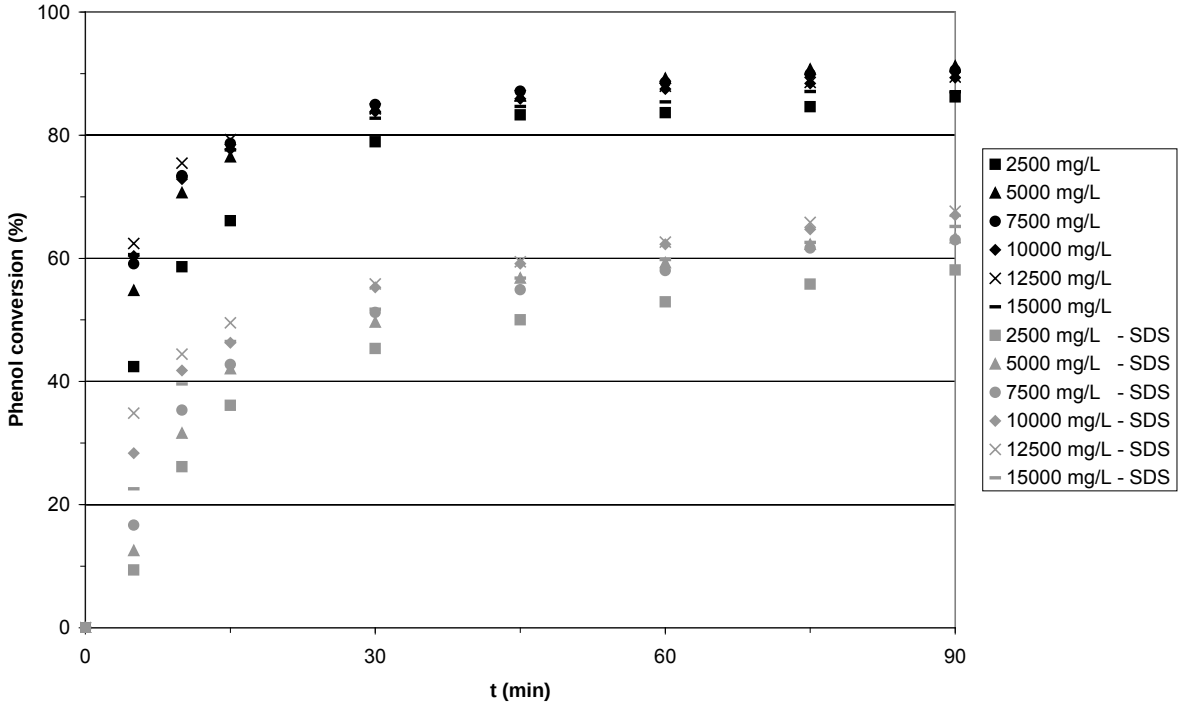

Figure 1. Effect of the oxidant concentration on the phenol conversion in absence (black symbols) and presence (grey symbols) of SDS. 2500 mg/L phenol; 7 mg/L Fe (II); 2307 mg/L SDS (when present).

As it can be seen, when no SDS was present, an increase in the oxidant concentration did not cause an important enhancement on the phenol conversion. Even when increasing the oxidant concentration beyond 12500 mg/L the phenol conversion decreased. This effect could be caused by its possible self-consumption at high concentrations, as previously reported (Cobra Guimaraes et al., 2008). At the same oxidation conditions but with the presence of SDS at its cmc, the phenol conversions decreased by a 20% compared to those obtained when no SDS was present. This may indicate that surfactant molecules are also attacked by the hydroxyl radicals. However, it could also occur that, as SDS micelles host phenol molecules due to their hydrophobic internal nature, it may be more difficult for OH• radicals to arrive to the interior of the micelles and attack the phenol molecules. It is worth mentioning that both possibilities may occur, decreasing the phenol conversion.

3.2 Iron (II) concentration and SDS presence effects

As with hydrogen peroxide, iron (II) concentration may have a strong effect on the phenol conversion as it is involved in the production of OH• radicals from the oxidant. Thus, in this section, the effect of the catalyst concentration on the phenol conversion is presented. As in the section 3.1, the effect of the presence of SDS is tested at a concentration equal to its cmc. The hydrogen peroxide concentration in these experiments was 12500 mg/L. Figure 2 shows the phenol conversion after 90 min of treatment as function of the iron concentration. As shown in Figure 2, the presence of SDS decreases the achieved phenol conversion at low iron concentrations. These results can be explained by the difficulty for the hydroxyl radicals to arrive to the micelar interior and/or the codegradation of SDS micelles, as when exploring the effect of the oxidant concentration.

As it can be deducted from Figure 2, the iron content has an important effect on the phenol conversion as an almost complete oxidation of phenol of almost 100% can be attained at high catalyst doses, both in absence and presence of SDS at its cmc. It is important to note that an almost complete degradation does not mean a total mineralisation of the effluent as oxidation intermediates may appear in the effluent from the Fenton process. These results could indicate that as the concentration of catalyst increases, the amount of produced OH• radicals may increase, causing a higher degradation of SDS molecules. This would release the phenol molecules from the micelles, enhancing the phenol degradation. Besides, it could also occur that, as the amount of OH• radicals is higher at elevate Fe concentrations, there are more OH• radicals available, which cross the micelles and attack the phenol molecules inside the micelles. As aforesaid, both possibilities could occur at the same time.

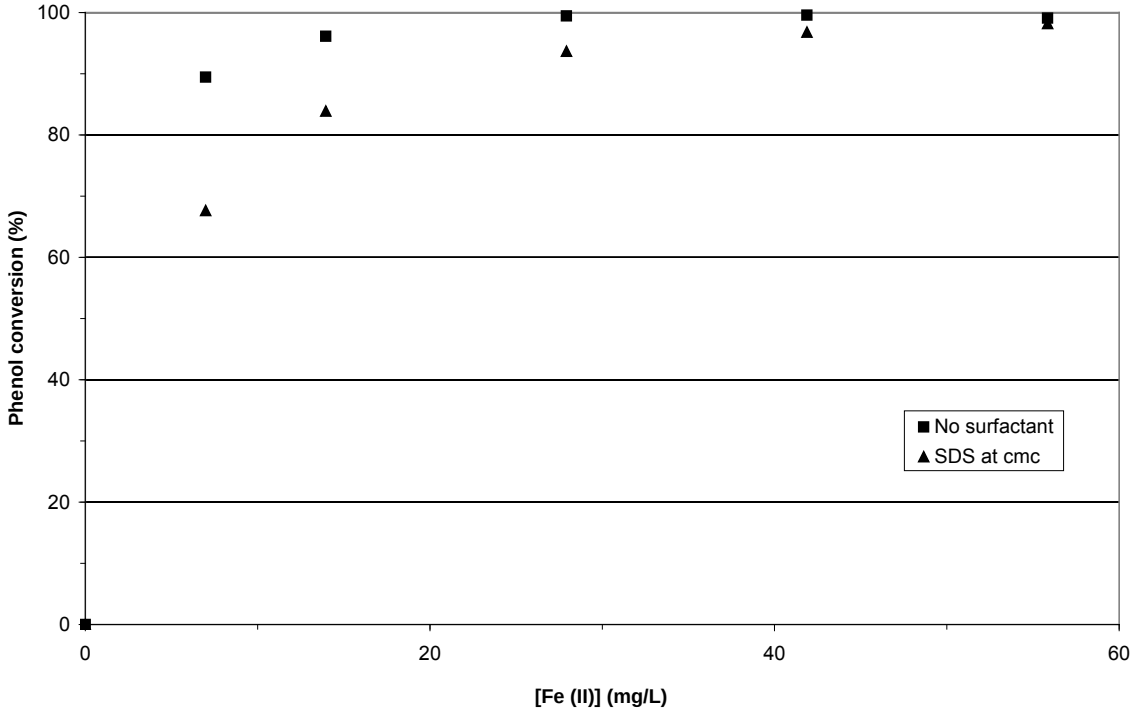

Figure 2. Effect of the iron concentration on the phenol conversion in the absence/presence of SDS at its cmc after 90 min. 2500 mg/L phenol; 12500 mg/L H_2O_2; 2307 mg/L SDS (when present).

3.3 SDS morphology effect

The effect of the SDS concentration on the phenol conversion is discussed in this section as it can affect both on its degradation as well as on that of the phenol. The iron and hydrogen peroxide concentrations in these experiments were 7 and 12500 mg/L, respectively. Figure 3

shows the effect of the SDS concentration on the phenol conversion along the time. As it can be observed, an increase of the SDS concentration, up to its cmc (2307 mg/L), results in a phenol conversion decrease. However, any further increase on the SDS beyond its cmc does not change the phenol conversion. Thus, it is clear that the morphology of the surfactant molecules plays a key role on the phenol degradation efficiency. As the oxidation conditions (iron and hydrogen peroxide concentrations) remain unchanged in the experiments of this section, the amount of produced OH• radicals is assumed to be the same in all cases. Thus, any increase on the SDS concentration would result in higher SDS degradation (if occurring), therefore in a lower phenol degradation, if the degradation of SDS is seen as a parallel reaction competing for the radicals. As the results do not show this tendency, it can be deducted that the decrease on the phenol conversion when SDS is present in solution is mainly due to the fact that phenol molecules are hosted in the interior of surfactant micelles, decreasing their availability to be oxidised by the OH• radicals produced in the bulk solution.

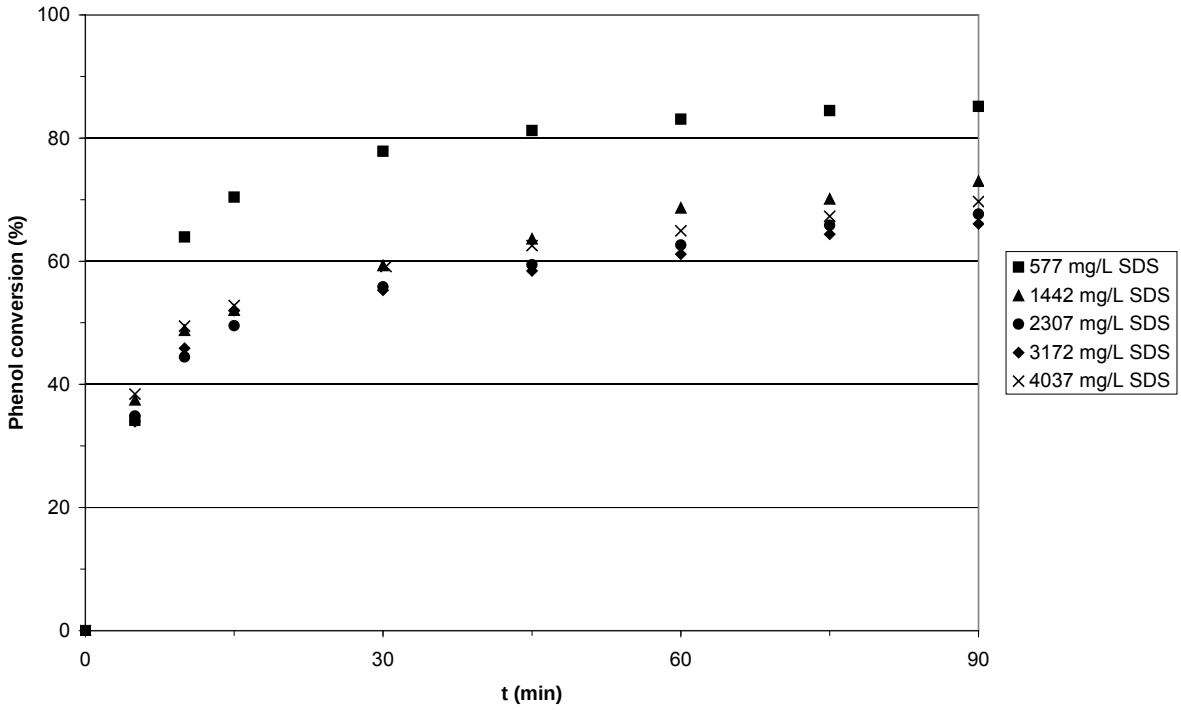

Figure 3. Effect of the SDS concentration on the phenol conversion. 2500 mg/L phenol; 12500 mg/L H_2O_2; 7 mg/L Fe (II).

4 Conclusions

The Fenton process is an adequate oxidation process for dealing with aqueous phenol solutions. However, at the same oxidation conditions, when SDS is present in the phenolic solution, the phenol conversion is lower at low iron (II) concentrations (below around 40 mg/L) than when no SDS is present in the solutions to be treated. Nevertheless, increasing the Fe (II) concentration, an almost complete oxidation of the phenol can be achieved even when SDS is present in the polluted solution at a concentration equal to its cmc. The effect of the concentration of hydrogen peroxide is not a crucial parameter as it does not enhance the oxidation efficiency at the tested conditions. On the contrary, when working at high oxidant concentrations, the phenol conversion decreases (in absence/presence of SDS) owing to its self-consumption.

A possible codegradation of the SDS molecules as well as the fact that phenol molecules are hosted in the SDS micelles interior, thus decreasing their availability to be attacked by the hydroxyl radicals involved in the process, may be the reason of the decrease of phenol

degradation when SDS is present at its cmc concentration. The results obtained at variable SDS concentrations demonstrate that the morphology of the SDS in solution is crucial for the decrease of the oxidation efficiency. At SDS concentrations lower than the cmc, an increase on the SDS concentration causes a decrease on the phenol conversion. However, beyond the cmc, any further increase on the SDS concentration does not render any change on the phenol conversion. These experimental findings seem to indicate that the main phenomenon responsible of the phenol conversion decrease is the presence of SDS in micelar form. These micelles host phenol molecules in their interior, which are more difficult to be attacked by the OH• radicals produced in the bulk solution. Although the previous hypothesis seems to be the most likely for describing the presented results, a possible codegradation of the SDS cannot be completely rejected as the OH• radicals involved in the Fenton's reaction are non-selective radicals and might also attack the SDS molecules.

Topic: Sustainable process-product development through green chemistry (Sustainable & clean technologies).

Introduction

The impact of pesticides on the quality of groundwaters has been subject of scientific and public health concerns in the entire planet, especially in the areas where groundwaters are mainly used for human consumption. The intensive use of pesticides in agriculture and the high persistence of several of these chemicals has required a rigorous control of possible environmental contaminations, especially of drinking water sources.

Atrazine (2-chlorine-4-etil-6-isopropil-1,3,5-triazin), is a herbicide that is still used extensively in Brazilian agriculture, specifically for corn, cotton, sorghum and sugar-cane. It is one of the largest pollutants of groundwater in many countries (Dörfler et al., 1997) and was selected for study because of its widespread use.

Atrazine is frequently detected in natural waters, and has been known to affect reproduction of aquatic flora and fauna, which in turn impacts on the community structure as a whole (Graymore et al., 2001).

The *in situ* chemical oxidation technology uses chemical oxidants that directly destroy dissolved contaminants in a subsurface medium. Because the process is *in situ*, no surface treatment system for the contaminants is needed and there is no treated groundwater to be discharged.

Ozone is a powerful oxidant (e^0 = 1,51 V *vs* Standard Hydrogen Electrode Potential) that does not produce toxic byproducts when decomposed and has been used in degradation of organic compounds present in soils and aquifers.

The technology of permeable reactive barriers (PRBs) is one of the remediation alternatives of greater acceptance. This technique has some advantages, such as: it is an *in situ* method; it is adequate to treat persistent pollutants in aquifers; it does not produce important physical and chemical alterations to the ground.

A new technology uses groups of electrodes as active reactive medium of the PRB to treat contaminated underground waters (e-barriers) (Wani et al., 2006). This technology can be used in situ in combination with the advanced chemical oxidation technology for the treatment of pollutants. An oxidant (ozone) is electrochemically produced in one of the electrodes that is part of the electrochemical barrier. Pollutants of interest would be transformed by the generated ozone instead of directly on the surface of the electrode. This creates an in situ degradation system constituted by an electrochemical cell that generates an oxidant substance which will transform the pollutants present in underground waters.

A study on the evaluation of the effectiveness, in a laboratory scale, of this in situ new treatment technique for atrazine was conducted. The work is divided in three main stages: 1) electrochemical ozone production in an electrochemical cell at different values of applied current as well as the determination of the dissolved ozone

concentration; 2) degradation of the atrazine in aqueous solution in order to obtain depletion curves of contaminants at different electrolysis current; 3) degradation of the atrazine in horizontally mounted column packed with cleaned sand. The results of the study are presented in this work.

Materials and methods

The Ti plates (De Nora Brazil) were polished with sand paper. The plates were degreased in 40% NaOH solution for 2 hours at 313K, pretreated by etching in boiling 10% oxalic acid for 2 hours until TiO_2 was thoroughly dissolved, and a reddish-brown titanium oxalate was produced, and conserved in an aqueous solution of 1% oxalic acid to avoid the re-formation of TiO_2 (Liu and Liu, 2008).

β-PbO_2 electrodes were prepared by electrodeposition on Ti plates a solution of $Pb(NO_3)_2$ (0.2 mol L^{-1}; pH 2; T=60 ^oC). β-PbO2 deposition was done at constant anodic current (20 mA cm^{-2}; t=20 min). The β-PbO_2 coating was deposited on top of an intermediate platinum interlayer obtained by electrodeposition at 30 mA cm^{-2} (t=5 min) from H_2PtCl_6 solution (0.002 mol L^{-1}).

The electrochemical ozone production for different current densities (50, 100 and 150 mA cm^{-2}) was achieved in a divided cell comprising one β-PbO_2 coated titanium anode and one ruthenium oxide-coated titanium cathode. Each compartment has a volume of around 500 mL.The geometric area of the electrodes was 15 cm^2. A phosphate buffer solution 0.1 M (pH=7) was used. Nitrogen gas was passed through both side of the cell and the gas exiting the anode was bubbled through a solution of 20g L^{-1} KI. The iodine formed from the oxidation of iodide with ozone was determined by titration with sodium thiosulphate. Starch solution was used as indicator (Gordon et al., 1989).

Determination of dissolved ozone is made in a one-compartment cell. The electrolysis cell is cooled by tap water circulating around it. The electrodes and electrolytic solution are the same as above. The volume of solution was 400 mL. The dissolved ozone concentration was measured by the indigo method (Bader and Hoigné, 1981).

The degradation of a 400 mL of a phosphate buffered (0.1 M, pH=7) solution containing an atrazine concentration of 1 mgL^{-1} by electrochemically produced ozone has been studied by applying three different current densities (50, 100 and 150 mA cm^{-2}). The atrazine depletion concentration in solution was determined by HPLC analytical method.

The acrylic column (25 cm x 4 cm ID) contained a single set of electrodes. Two expanded titanium mesh coated with β-PbO_2 and RuO_2 (De Nora Brazil) served as anode and cathode, respectively. The surface area of a single electrode was approximately 15 cm^2. The electrodes were mounted at 12.6 cm (anode) and 13.4 cm (cathode) from the inlet to the e-barrier column. The inter-electrode space was filled with a 6 mm layer of glass beads. The remainder of the column was packed with cleaned sand intended to approximate the aquifer material. A reference electrode of Ag/AgCl/Cl^-(saturated) was installed in the vicinity of the anode to measure the electrode potential.

A solution with a concentration close to 1 mg L^{-1} was pumped through the column using a peristaltic pump at a flow around 0.5 ml min^{-1}. After the reactor was completely filled with the pesticide solution, a constant current was applied to the electrodes in two steps, 400 mA for 4.5 hours followed by 1.5 hours at 600 mA (26.7 and 40 mA cm^{-2}, respectively).

Three glass sample ports allow for the collection of aqueous samples for bed profile analysis. One sampling port was positioned in the middle of the electrodes and the others upstream and downstream of the electrodes.

A tracer test was performed to evaluate the hydrodynamic properties of the sand pack in the column. Tracer test was performed by adding chloride at a 1000 mg L^{-1} and sampling the effluent periodically to develop a breakthrough curve. An advection-dispersion model was fitted to the data to determine dispersivity and bed porosity.

Results

The obtained results show that the ozone production increases with incrementing the current density. The rate of ozone production during the electrolysis was 4.8, 18.0 and 38.6 mg h^{-1} for current densities of 50, 100 and 150 $mAcm^{-2}$, respectively.

In addition, for all density current values considered in the dissolved ozone experiments (0.5 x 10^3, 1 x 10^3 and 1.5 x 10^3 Am^{-2}), the dissolved ozone concentration increases with time, remaining constant beyond a certain time (around 50 minutes). The dissolved ozone concentration for current densities of 100 and 150 $mAcm^{-2}$ was higher than for a current density of 50 $mAcm^{-2}$. The rate of ozone production at 150 $mAcm^{-2}$ was two times the rate at 100 $mAcm^{-2}$, however the dissolved ozone concentration in solution during the experiments was very similar at these two current densities as shown in Figure 1.

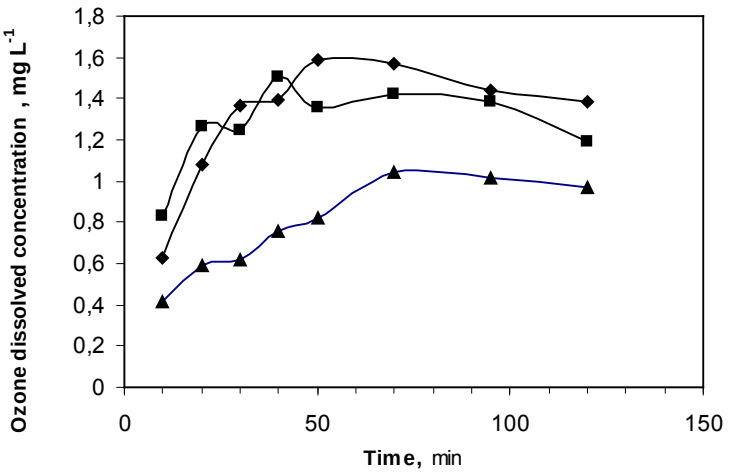

Fig. 1. Effect of current density on ozone dissolved concentration with β-PbO_2 anode (electrolyte, 0.1M phosphate buffer; pH 7): (▲) 50$mAcm^{-2}$, (■) 100$mAcm^{-2}$, and (♦) 150$mAcm^{-2}$.

In the experiments of atrazine degradation by electrochemically generated ozone a difference in atrazine degradation was found when the applied current density was varied, as shown in Figure 2. The results show that electrolytic transformation of atrazine occurred under different rates that depend upon current density. This is indicative of a greater oxidation ability of the anode with increasing the current applied due to the production of more electrogenerated active oxidant (O_3). The extent of O_3 generation can be controlled by a proper choice of current, thus it is quite possible to obtain the higher degradation efficiency.

The kinetic analysis of the above results related to different reaction orders gave good linear correlations, when the data was fitted with a pseudo first-order reaction rate equation. The straight lines thus obtained for three different current densities with an initial concentration of 1 mg L^{-1}, are presented as an inset in Figure 2. The pseudo first-order rate constants obtained are 6.2×10^{-3}, 9.7×10^{-3}, and 1.21×10^{-2} s^{-1} for 50, 100, and 150$mAcm^{-2}$, respectively.

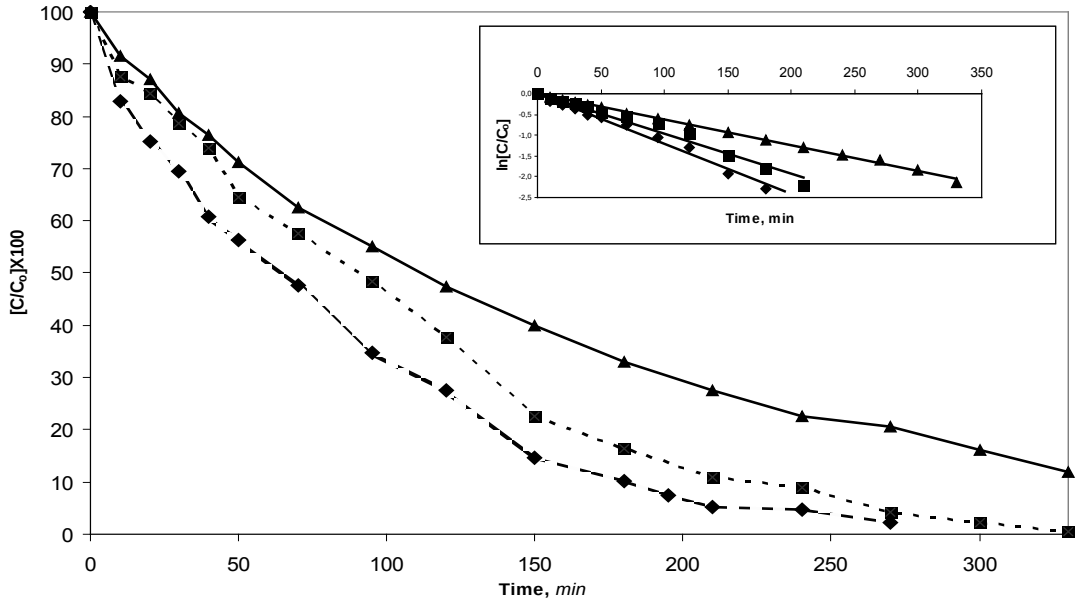

Fig. 2. Effect of current density on atrazine degradation with β-PbO_2 anode (atrazine, 1mgL^{-1}; electrolyte, 0.1M phosphate buffer; pH 7): (▲) 50mAcm^{-2}, (■) 100mAcm^{-2}, and (♦) 150mAcm^{-2}. *Inset*: Corresponding kinetic analysis assuming a pseudo first-order reaction for atrazine decay.

The results of tracer tests revealed that the e-barrier column packing material has an effective porosity of 0.15 and dispersivity of 0.24 cm.

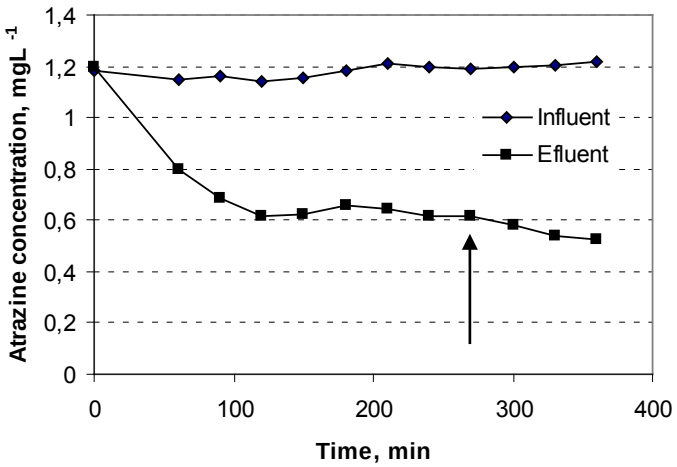

Fig. 3. Atrazine concentration, in the influent and effluent to column, as a function of time. Arrow indicates the time when the current applied was augmented from 400 mA to 600 mA.

Atrazine concentrations in the influent and effluent streams from the e-barrier column were monitored over time and are shown in the Figure 3. The increase in current results in increased transformation of atrazine. Atrazine inlet concentrations of ~1.2 mg L^{-1} were reduced to about 0.52 mg L^{-1}.

Conclusion

The column study reported herein demonstrated that approximately 56% of influent atrazine concentrations can be transformed. These results confirm the potential applicability of this type of groundwater plume control strategy. Based on the results of this study, it is expected that in a field application more than one set of electrodes would be required to completely transform atrazine to environmentally benign products.

Topic: Advancing the chemical and biological engineering fundamentals

Abstract

The present work reports data on the catalytic ozonation of three commercial dyes from different chemical classes. One acid azo dye, CI Acid Blue 113, and two reactive dyes, CI Reactive Yellow 3 and CI Reactive Blue 5, with azo and anthraquinone chromophores, respectively, were used as representative textile dyes. The catalytic activities of activated carbon, cerium oxide and a ceria-activated carbon composite were evaluated in the mineralisation of the selected dyes. In all cases, complete decolourisation was achieved by single ozonation. The ceria-activated carbon composite allowed the highest removal of total organic carbon. For the lower dye concentrations, total mineralisation was achieved with the composite after two hours of reaction. The activity of the catalyst containing cerium was affected by the presence of carbonate and bicarbonate ions due to their scavenging effect towards hydroxyl radicals. All the catalytic systems were evaluated in the treatment of a textile effluent, collected after conventional biological treatment. Catalytic ozonation was proven to be effective when used as tertiary treatment for bio-treated effluents.

1 Introduction

Intense colour is one of the main characteristics of textile wastewater originated from spent dye baths and dye rinsing operations. Besides the undesirable aesthetic impact caused by such effluents in receiving natural water courses, the persisting colour and the non-biodegradable nature of most of the textile dyes represent serious problems to the environment. Conventional aerobic biological treatments have proven insufficient to completely remove colour from textile plant effluents (Marmagne and Coste 1996; Vandevivere et al. 1998). Although there are several physical-chemical methods applied for colour removal, such as adsorption, membrane processes or physico-chemical treatments, chemical oxidation has become the method of choice due to its high efficiency and ease of operation. Owing to its extremely high redox potential, ozone is one of the most effective oxidant agents used for this purpose. The oxidation of dyes and chemical auxiliaries present in textile effluents lead to the formation of intermediates that are frequently resistant to ozone attack. Such compounds of low reactivity towards ozone may be efficiently removed by oxidation via $HO^{\bullet}$ radicals (Hoigné and Bader 1983). Presently, advanced oxidation processes and catalytic oxidation are the main emerging routes for the removal of such compounds. Heterogeneous catalytic ozonation aims to enhance the removal of more refractory compounds by the transformation of ozone into more reactive species and/or by adsorption and reaction of the pollutants on the surface of the catalyst (Legube and Leitner 1999). Oxides of transition metals are trendy catalysts in ozonation processes, and activated carbon is also an attractive and promising alternative to the treatment of wastewater containing dyes or other organic contaminants (Lin and Lai 2000; Rivera-Utrilla and Sánchez-Polo 2002; Faria et al. 2005; Beltrán et al. 2006; Faria et al. 2008a). development of highly effective catalysts for the application in ozonation processes, and the understanding of the inherent mechanisms are of great relevance.

2 Material and Methods

Three commercial textile dyes from different classes (CI Reactive Blue 5, CI Reactive Yellow 3 and CI Acid Blue 113), with known molecular structure, were selected for this study. The experiments were carried out at the natural pH of the solutions. The concentration of each dye in solution was followed by UV/Vis spectrophotometry. The mineralisation of the solutions was followed by measuring the total organic carbon (TOC).

Cerium oxide (Ce-O) was prepared by precipitation from the corresponding nitrate aqueous solution ($Ce(NO_3)_3.6H_2O$) (Imamura et al. 1985). A composite of activated carbon/cerium oxide (AC_0-Ce-O) was prepared by a similar procedure used for the preparation of sample Ce-O, where a given amount of activated carbon (AC_0) was dispersed in the cerium nitrate solution before precipitation. The textural characterization of the materials was based on the corresponding N_2 equilibrium adsorption isotherms. Cerium containing samples were characterized by XRD, XPS and SEM. Thermal analysis of sample AC_0-Ce-O, carried out under a flow of air, revealed a cerium oxide average content of 45% wt. Samples Ce-O and AC_0-Ce-O have BET surface areas of 72 and 583 m^2/g, respectively. The selected activated carbon has a BET surface area of 909 m^2/g, and its complete characterization is reported elsewhere (Faria et al. 2006). According to the XRD results, the dominant diffraction peaks observed for both samples are those characteristic of cerianite (CeO_2). The presence of the Ce (IV)/Ce (III) redox couple on the surface of the prepared ceria containing catalysts was evidenced by XPS analysis. Additional detailed information on the characterization of the ceria materials is reported elsewhere (Faria et al. 2008b)

3 Results and Discussion

The mineralisation of the AB113, RY3, and RB5 solutions with an initial concentration of 50 mg/L was carried out by ozonation catalysed by AC_0, Ce-O and AC_0-Ce-O. Experimental data corresponding to the decolourisation kinetics of AB113, RY3 and RB5 by non-catalytic ozonation and adsorption on AC_0 are depicted in Figure 1, in order to allow the comparison of the performance of the different dyes towards activated carbon adsorption and ozone attack.

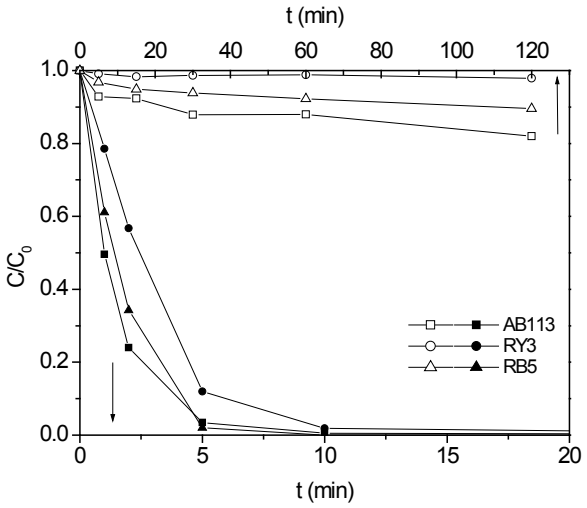

Figure 1 Kinetics of the non-catalytic ozonation (filled symbols) and adsorption on AC_0 (open symbols) of AB113, RY3 and RB5 at the natural pH of the solutions (C_0 = 50mg/L, AC_0 = 0.5 g/L).

Under the experimental conditions used in this work, the adsorption of the selected dyes is rather limited, as shown in Figure 1. In fact, the RY3 dye has a very low affinity towards activated carbon. After 120 min, the removal of AB113 and RB5 by adsorption on AC_0 was ca. 18% and 11%, respectively. The presented data show that adsorption is not effective for the decolourisation of these solutions. On the other hand, single ozonation allows a fast colour removal in short reaction times (less than 10 min).

Even though the decolourisation of the synthetic coloured solutions was not visibly enhanced by the studied catalytic systems, entirely different results were observed when analyzing the extent of the mineralisation achieved during catalytic ozonation. The kinetic data corresponding to the evolution of TOC during the catalytic ozonation of RY3 and RB5 are presented in Figure 2.

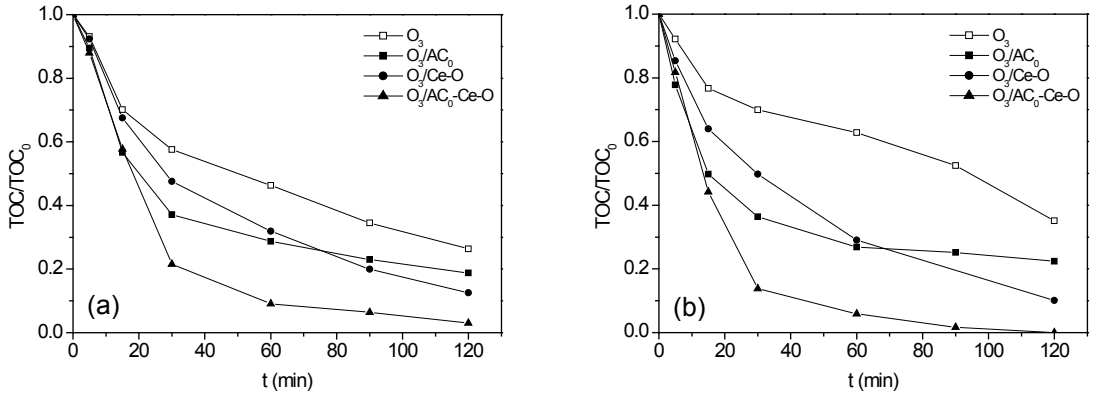

Figure 2 Evolution of dimensionless TOC during non-catalytic and catalytic ozonation of (a) RY3 (C_0 = 50 mg/L, pHi = 5.8) and (b) RB5 (C_0 = 50 mg/L, pHi = 5.6).

A very similar trend was observed for all the studied dyes. In the case of RY3 the simultaneous use of ozone and activated carbon led to an enhanced TOC removal when compared to single ozonation (Figure 2a). As previously shown, RY3 has very little affinity towards activated carbon; therefore, the enhanced results may be attributed to the catalytic effect of activated carbon mainly in the oxidation of intermediate products. Comparatively to non-catalytic ozonation, the simultaneous use of ozone and activated carbon increased the removal of TOC from 42% to 63%, after 30 min. The highest mineralisation extent was obtained with the activated carbon-ceria composite. After 30 min of reaction, the TOC removal achieved was 78% against 42% obtained by single ozonation. Sample AC_0-Ce-O allowed nearly total mineralisation of the solution after a longer reaction period.

The reactive blue dye RB5 was shown to be the most refractory towards single ozonation and the biggest difference between non-catalytic and catalytic ozonation was observed in this case (Figure 2b). After 30 minutes of reaction, the mineralisation extent obtained in non-catalytic ozonation was only about 30%, but the addition of the activated carbon to the process approximately doubled the percentage of TOC removed. A remarkable enhancement in the mineralisation degree was obtained during the ozonation catalysed by the composite AC_0-Ce-O. After 30 min, less than 14% of the initial TOC is present in solution and total mineralisation is achieved in less than 2 h of reaction.

In all cases, cerium oxide was found to be an efficient ozonation catalyst and higher mineralisation degrees were achieved comparatively to the performance of activated carbon, but only for longer reaction periods (higher than ca. 60 min). Superior initial reaction rates are observed for the TOC removal during ozonation catalysed by both AC_0 and AC_0-Ce-O. This observation suggests a reaction mechanism distinct from that of cerium oxide catalytic ozonation. The latter is dependent of the formation of $HO^{\bullet}$ radicals (Faria et al. 2008b), while the former namely comprises surface reactions on the activated carbon, as reported in a

previous work (Faria et al. 2008a). It was suggested that cerium oxide promotes the decomposition of ozone into $HO^{\bullet}$ radicals, which are the main oxidant species responsible for the oxidation of the compounds in the liquid phase. A strong synergic effect was observed between activated carbon and cerium oxide in the AC_0-Ce-O composite. The reaction mechanism is believed to comprise both surface reactions, similar to what occurs with activated carbon promoted ozonation and also liquid bulk reactions involving $HO^{\bullet}$ radicals. It was assumed that the existence of delocalized electrons on the basal planes of the activated carbon contributes to the formation of Ce (III) species, which are thought to be necessary for promoting the decomposition of O_3 into $HO^{\cdot}$ radicals by redox reactions on the catalyst surface involving the pair Ce(III)/Ce(IV).

Generally, in addition to dyes, reactive dye baths involve the use of several auxiliary chemicals, such as sodium chloride (NaCl), sodium carbonate (Na_2CO_3), and sequestering agents. The main role of the Na_2CO_3 is to increase and buffer the pH of the dye bath, favouring the reaction between the reactive group of the dye and the -OH groups of cellulose. The influence of the addition of Na_2CO_3 in the catalytic ozonation of dye solutions was also assessed. The simulated effluent containing 300 mg/L of RB5 and 1 g/L of Na_2CO_3 was treated by catalytic and non-catalytic ozonation. After 15 min of reaction, the colour removal achieved lies between 97% and 98% for all the catalytic systems and the time required for nearly total decolourisation was less than 30 minutes. The effect of the addition of sodium carbonate was mostly noticeable in the extent of the mineralisation of the solution. Experimental data referring to the TOC removal in the studied catalytic systems is depicted in Figure 3.

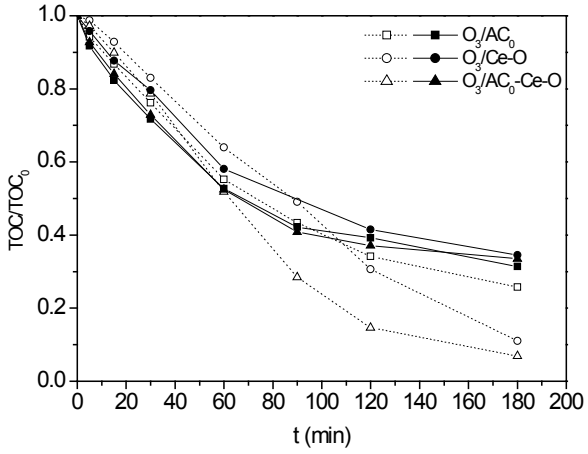

Figure 3 Effect of the presence of HCO_3^-/ CO_3^{2-} (filled symbols) on the evolution of dimensionless TOC during catalytic ozonation of RB5 C_0 = 300 mg/L.

The presence of HCO_3^-/ CO_3^{2-} was found to significantly affect the activity of Ce-O for the mineralisation of RB5. A similar effect was observed for the composite AC_0-Ce-O. On the contrary, the catalytic action of AC_0 is only slightly affected, if compared with the results obtained in the absence of Na_2CO_3. As previously mentioned, the addition of Na_2CO_3 increases the solution pH and alkalinity. The mineralisation of organic compounds, achieved by ozonation, is usually favoured at higher pH values, due to the participation of $HO^{\bullet}$ radicals in the reaction mechanism. However, the scavenging effect of both of HCO_3^- and CO_3^{2-} species decrease the amount of $HO^{\bullet}$ radicals available for reaction with the organic compounds, therefore partially inhibiting the mineralisation process. In a previous work (Faria et al. 2008b), cerium oxide was shown to catalyse the ozonation of carboxylic acids manly through reactions involving $HO^{\bullet}$ radicals. In this work, the inhibiting effect of the HCO_3^-/ CO_3^{2-} confirms that the mineralisation of the intermediates of the process also occurs by a radical

mediated reaction mechanism. Nevertheless, Ce-O still has a significant catalytic activity, as higher mineralisation is attained when compared to single ozonation. In the case of the composite, the results obtained up to 60 minutes of reaction are not noticeably affected by the presence of sodium carbonate (see Figure 3). After this period, a significant reduction in the catalyst activity was observed. The removal of TOC obtained after 120 min of reaction was 63% contrasting with the 85% obtained in the absence of carbonates.

The similarity of the performance of AC_0 and AC_0-Ce-O in the mineralisation of the CI RB5 should be pointed out. Apparently, the presence of the scavenger has very little effect on the activity of the activated carbon, since only a slight reduction in the removal of TOC was observed for longer reaction period comparatively to the results obtained in the absence of the carbonates. This observation suggests that the contribution to the production of $HO^{\bullet}$ radicals is not the only role of activated carbon. It is thought that activated carbon also promotes the decomposition of dissolved ozone that may originate surface oxygen-containing radical species, which participate in the oxidation of the organic compounds. In this way, activated carbon seems to be a good catalyst for practical purposes, as its activity is not significantly affected by the presence of $HO^{\bullet}$ scavenging species.

Catalytic ozonation is a powerful chemical oxidation process that can be applied to the treatment of a vast range of organic pollutants, and it has been shown to be a promising technique to the treatment of wastewater from the textile industry. In order to evaluate the efficiency of the selected catalysts in the ozonation of real wastewater samples, a mixed textile effluent collected after biological treatment was used as a case study. Despite the strong visible colour of the effluent, complete decolourisation was achieved by single ozonation shortly after 5 minutes, confirming the strong decolourisation potential of ozone.

A higher mineralisation degree was achieved with catalytic ozonation, being AC_0 and AC_0-Ce-O the catalysts leading to the best results. In the presence of activated carbon, the removal of TOC achieved after 30 min was approximately 57%, which is significantly higher when compared to the 30% TOC removal achieved in non-catalytic ozonation. Unlike what was observed for all the studied dye solutions, no major differences were observed between activated carbon and the composite. Additionally, sample Ce-O was visibly less active. The performance observed during the catalytic ozonation of the bio-treated effluent was attributed to the presence of HCO_3^- and CO_3^{2-}, which, as explained in the previous section, act as radical scavengers, therefore inhibiting the mineralisation of the organic compounds via $HO^{\bullet}$ oxidation. AC_0 and AC_0-Ce-O have similar catalytic activities, which may be explained by the contribution of the surface reactions that are believed to occur preferentially on the activated carbon, therefore not involving $HO^{\bullet}$ radicals in solution.

The application of ozone processes as post-treatment for a refined depuration of wastewater is of great interest. In the case of liquid effluents from the textile industry, ozone has proven to be highly effective for an extensive elimination of colour. Concerning the removal of recalcitrant compounds, which cannot be eliminated in biological processes, catalytic ozonation emerges as a feasible solution to significantly enhance the mineralisation of such effluents.

4. Conclusions

Ozonation is a powerful oxidation process for fast and total decolourisation of both synthetic dye solutions and real textile effluents.

The combination of activated carbon with ozone enhanced the mineralisation levels of both the dye solutions and the textile effluents. The results obtained in this study show that cerium oxide is an effective ozonation catalyst for the mineralisation of textile dye solutions. Comparatively to the performance of the commercial activated carbon, an enhanced mineralisation extent was achieved, which is explained by a higher ability to catalyse the decomposition of ozone into $HO^{\bullet}$ radicals. A strong synergic effect was observed between activated carbon and cerium oxide in the prepared composite, leading to enhanced

mineralisation degrees for all the studied dye solutions. The mechanism of the ozonation catalysed by the ceria-activated carbon composite is believed to comprise both surface reactions, similar to what occurs with activated carbon promoted ozonation, and also liquid bulk reactions involving $HO^{\bullet}$ radicals, resultant from the catalytic decomposition of ozone on the surface of the catalyst, mainly in the presence of cerium oxide.

The presence of bicarbonate and carbonate ions in solution was shown to partially inhibit the mineralisation of the CI Reactive Blue 5 dye. The negative impact on both Ce-O and AC_0-Ce-O activities is supposed to be related to the scavenging effect of those inorganic ions on the $HO^{\bullet}$ radicals formed. The presence of high concentrations of inorganic ions with scavenging properties may restrain the results obtained in wastewater treatment by advanced oxidation processes. Activated carbon catalysts also promote surface oxidation reactions that do not involve $HO^{\bullet}$ radicals in solution; therefore their activity is not severely affected by the presence of scavenger species. This was confirmed by testing the efficiency of these catalytic systems in the mineralisation of a bio-treated textile effluent.

Keywords: Ion exchange membrane bioreactor, Donnan dialysis, Water treatment, Anionic micropollutants, Modelling
Topic: Sustainable process-product development through green chemistry

Abstract

This paper gives an overview of our most recent studies on the Ion Exchange Membrane Bioreactor concept for treating drinking water streams polluted with anionic micropollutants such as nitrate, perchlorate and bromate. Special focus is put on the process modelling strategies, including mechanistic, non-parametric as well as hybrid models, in order to allow for covering a broader range of possible polluted water treatment scenarios and operating conditions. A recent modification of the IEMB concept to situations, in which biotransformation is not an advantageous solution (e.g. arsenate) is also mentioned briefly.

1 Introduction

A general limitation of using ion exchange membranes for removal of micropollutants from water is the formation of a toxic brine stream, which has to be treated before disposal. Oppositely, biological treatment processes are able to degrade the pollutants transforming them into harmless products. However, biodegradation may induce secondary contamination of the treated water by microbial cells, nutrients and metabolic by-products. Therefore, integrated and eco-efficient process solutions are highly desirable.

The ion exchange membrane bioreactor (IEMB) (Velizarov et al., 2000/2001; Crespo and Reis, 2003) combines the transport of charged pollutants through a dense ion exchange membrane with their simultaneous biodegradation by an anoxic microbial culture in a separated compartment (biological compartment) as schematically illustrated in Figure 1. The membrane is positively charged, thus allowing the passage of anions like nitrate, perchlorate, bromate, etc. Once in the biological compartment these anions are reduced to innocuous species, such as nitrogen, chloride, bromide respectively. Using this technology, no toxic brine is produced and, due to a physical separation of the water and the biological compartment, no secondary contamination of the treated water occurs. The transport across the membrane is governed by the Donnan dialysis principles, using chloride as the driving counter-ion. Therefore, the transport of target anions can be improved using an excess of chloride in the biological compartment.

Besides exploring the IEMB concept for the removal of cationic micropollutants such as heavy metals (e.g. Hg^{2+}, Velizarov et al., 2008), we are presently focusing on the impact of the membrane choice (lower cost common anion exchange membranes versus mono-anion selective anion exchange membranes) on the process performance and on optimizing the IEMB process regarding the biomedium composition and biocompartment operating conditions.

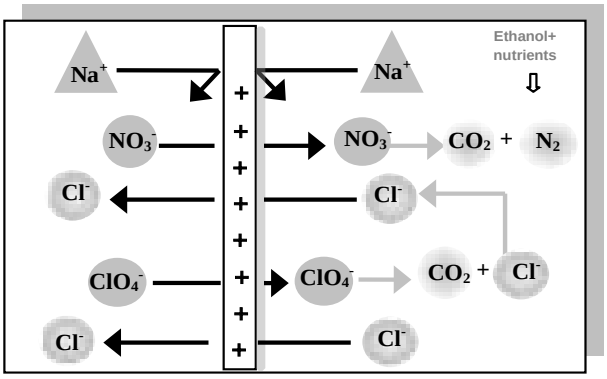

Figure 1. Shematic diagram of target polluting anions (NO_3^- and ClO_4^-) transport and bioreduction in the IEMB. Driving anion: Cl^-. Electron donor and carbon source: Ethanol.

2 Materials and methods

Two different membranes were used, an anion exchange membrane, Excellion™ I-200, produced by SnowPure (USA) and a mono-anion selective membrane Neosepta ACS, manufactured by Tokuyama Soda (Japan). The IEMB set-up was composed by a membrane module with two identical rectangular channels separated by the membrane under study, with an effective working area of 39 cm^2. One of the channels was connected through a gear pump to an external loop, where water supplemented with nitrate and perchlorate was recirculated at a flow rate of 97.2 l/h, corresponding to a Reynolds number of 3000. This compartment, referred to as water compartment, was continuously fed with the polluted water at different flow rates per membrane area (F/A), depending on the objective of the experiment. The other module channel was connected to a stirred vessel through another recirculation loop, also kept at a Reynolds number of 3000. This vessel was inoculated with 100 ml of an enriched microbial culture and continuously fed at a flow rate of 0.0048 l/h with a mineral medium composed of 1 g/l of K_2HPO_4, 0.592 g/l of KH_2PO_4, 0.5 g/l of NaH_2PO_4, 0.233 g/l of NH_4Cl, 0.1 g/l of $MgSO_4.7H_2O$ and 5.84 g/l of NaCl and of 280 to 560 mg/l of ethanol as a carbon source, depending on the experiment. This compartment was operated at an hydraulic retention time (HRT) of 5 days. The IEMB was operated using the Excellion membrane and compared to control trials performed with the Neosepta ACS. All experiments were run for at least one week and samples were taken periodically from the polluted water feed, treated water outlet, biomedium feed and biocompartment. These samples were used for conductivity measurements as well as for determination of the concentration of ions, ethanol and cells. All experiments were performed at a temperature of 23 ± 1 ºC in an air-conditioned room.

Anion concentrations, were determined as recently described (Matos et al., 2008) using a Dionex ion exchange chromatography system constituted by an ED 50 electrochemical detector, suitable analytical columns and an Anion Suppressor-ULTRA (4 mm). For the ClO_4^- analyses, a Ionpac AG16 Guard and Analytical AS16 (4 mm) columns were used. For the analysis of ClO_4^- in the samples taken from the water compartment, the detection limit was 1 ppb (injecting 1 ml of sample).

3 Results and discussion

Mechanistic modelling

With the objective of predicting the flux a target pollutant in the IEMB process at steady state, a mechanistic resistances-in-series trace counter-ion transport model was elaborated:

$$J_i = \frac{\frac{C_{i,1}}{C_{a,1}^{\ z}} - \frac{C_{i,2}}{C_{a,2}^{\ z}}}{\frac{L}{P_{i,m} \times \left(\frac{Q}{a}\right)^z} + \frac{\delta_1}{D_{i,w} \times C_{a,1}^{\ z}} + \frac{\delta_2}{D_{i,w} \times C_{a,2}^{\ z}}} \qquad (1)$$

where $C_{i,1}$ and $C_{i,2}$ are the concentrations of the polluting anion *i* in the water and the receiving compartment (biocompartment), respectively noted as 1 and 2; $C_{a,1}$ and $C_{a,2}$ are the major driving counter-ion concentrations in each compartment (e. g. chloride); *z* represents the ratio between the valence of the target ion (*i*) and the valence of the major counter-ion (*a*); δ_1, δ_2 are the thickness of the corresponding boundary layers next to the membrane surfaces at the water and biomedium sides, respectively; *L* is the membrane thickness; $P_{i,m}$ is the membrane permeability to the target counter-ion; *Q* is the ion exchange capacity of the membrane and $D_{i,w}$ is the diffusion coefficient of the target counter-ion *i* in water. Equation 1 shows that the flux is proportional to the difference between the ratios of the target counter-ion (NO_3^-, ClO_4^- or BrO_3^-) to the major counter-ion (in this case, Cl^-) concentration in the two compartments. This difference is the process driving force. The second term in the driving force can usually be neglected because the target counter-ions are bio-reduced to very low concentrations in the biocompartment and the major counter-ion is kept at a relatively higher concentration in this compartment, in order to enhance the transport of the polluting anions from the water stream to the biocompartment. The overall transport resistance is given by three resistances in series: a resistance associated with the transport through the membrane, expressed by the first term in the denominator, while the second and the third terms represent the resistances due to the corresponding liquid phase boundary layers at the two membrane surfaces. This steady state mass transport model can only be applied after a bi-ionic approximation and in case of an effective Donnan exclusion of the co-ions by the membrane, if the ion exchange kinetics is considered not rate-controlling, and if the water flux due to osmosis can be neglected (Velizarov et al., 2003).

The performance of the IEMB system was evaluated for different concentration scenarios of pollutants (nitrate and perchlorate) in the water, using the Excellion membrane. Three experiments were performed at a water flow rate per membrane area ratio (F/A) of 3.1 l/(m^2h) at different anion concentrations. The accuracy of the transport model to predict the IEMB behaviour at steady state was evaluated. The target anion fluxes were calculated based on the corresponding mass balances while some of the required membrane properties were determined through independent experiments (Table 1).

Table 1. Membrane characteristics experimentally determined in this study

Parameter	Excellion I-200	Neosepta ACS
Ion Exchange capacity (meq/ g dry membrane, Cl^- form)	1.24 ± 0.06	1.42 ± 0.20
Density (g/cm^3 wet membrane, Cl^- form)	0.70 ± 0.02	1.13 ± 0.02
Water content (%)	42 – 44	24 – 29
Thickness (mm)	0.330 ± 0.001	0.130 ± 0.001

Figure 2 shows that the fluxes calculated by Equation 1 (the straight lines), using pre-determined values of P_m, are comparable with those obtained experimentally. This result confirms the applicability of the mechanistic model within this concentration range.

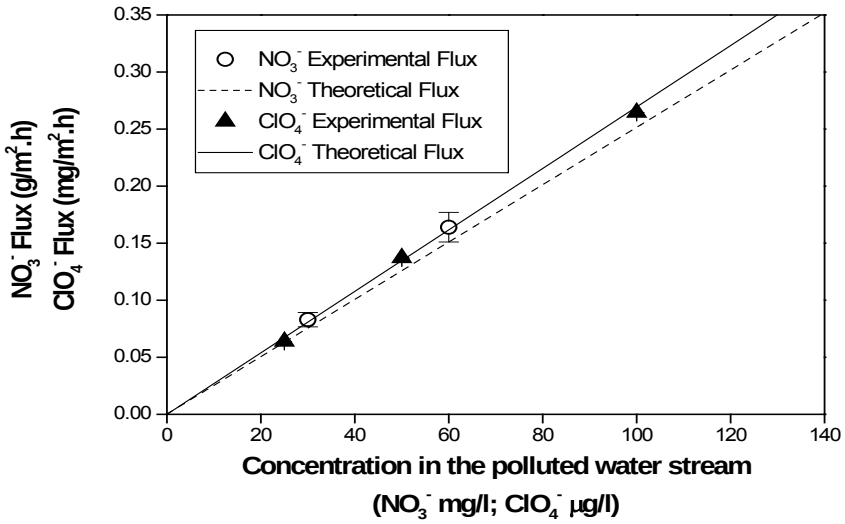

Figure 2. Effect of the pollutant concentration on the experimental and theoretical fluxes (predicted by Equation 1) of target anionic pollutants for an IEMB operation at an F/A ratio of 3.1 l/(m^2h), using the Excellion membrane (Matos et al. 2008).

Besides for treating polluted drinking water, the applicability of the IEMB process and the mechanistic model for the removal of nitrate from closed marine systems was also demonstrated. The IEMB process was able to remove naturally accumulated nitrate at concentrations of 251 mg/L and 380 mg/L to below 27 mg/L from water taken from the Lisbon oceanarium. Thus, the IEMB proved to be a selective technology for nitrate removal, while preserving the original composition of the water with respect to other ions. This is an advantage of the IEMB concept, since it allows for the reutilisation of the treated water by the aquarium, thus decreasing the need for water renewal and the frequency of wastewater discharge.

Hybrid modelling

For situations, in which the mass transfer assumptions used in developing the mechanistic transport model (Equation 1) are not satisfied, or in which the biological reaction controls the IEMB process, due to intrinsic metabolic complexity and to non-linear kinetics of the biological activity and transport phenomena, the modelling of the IEMB can be extremely difficult.

Process optimization aims at increasing the economical viability and minimizing the biomass produced. To fulfil this aim, the main variables affecting the biological compartment were identified. Seven factors were selected and, in order to design a proper number of experiments, a statistical design of experiments was used. The Plackett-Burman design is selected for screening proposes since it uses an orthogonal matrix in order to decrease the number of experiments to be performed.

The results obtained cover a wide range of conditions under which the mechanistic model was not able to correctly predict the transport fluxes of the target pollutants. Therefore, the data obtained in these experiments were further analyzed by chemometric techniques, which use mathematical and statistical methods to obtain relations between data sets. A hybrid semi-parametric model (Teixeira et al., 2006) was also adopted that combines mechanistic and black-box models according to the structure shown in Figure 3. In this strategy, two phases of the process are modelled, the transport across the membrane and the consumption in the biocompartment. For the membrane transport, a black-box model (BB1) compensates for the mechanistic model inaccuracies. A second black-box model (BB2) is used to identify the

biological reaction kinetics.

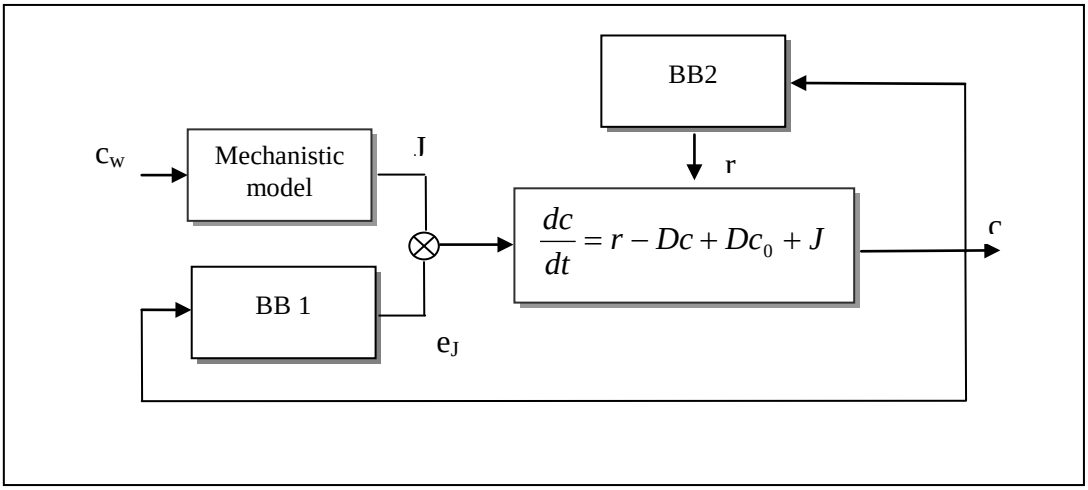

Figure 3: Hybrid model structure (c_w: ion concentration in water, e_j: transport kinetics residual).

This approach, based on hybrid structure, has the advantage of requiring less data than purely black-box models. The back-bone of the hybrid model consists of the dynamic material balance equations of the biological compartment, which account for the biological reaction kinetics (r), transport kinetics (J) and dilution terms (Dc_0-Dc). This global model is expected to predict the system performance over a broader range of operating conditions, and can be used for operational parameters optimization in the two compartments of the IEMB.

Removal of arsenic

Arsenic is generally present in polluted drinking water sources as negatively charged arsenate ($H_2AsO_4^-$) or arsenite ($H_2AsO_3^-$). However, contrary to the cases of nitrate, perchlorate and bromate, biodegradation of arsenate/arsenite to a harmless by-product(s) is not feasible. Therefore a modification to the IEMB concept was developed replacing the usual application of a mixed microbial culture by co-precipitation with iron as a means of achieving cost-effective arsenic removal in the stripping solution (Figure 4).

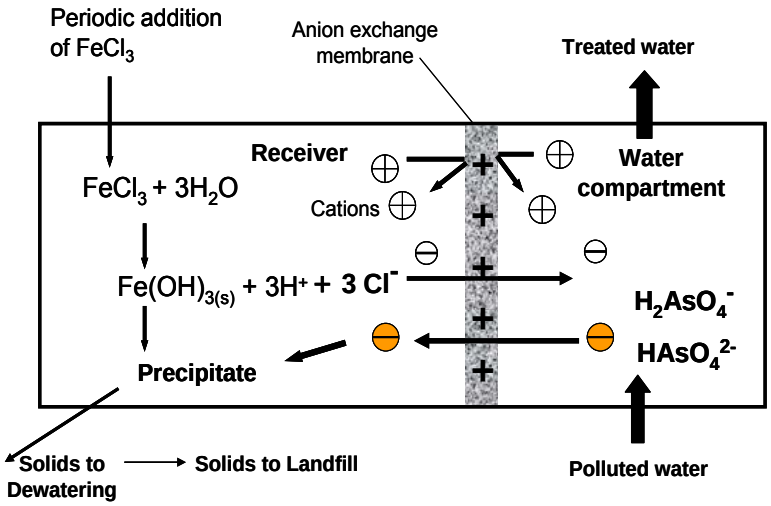

Figure 4. Integrated Ion Exchange Membrane process for removal of negatively charged arsenic-containing species from polluted drinking water streams.

The co-precipitation process with $FeCl_3$ is usually considered as one of the most feasible and economically adequate since this chemical is easily available and cheap. The disadvantages are mainly related to the need for its direct addition to the water, thus leading to residual levels of iron as well as to increased levels of chloride, which is not beneficial. The process is also sensitive to pH and requires its adjustment in some cases. Therefore its integration with an anion exchange membrane transport of the pollutant (in a way similar to the IEMB concept) but using a physicochemical process (instead of a bioprocess) could solve these problems.

In preliminary experiments performed with the integrated system with a naturally polluted groundwater, taken from the region of Ponte de Sôr, Portugal, and under conditions, in which the stripping solution was totally recirculated in a closed stripping compartment, it was clear that the addition of a precipitation agent ($FeCl_3$) to the stripping compartment improved the degree of arsenic removal from the water compartment, This can be attributed to the higher driving force for arsenic transport due to its precipitation by $FeCl_3$. In this case, $FeCl_3$ is completely utilized as a chemical precipitant (i.e. Fe^{3+}) and as a source of counter-ions for arsenate transport (i.e. Cl^-), simultaneously achieving both purposes with the addition of only one chemical (Figure 4). Process optimisation is currently in progress, where factors such as the hydrodynamic conditions in the water compartment, the effect of pH of the stripping solution and possible transport competition through the anion exchange membrane by other anions present in water are being tested.

Performance comparison of biological and Fenton processes for COD degradation of urban landfill leachates

Cátia M. Augusto, Margarida J. Quina, Licínio M. Gando-Ferreira[1*]

GERSE – Group on Environmental, Reaction and Separation Engineering, Department of Chemical Engineering, University of Coimbra, Pólo II, Rua Sílvio Lima, 3030-790 Coimbra, Portugal.

Keywords: Biological treatment, Fenton process, landfill leachate, COD degradation
Topic: Advancing the chemical and biological engineering fundamentals

Abstract

The urban landfill leachate is usually considered as a refractory effluent, mainly due to the presence of specific substances (e.g., xenobiotic organics compounds). Currently, the landfill leachate is usually treated by biological aerobic processes, since they reveal high efficiency and low cost. However, when the landfill leachate is produced in old sites, the presence of toxic or refractory components requires other alternatives such as Advanced Oxidation Processes (AOP).

In this study, the biological and Fenton processes were tested for the landfill leachate treatment in which the effluent degradation was evaluated mainly through Chemical Oxygen Demand (COD) removal. Leachate samples collected in an urban sanitary landfill from the centre region of Portugal were used for both processes. The characterization of these leachate samples entails the evaluation of pH, COD, BOD_5, the ratio BOD_5 to COD, TSS and VSS. By comparing the performance of both treatment processes one may notice that the largest COD removal occurred for the biological treatment (70% reduction at maximum) against 27%, for the Fenton process. For the leachate in analysis, the integration of both processes (biological followed by fenton) may be an attractive solution.

1 Introduction

The Urban landfill leachates are liquids generated by infiltration of water from externals sources that percolates through the mass of waste and by the biological decomposition of organic material within the municipal solid waste (MSW). A set of physical, chemical and microbiological transformations promote the transference of the pollutants from the waste to the water. With the increase of the landfill age, the disposed material undergoes several phases of decomposition, producing leachates with different physical-chemical characteristics, as a consequence of the transformation processes within the landfill (Duggan, 2005 and Slack*, et al*., 2005). The composition and the amount of leachate vary with the state of degradation, the decomposition of the MSW and the movement of the water in landfill (Öman and Junestedt, 2007). The pollutants observed in landfill leachates can be associated in four groups: dissolved organic matter, inorganic macro components, heavy metals and xenobiotic organics components (XOC) (Öman and Junestedt, 2007; Christensen *et al*., 1998). The hazardous characteristics of this type of effluent are attributed not only to the presence of toxics components, but mainly to the synergic effect between different substances of the leachate.
In the recent literature, some studies indicate new methods for the treatment of landfill leachate (Laconi *et al*., 2006; Kurniawan *et al*., 2006; Sarasa *et al*., 2006). However, the process often used in full scale still is the aerobic biological treatment, which usually leads to

* Corresponding author. Tel + 351-239-798700. E-mail:lferreira@eq.uc.pt

satisfactory results. The objectives of the biological treatment deal with the stabilization of organic matter and the removal of solids (Laconi *et al*., 2006; Metcalf & Eddy, 1991). The activated-sludge processes are largely used worldwide, once they required reduced installation areas and lead to high quality of the final effluent. Usually, this process includes a biological reactor and a sedimentation tank with recirculation of sludge (Metcalf & Eddy, 1991). Some physicochemical treatments are associated to aid the biological process, but they should not interfere with the microbiology. The biomass growth reflects the state of the biological treatment, and thus requires stable environmental conditions such as pH, temperature, nutrients, dissolved oxygen and time of contact between biomass and substrate (Metcalf & Eddy, 1991).

The Advanced Oxidation Processes (AOP) come out as a promising alternative due to the high removal percentages of toxic pollutants and bio-recalcitrant chemical species. The AOP were defined in 1994 by Glaze as processes that generate hydroxyl radicals (HO) which are known to have high oxidant power (2.33 V) reacting with several organic and inorganic species at high kinetic constants values. Generally, the goal is to obtain total mineralization of the organic matter into water and carbon dioxide, however for economical reasons it may be favourable to achieve partial oxidation of the organic compounds into biological degradable matter (Morais and Zamora, 2005).

The Fenton process remained without importance for a few years ago. Currently, this process had been demonstrated significant oxidizing potential for organic compounds. The Fenton reagent is a suitable process in acidic conditions, where a combination of an iron salt with hydrogen peroxide occurs, leading to the generation of hydroxyl radicals (HO·).The radical acts in the decomposition of organic compounds (RH), as oxidizing agent, and promote radical oxidation reactions. It should be noted that the Fenton reagent converts complex and toxic compounds, but fails in some cases such as small chlorinate alkenes, paraffines and small carboxylic acids (Zhang *et al*., 2005).

2 Experimental Procedures

The effluent considered in this study was municipal landfill leachate collected in an urban sanitary landfill located near to Coimbra. The samples were characterized and treated.

Characterization

Seven samples of leachate were collected, transported to the laboratory and immediately preserved at a temperature lower than 4ºC. The characterizations of the samples involved pH, Chemical Oxygen Demand (COD), Biochemical Oxygen Demand (BOD), BOD_5/COD ratio, Total Suspended Solids (TSS) and Volatile Suspended Solids (VSS). The COD was measured with photometer (WTW CR3000) using commercial kits containing an oxidant mixture of potassium dichromate under acidic conditions (sulphuric acid) and using silver sulphate as catalyst. The BOD was determined according to Standard Methods (1985) measuring the dissolved oxygen in the initial diluted sample and after 5 days of incubation (BOD_5) at 20 ºC. The TSS and VSS were determined by gravimetry, being the solids separated using a 0.45 µm pore filter, according to Standard Methods (1985). The pH was measured by potentiometry (WTW pH-electrode SenTix 21).

Biological treatment

For the assessment of the biological treatment, the organic matter degradation of six samples (S1-S6) of leachate was investigated. The treatment was carried out by using a reactor of 1 L with bottom aeration. The oxygen concentration in the liquid phase was continuously monitored using an adequate sensor. The system was agitated by a magnetic stirrer to provide homogenization and ensure uniform distribution of the oxygen and nutrients. In general, 20% (v/v) of inoculum was mixed with 80% (v/v) of the leached solution. The inoculum was previously obtained in an acclimation phase that ensures active biomass for

the treatment. The temperature, pH and dissolved oxygen (OD) was recorded along the time. The Mixed Liquid Volatile Suspended Solids (MLVSS) were determined as a measure of the biomass growing. At the end of treatment also the COD was evaluated to assess the degradation of the organic matter of effluent.

Fenton Treatment

The Fenton process was employed for only one sample (S7), but in this case a design of experiments was used for testing the influence of 3 factors: initial concentration of H_2O_2, initial concentration of Fe, and initial pH. In practice, the 3 factors were tested according to a full factorial design (2^k). Thus, 8 experiments were performed (2^3), involving 3 factors (k=3) at 2 levels. Fenton experiments were carried out in batch mode using a Jarr-test system, providing a 200 rpm stirring speed with baffles paddles. When necessary, sulphuric acid was added to 300 mL of effluent for pH adjustment. After the samples for analysis were collected, the oxidation reaction must be stopped to avoid its interference into COD measurements, and for this a sodium hydroxide solution was added. During the Fenton treatment, the COD was measured for evaluating the organic matter degradation at different times.

3 Results and Discussion

This study is related with the urban landfill leachates and the main objective was the characterization and the evaluation of the performance of Biological and Fenton treatments.

3.1 Characterization of the landfill leachate

It is well known that the landfill leachate may be characterized by a significant variability. The parameters determined in this study were the pH, COD, BOD_5, the ratio BOD_5 to COD, TSS and VSS, and the obtained values are indicated in Table 1. The different samples analysed (S1 to S7) were characterized by pH values in the range between of 7 to 8; The COD of the leachate are within 630-2780 mg O_2/L, reflecting a significant amount of organic matter. As expected, the BOD_5 is lower than COD for all samples and the determined amounts were in the range of 525 to 2510 mg O_2/L; the observed ratio for BOD_5 to COD was 0.76 to 0.90, which correspond to values of high biodegradability. Regarding the TSS and VSS parameters, significant variability was observed (114-2690 mg/L), which causes difficulties during the treatment of the effluent.

Table 1 – Characterization of leachate samples (S1-S7).

Parameters	S1	S2	S3	S4	S5	S6	S7
pH	7.42	7.73	7.72	7.64	7.56	7.54	7.90
COD (mg/L)	1000	2000	2780	1380	630	1940	2350
BOD_5 (mg/L)	(a)	1673	2510	1150	525	1470	1560
BOD_5/COD	(a)	0.84	0.90	0.83	0.83	0.76	0.70
TSS (mg/L)	730	114	1440	620	445	334	2690
VSS (mg/L)	690	127	1010	580	200	260	(a)

(a)- Values not determined.

3.2 Biological treatment of the landfill leachate

For monitoring the biological treatment several parameters were evaluated along time. Figure 1 shows the evolution of MLVSS of the leachate suspension for six samples in analysis (S1-S6), characterized by initial concentrations of 630 to 2780 mg/L of COD. These

analyses allowed the monitoring of biomass growth, being possible to conclude that the concentration of microrganisms increases along the time in all experiments. As an example, in Figure 2, the parameter MLVSS and MLTSS are represented for the sample S4, and as expected, one may use both of them for following biomass in the biological reactor. To ensure suitable operating conditions, the temperature, pH and Dissolved Oxygen (DO) were monitored during the biological degradation, and Figure 2 shows that these parameters were almost constant over the time of operation.

The initial concentration of substrate had some influence in the biological suspension characteristics. In fact, in sample S3, a higher concentration of microrganisms was achieved, being reached values 25000 mg/L of MLVSS. On the other hand, lower growth efficiency was observed for sample S5, since in this case the initial substrate concentration may be a limiting factor.

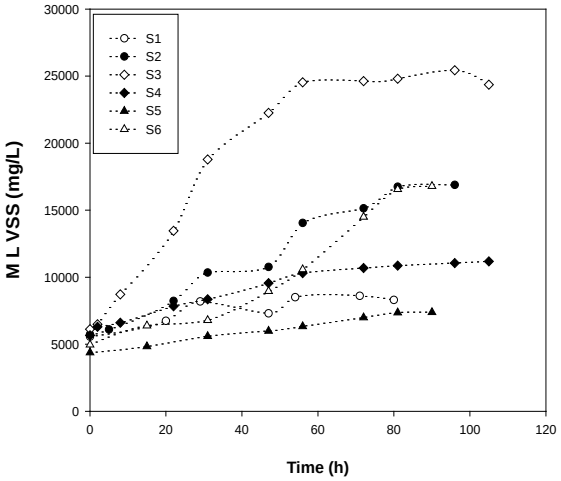

Figure 1 – Evolution along time of MLVSS for samples S1 to S6.

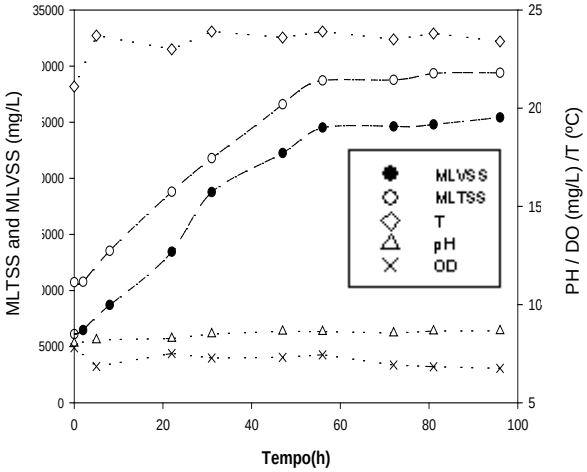

Figure 2 – Evolution along time of MLVSS, MLTSS, Temperature, pH and OD for sample S4.

3.3 Fenton treatment of landfill leachate

The most important variables whose initial values determine the Fenton process performance are: pH, amount of iron and hydrogen peroxide concentration. For evaluating the importance of these 3 factors, a design of experiments was tested according to a full factorial strategy at 2 levels (Table 2). Therefore, the number of experiments tested was 2^3=8. The minimum and maximum values tested for each variable were selected according to literature. Thus, pH was tested at 3.0 and 7.9; the H_2O_2 concentration at 7 and 14 g/L; and the iron concentration at 0 and 1.5 g/L .

The Fenton treatment was monitored for 120 minutes. However, for all conditions tested less than 30 minutes seems to be enough for reaching steady state conditions (Figure 3). The results show that the greater degradation occurred in F1 experiment (14 g H_2O_2 /L; 1.5 g Fe^{2+} /L; pH = 7.9). However, the faster reduction of COD was observed for the experiment F5. The worst results were observed for lower concentration of H_2O_2, higher concentration of iron and higher pH (F7 experiment). In fact, the analyse of the outputs obtained from the design of experiments enabled to conclude that among the parameters tested, only the H_2O_2 initial concentration should be considered as a relevant main factor from the statistical point of view. Moreover, none interaction between factors was statistically significant.

Table 2 – Design of Experiment condition tested for Fenton Process.

Experiments	H_2O_2(g/L)	Fe^{2+}(g/L)	pH
F1	14	1.5	7.9
F2	7.0	0.0	3.0
F3	7.0	1.5	3.0
F4	14	0.0	3.0
F5	14	1.5	3.0
F6	7.0	1.5	7.9
F7	7.0	0.0	7.9
F8	14	0.0	7.9

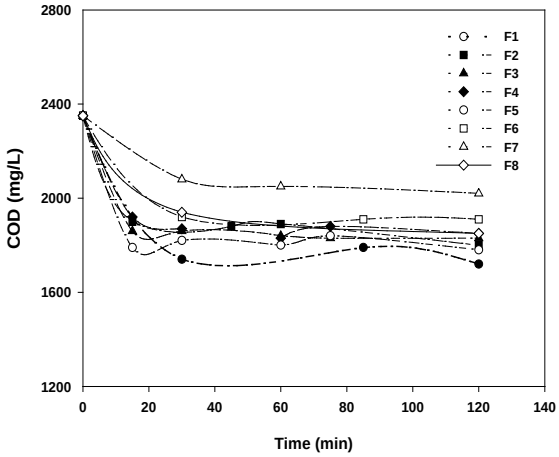

Figure 3 – Evolution along time of COD for sample S7 at condition F1 to F8 (Table 2).

3.4 Biological and Fenton treatments

For comparing both treatments, the initial and final COD, at the end of each treatment, were represented in Figure 4 and 5, where the percentage values indicate a reduction in these parameters. From these Figures, it is noticeable that the largest removal occurred for the biological treatment (70% reduction maximum) against 27% for Fenton process. However, the reaction time is much longer in biological treatment (order of days) while for Fenton process only a few minutes are required for partial chemical oxidation. These results were expected taking into account the characterization of landfill leachate tested. In fact, the effluent is characterized by high biodegradability (high BOD_5/COD), and thus one may conclude that the biological process is suitable for the treatment of this effluent. In this case, the Fenton process may be used in an integrated approach. At industrial level, the efficiency of the system of activated sludges is not enough for discharging the effluent into the environment. From our study, it seems that the Fenton process may be used after the leachate to be pre-treated by the biological process.

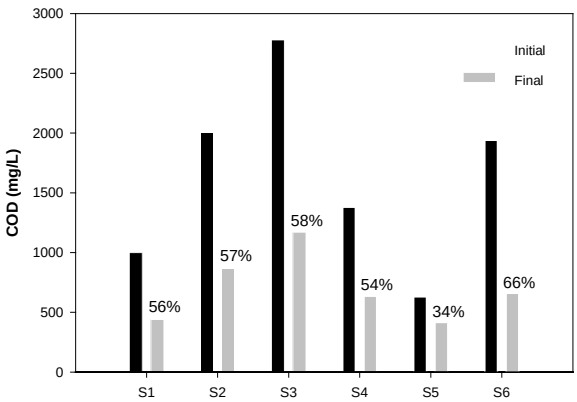

Figure 4 – COD removal for sapmles S1 to S6.

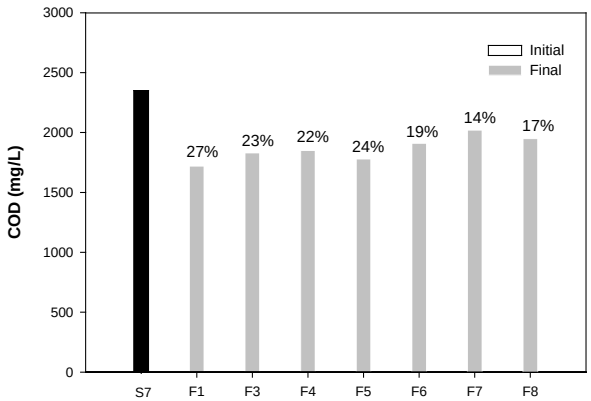

Figure 5 – COD removal for sample S7 and for experiments F1 to F8.

4 Conclusions

The main objective of this work was to compare the performance of the biological treatment with Fenton process for landfill leachate. Once the tested effluent is characterized by high biodegradability (high CBO_5/COD), the biological treatment leads to better results than the process of Fenton. However, the biological process needs a long period for degradation. Contrarily, Fenton process is fast for COD removal, being necessary only a few minutes (15 - 30 min). Moreover, the analyse of the outputs obtained from the design of experiments enabled to conclude that among the parameters tested and for the system under study, only the H_2O_2 initial concentration should be considered as a relevant main factor from the statistical point of view. Since at industrial scale, the biological treatment is not enough to achieve the compliance with regulatory limits, one may suggest the integration of biological treatment followed by Fenton.

Topic: Sustainable process-product development through green chemistry.

Abstract

Drill-in fluid systems usually comprise natural polymers like starch as the main component. During the drilling operation, the polymer deposit as a filter-cake on the wellbore wall in permeable formations due to its filtration into the rock pores. Before prodution or injetion could start, filter-cake removal is a demand. The application of acids or strong oxidative solutions is a traditional approach to well clean-up. However, these compounds are non-specific and can react with species that are acid soluble or oxidizable, including formation walls, lines, hydrocarbons, etc. Thus, enzymatic preparations are an alternative to filter-cake removal. Enzymes are very specific catalysts, inherent environmental friendly and can be used to hydrolyse filter-cake main polymer, as starch. In this work, a kinetic study of a filter-cake enzymatic breaker and a commercial α-amylase were investigated face to their starch hydrolysis capability at 65 and 80^{o}C in brine solution. Their kinetic parameters (Km and Vmax) were obtained under well operational conditions. In brine solution ocurred a mixed-type inhibition. Synthetic unconsolidated sandstone samples were used to simulate a natural formation reservoir from typical deep oil field at Campos Basin (Rio de Janeiro-RJ, Brazil) in filtration tests carried in HPHT (high pressure high temperature) cell, with a 5% (w/v) enzymatic fluid at 65^{o}C. Both enzymatic products were able to hydrolyse starch in the internal filter-cake, leading glucose and maltose as main reaction products. Filtration rates were measured and the filter-cake enzymatic breaker presented a higher filtration rate mostly due to the emulsification activity (28.57%) detected, indicating that the enzymatic breaker probably attained a better self-diffusion into the filter-cake.

1 Introduction

Horizontal wells are increasingly used to maximize well productivity due to its higher efficiency and cost effective in draining hydrocarbons from the underground. Drilling fluids are used in field operations for cooling the drilling head, transporting stone and control well pressure. Most drilling fluids are designed to build up a filter-cake on the boreole wall formation production or injection zone to ensure fluid loss. Initialy a filter-cake is needed to limit the leak-off of drilling fluid and fitrate into the formation. In many well completions, before production or injection operations can start, filter-cake must be removed and it can be done by mechanical and/or chemical procedures. When the filter-cake is not properly cleaned-up, it causes formation damage reducing the productivity (Hanssen *et al.*, 1999). Thus, the filter-cake removal process reduces significantly the formation damage and improves the oil production. Drill-in fluids systems are usually comprised of starch, xanthan gum and calcim carbonete in a base brine solution. Starch is the main component in many drilling fluids and consequently in filter-cake. Thus, starch degradation improves significantly filter-cake removal (Queiroz, 2006).

* Corresponding author. Tel +5521 25627622. E-mail: alice@eq.ufrj.br

The application of acids or strong oxidative solutions is a traditional approach to well clean-up. However, these compounds are non-specific and can cause permeability damage by re-precipitation of dissolved components (Hanssen *et al.*, 1999). Considering such problems, enzymatic preparations are presented as an alternative to filter-cake removal. First applications in oil industry were as blends of few generic hydrolytic enzymes. Enzymes are very specific catalysts, inherent environmental friendly and can be used to hydrolyse filter-cake main polymer, as starch (Batttistel *et al.*, 2005). Although downhole conditions may limit enzyme activity, many wells operate within the range 65-80^{o}C, as Brazilian ones, and some biocatalysts may tolerate well environmental conditions of pressure and temperature. (Kameda *et al.*,2007).

The main motivation for this work was to investigate starch degradation under openhole operation conditions for a commercial α-amylase and a filter-cake enzymatic breaker through a kinetic analysis. Filtration tests to evaluate stach degradation on filter-cake were taken as well.

2 Materials and Methods

Materials

Commercial amylase (Termamyl) from *Bacillus licheniformis* was gently provided by Novozyme A/S (Paraná, Brazil) and a commercial enzymatic filter-cake breaker (CENPES/PETROBRAS, Brazil) were used for comparative studies. CENPES/PETROBRAS also gently provided a completion fluid, i.e. a brine solution 9.4 ppg (pounds per gallon) / 203.57g/L NaCl, and drilling fluid comprising starch (8g), xantam gum (1.5g), NaCl (9g), $CaCO_3$ (35g) glutaraldehyde (1mL), MgO (1g) and distilled water (350mL).

Amylolytic activity

The enzymatic activity was measured by the increase of reducing sugars content as a result of starch hydrolysis, spectrophotometrically quantified according to modified dinitrosalicylic acid (DNSA) method (Miller, 1959). α-amylase activity was assayed by incubating 0.5mL of enzyme solution within 0.5mL soluble starch (1%, w/v) prepared in 0.02M sodium phosphate buffer (pH 6.9 and NaCl 0.05M). After 5min incubation at 30^{o}C the reaction was stopped by the addition of 1mL of DNSA solution and the resultant mixture was immediately heated at 100^{o}C for 10 minutes. The reducing sugars released were quantified at 540nm in a Hach DR/4000UV spectrophotometer. One activity unit (U) was defined as the amount of enzyme which releases 1 µmol of reducing end groups per minute in 0.02 M sodium phosphate buffer (pH 6.9) with 1.0% (w/v) soluble starch as substrate at 30^{o}C.

Emulsification index (EI)

The emulsification index was determined according to Iqbal *et al.* (1995) with a modification. The EI was determined by adding 1 ml of hexadecane to the same amount of sample, vortex-mixing for 2 min and leaving to stand for 24 hours. The sample EI is given as percentage of height of emulsified layer (cm) divided by total height of the liquid column (cm).

Determination of kinetics parameters

The enzyme kinetic parameters (Km and Vmax) were obtained at 65 and 80^{o}C. A sample of enzymatic product was incubated in a soluble starch solution (concentration ranging from 1.25 to 8.75mg/mL) prepared in 0.02 M sodium phosphate buffer (pH 6.9 and NaCl 0.05) or completion fluid (brine solution). The amount of reducing end groups formed was measured according to modified dinitrosalicylic acid (DNS) method (Miller, 1959) as previously described.

Filtration tests

The filtercake was build on the top of synthetic unconsolidated sandstone plugs (Figure 1) in a HPHT (high pressure high temperature) filter press working at 65°C with 500 psi (34,47 bar) overpressure for 2 hours. External filtercake was mechanically removed by a spatula. The plug with internal filter-cake was inserted into a HPHT cell and soaked with a 5% (v/v) enzymatic fluid (enzyme product in the brine solution) at 65°C. A overpressure range of 0 to 22psi was gently applied to enzymatic fluid pass through the plug and internal filter-cake, taking care to degrade filter-cake in the plug by enzymatic fluid while do not disturbing it mechanically. Fluid filtration through the plug was measured determining the filtrate fluid mass (Figure 2) along the assay. Internal filter-cake degradation was evaluated by the amount of reducing end groups formed in filtrate fluid. Control assays were also carried out by soaking internal filter-cake in brine solution without enzymatic products.

Figure 1.Synthetic unconsolidated sandstone plug

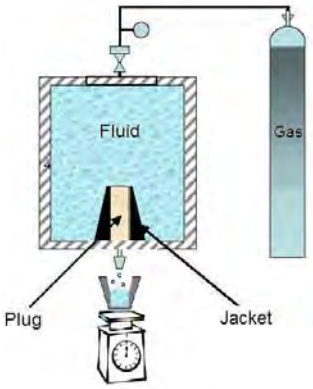

Figure 2. HPHT filtration system

3 Results and Discussion

Kinetic parameters

In previous work, Kameda *et al.* (2007) demonstrated that a commercial α-amylase solution were thermostable under certain completion conditions (65°C in brine solution - NaCl 3.5M or 203.57g/L), but at 80°C some reduction in amylolytic activity occurred and at 95°C no activity remained. A filter-cake enzymatic breaker catalysis was herein investigated under identical conditions (65 or 80°C in brine and in buffer solutions) and its performance was compared to the previously reported commercial α-amylase, through a kinetic study of both products. The results demonstrated that both were able to hydrolize starch in the assay conditions.

Commercial α-amylase seems to behave according to Michaelis-Menten kinetics in buffer solution (Figure 3) as expected (Li *et al.*, 2007, Toledo *et al.*, 2007, Lopez *et al.*, 2006) and in brine solution as well. Enzymatic breaker seems also to follow Michaelis-Menten kinetics in buffer and brine solution (Figure 4). However reaction velocity clearly decline in brine solution for both products assays.

Kinetic parameters (Km and Vmax) for both products were determinated by Lineaweaver-Burk plot for all conditions tested (Table 1). At 65°C (Figures 5 and 6) and 80°C (Figures 7 and 8) as well, a mixed-type inhibition in brine solution can be considered affecting both Km and Vmax values of the enzyme formulations (Segel, 1993). Higher Km values of commercial α-amylase suggest lower affinity in brine solution at both temperatures tested (Table 1). Identical behavior occurred also with enzymatic breaker.

Table 1. Kinetic parameters of commercial α-amylase and enzymatic braker in starch hidrolisis reaction under assay conditions.

	Temperature (°C)	Media	Km (mg/mL)	Vmax (µmol/mL.min)	R^2
α-Amylase	65ºC	Buffer solution	1,26	1,45	0,98
		Brine solution	8,50	0,93	0,99
	80ºC	Buffer solution	1,24	2,41	0,98
		Brine solution	5,70	0,91	0,99
Enzymatic breaker	65ºC	Buffer solution	3,36	3,80	0,99
		Brine solution	6,54	0,94	0,99
	80ºC	Buffer solution	3,42	4,23	0,99
		Brine solution	2,75	0,41	0,99

Filtration tests

Synthetic unconsolidated sandstone samples (Figure 1) were prepared appropriately accordding the method described by Queiroz (2006) to simulate a natural formation reservoir from typical deep oil field at Campos Basin (Rio de Janeiro-RJ, Brazil). Resultant filtrate mass was measured and the filtration rate was determinated (Table 2). Battistel *et al.* (2005); Al-Otaibi *et al.* (2004) and, Hanssen *et al.* (1999) reported higher overpressure range (100 – 500psi) compared to the values herein reported. However, these authors used ceramic discs as filtration medium that present lower permeability than the synthetic unconsolidated sandstone samples herein used.

Table 2. Filtration rates of enzymatic fluids at 65°C through internal filter-cake in synthetic unconsolidated sandstone samples.

Fluid	Filtration rate (g/min)	Δt (t_{final}-$t_{initial}$) (min)	Overpressure range (psi)	R^2
Brine solution (blank test)	3,8047 (±0,15)	19	20 - 22	0,99
α-Amylase	7,2431 (±0,93)	20	22 - 22	0,99
Enzymatic breaker	30,317 (±7,51)	10	17 - 20	0,99

1 bar ≅ 14,5 psi

Filtrations tests results showed that enzymatic fluids enhance filtrations rates (Table 2). Enzymatic fluid should contact the polymer into the filtercake to clean-up the rock pore. This contact could be established by enzyme flowing into the filter-cake with the help of additives that can act as a surfactant. Since the enzymatic breaker fluid showed higher filtration rate than commercial α-amylase (Table 2), assays for emulsification activity were carried and the former product presented emulsification activity (EI=28.57%) while the commercial α-amylase does not. Such result indicates that probably the enzymatic breaker attained a better self-diffusion into the filtercake, leading to such higher filtration rate.

Filter-cake degradation was evaluated by quantifying reducing sugars in the filtrate. As shown in Table 3, both enzymatic products were able to hydrolyse starch in the internal filter-cake being glucose and maltose detected as the main reaction products by high performance liquid chromatography (HPLC – data not shown). These results showed that both products could produce almost same reducing sugar quantity.

Table 3. Reducing sugar concentration in resultant fluid from filtration tests.

Fluid	Reducing sugar in resultant fluid (μmoles/mL)
Brine solution (blank test)	0,28
α-Amylase	2,89
Enzymatic breaker	3,16

4 Conclusions

Commercial α-amylase and filter-cake enzymatic breaker were able to hydrolise starch in completion operation conditions in all assays tested. Kinetics parameters values were affected in brine solution for both products, leading to a mixed-type inhibition in this latter condition.

On filtration tests, filter-cake enzymatic breaker presented higher filtration rate most probably due to the emulsification activity detected improving enzymatic breaker filtration rate, since both products produced almost same quantity of reducing sugar in the resultant fluid.

Topic: Integration of life sciences & engineering.

Abstract

Inhibition of angiotensin converting enzyme (ACE) has proved to have beneficial effects in the treatment of several cardiovascular disorders. The aim of this study was to evaluate ACE inhibitory potential of phenolic compounds. Isolated compounds and white grape seeds polyphenolic extracts were studied. A fluorometric method was used to detect the formation of histidyl-leucine, after hydrolyses of hippuryl-histidyl-leucine by ACE action, in the presence and absence of polyphenolic compounds. Phenolic extracts from grape seeds are endowed with higher inhibitory power of ACE than the pure monomers. A synergetisc effect of different compounds, longer polymerization degree in the extracts composition, associated with the view that the structure and hydroxyl groups can define inhibitory effect, may explain these unexpected findings.

1. Introduction

Several epidemiological studies have shown associations between the regular consumption of flavonoid-rich foods and a decreased risk for cardiovascular disease (Middleton et al., 2000; Nijveldt et al., 2001; Hung et al. 2004). Angiotensin II is a very potent agent that causes the muscles surrounding blood vessels to contract and thereby decreases blood flow. The angiotensin-induced constriction of blood vessels increases the pressure within the vessels and can cause hypertension. Angiotensin II is formed from angiotensin I in the blood by an enzyme, the Angiotensin I Converting Enzyme (ACE).

ACE is a glycoprotein peptidyldipeptide hydrolase, that cleaves angiotensin-I to produce angiotensin-II and also hydrolyzes and inactivates the vasodilator peptide, bradykinin to inactive peptides (Actis-Goretta, et al., 2003, 2006).

ACE inhibition is considered to be an important therapeutic approach in the treatment of high blood pressure, and the intake of certain synthetic inhibitors provides definitive positive health effects ((Middleton et al., 2000; Nijveldt et al., 2001; Hung et al. 2004). However, as ACE inhibitors are pharmacological drugs their use in healthy or low-risk populations is not advisable. The finding that certain flavonoid-rich foods can reduce blood pressure and inhibit ACE activity, opens up the possibility that consumption of select flavonoid-rich foods may

* Corresponding Author: Tel.: +351 225 513 642; E-mail: jafonso@med.up.pt

mimic synthetic ACE inhibitors and provide health benefits, but without adverse side effects (Actis-Goretta, et al., 2003, 2006).

Grape seed (*Vitis vinifera*) is a well known oilseed crop containing typically between 5-10% of phenolic compounds, and may be obtained by solid-liquid extraction with methanol and acetone/water. Subsequent fractionation may be carried out by graded methanol/chloroform precipitation, producing a broad range of extracts with decreasing average degree of polymerization (DPn)

Our research team accomplished previous tasks and characterized such fractions by ESI-MS/MS (Passos et al., 2007) and thiolysis (pre-treatment) followed by HPLC-UV detection, from which the corresponding DPn values were determined. The same extracts have been also characterized by FT-IR spectroscopy within the region of 1300-800 cm^{-1} (Passos et al., 2008).

The main objective of this work is the evaluation of the impact such natural phenolic extracts have upon ACE activity. This study started with monomers (+)-catechin, (-)-epicatechin, catechin-*O*-gallate and epigallocatechin. Afterwards, fractions of natural extracts of grape seed have been also evaluated. A comparison is accomplished with captopril, a synthetic compound commonly used for the treatment of hypertension and some types of congestive heart failure.

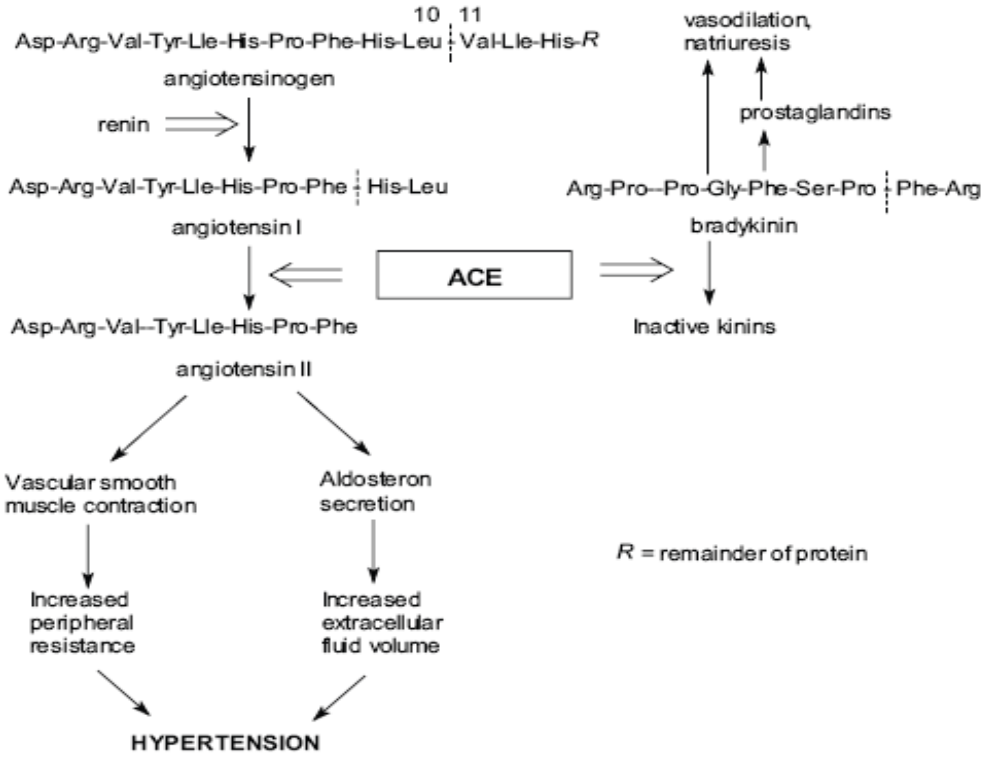

Figure 1 – The suggested hypertensive mechanism of Angiotensin (Hansen et al., 1995; Barbosa-Filho et al., 2006).

2. Materials and Methods

2.1 Extraction/fractionation of procyanidins crude extract (PCE) from grape seed

Detailed experimental procedure may be found elsewhere (Passos et al., 2008). In the following the main guidelines are presented.

Seeds were immersed into liquid nitrogen, milled in a domestic coffee mill and sieved (pore size<0.75 mm diameter). Extraction procedure was adapted from Guyot, Marnet, and Drileau (2001). A pre-treatment of three times extraction using n-hexane was applied to the seed powder to remove the lipids. Phenolic compounds were then extracted with a three times treatment with methanol containing 5% acetic acid (100 g seed powder/L MeOH). The acetic acid avoids the oxidation of compounds during extraction. The phenolic extracts were combined and filtered through, first a G1 and then a G3 sintered glass filter, and concentrated under vacuum at 40ºC, with several additions of water to assure the complete removal of methanol and acetic acid. Further, the see powder product of methanol extraction is treated with a mixture of acetone:water (2:3) and 5% acetic acid. The extraction with acetone: water mixture was repeated three times and the phenolic extract was treated in the same procedure as phenolic extract from methanol. Both methanol and acetone:water extracts were fractionated according to the methanol/chloroform graded precipitation proposed by Saucier et al (2001).

2.2 Inhibition of purified ACE activity

The ACE activity was assayed by fluorometric determination of the amount of histidyl-leucine (His-Leu) released from a substrate, hippuryl-histidyl-leucine (Hip-His-Leu), in the present of ACE. For the determination of ACE activity, 0,7 mM Hip-His-Leu substrate, in a reaction medium of 100 mM HEPES buffer (pH 8.3) containing 300 mM NaC1, was used to initiate all reactions after pre-incubation of ACE (0.75mU) at 37°C, for 3 min. When ACE activity was determined in the presence of inhibitor, the inhibitor was pre-incubated for 15 min with the enzyme before adding the substrate. The enzyme reaction was carried out at 37°C, for 30 min and then terminated with 1N sodium hydroxide. The His-Leu product in the reaction mixture was estimated following o-phthalaldehyde (0,2% in methanol) treatment, during 15 min, in the dark at 0ºC followed by neutralization with 1.5M phosphoric acid. The fluorescence of the o-phthalaldehyde condensation product of His-Leu was determined with a spectrophotofluorometer Spectramax Gemini (Molecular Devices, Sunnyvale, CA, USA) (360nm excitation, 480nm emission wavelength, cutoff of 420 nm). Different inhibitors were used. A first assay with pure phenolic compounds as inhibitors: catechin, epicatechin, catechin-O-gallate, epigallocatechin (0-100 uM) was tested. A second assay using different fractions of grape seeds extract was carried (0-30 mg extract/L).

3. Results and Discussion

Captopril was used as a positive control of ACE activity assay and shows a strongly effect on ACE inhibition in the nanomolar range (see Figure 2). Pure phenolic compounds were also tested: catechin, epicatechin, catechin-*O*-gallate and epigallocatechin. Catechin and catechin-*O*-gallate (100uM) decrease the ACE activity to 20.6 and 20.3%, respectively; epigallocatechin was able to decrease it in 35.5%; epicatechin performed in between.

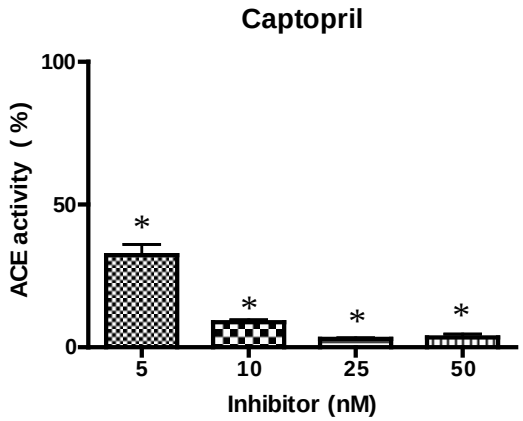

Figure 2 – Positive control of ACE activity assay. Captopril was incubated with ACE for 15 min, at 37ºC, previously the addition of substrate, HHL.

Phenolic extracts from white grape seeds were use to evaluate their capability to inhibit the ACE activity. The phenolic-grape seeds extracts used in this work were previously characterized (Passos et al., 2008). Extracts are constituted essentially by flavan-3-ols, a group with monomeric fractions of catechin, epicatechin, epicatechin-*O*-gallate units and polymerized molecules, the procyanidins. The three different fractions tested, WM-F2.2, WM-F2.6 and WA-F2.2, have different degrees of polymerization (DPn); WM stands for "white grape seed extracted with methanol", WA means "white grape seed extracted with a mixture acetone/water", and Fm.n identifies "fraction m.n" in the original work by Passos et al. (2007, 2008).

WM-F2.2 has the higher average DPn and WM-F2.6 the lower of the 3 extracts (8 and 6, respectively). The extract WM-F2.2 seems to a have highly inhibition effect on ACE activity, showing almost complete inhibition for 3 mg extract/L, whereas WM-F2.6 originates approximately 47% for the same concentration (see Figure 3).

WA-F2.2 has an average degree of polymerization DP_n=7, and produced inhibitory effects upon ACE well between those by WM-F2.2 and WM-F2.6.

The number of monomer units could define the extent and specificity of ACE inhibition. Studies evaluating the effect of albumin in the inhibitory action of procyanidins (since albumin has the ability to bind procyanidins) reveled that smaller oligomeric compounds (dimers and tetramers) were not affected in their inhibitory action on ACE while inhibitory action of hexamers were highly reduced. These results strengthen the view that larger procyanidins tend to exert broader interactions on protein surfaces. (Ottaviani, 2006). Moreover, kinetic analysis suggest that flavan-3-ols and procyanidins compete with the substrate for the active sites and indicating that larger molecules can inhibit both C- and N-active sites to a similar extent while monomers seem to inhibit preferentially the N-active site (Actis-Goretta, 2003).

However, the number of monomers appears not to define by itself the specificity of interaction with ACE. The way that monomers units are bound should also be considered, epicatechin dimers with different linkage bound structure had completely different effects in the activity of ACE (Ottaviani, 2006). Furthermore, when using an isolated enzyme, possible interactions with other cell structures by the higher procyanidins, are not taken in consideration. The number of hydroxyl groups on the procyanidins could also be related with

the interaction of procyanidins with the enzyme, since hydroxyl groups appear to determine the capability to adsorb to membrane surface (Actis-Goretta, 2003).

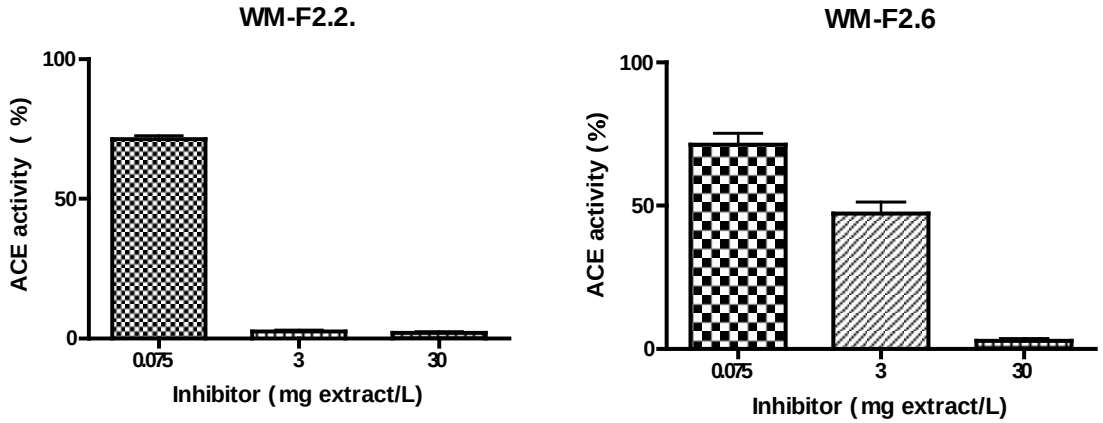

Figure 3 – ACE activity in the presence of different concentrations of white grape seed extracts obtained with methanol: WM-F2.2 and WM-F2.6.

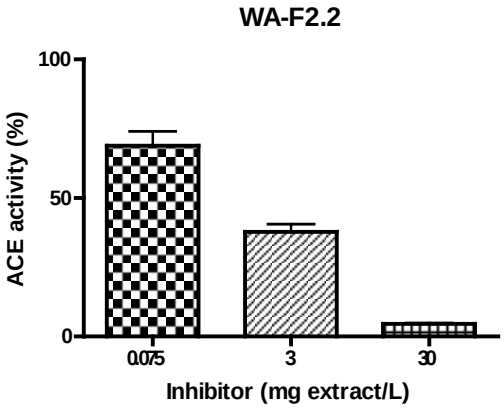

Figure 4 - ACE activity in the presence of different concentrations of the white grape seed extract obtained with a mixture of Acetone/Water: WA-F2.2.

4. Conclusions

Pure monomeric phenolic compounds were use to evaluate their capability to inhibit the ACE activity. Catechin, epicatechin, catechin-*O*-gallate, and epigallocatechin 100 μM decreased ACE activity to 20 to 35%.

Phenolic extracts from white grape seeds were also used to evaluate their inhibitory performance. A stronger effect has been clearly observed in comparison to the isolated monomers, suggesting that the longer degree of polymerization and perhaps a synergetic effect is achieved with such extracts. The differences found between different extracts indicate that the structure of procyanidins can define inhibitory effect in ACE as well hydroxyl group units.

Keywords: Polyurethanes**,** Aqueous dispersions, Solvent-free
Topic: Sustainable process–product development through green chemistry

Abstract

Over the past few decades, polyurethane-polyurea aqueous dispersions (PUDs) have developed a solid reputation for high performance applications, particularly in the field of adhesives and coatings. PUDs are mostly environmentally compatible products; they are totally devoid or contain only low amounts of volatile organic compounds (VOC). This is an important feature in view of the present environmental policies where governments and internal agencies are placing emphasis on developing sustainable processes, improving work conditions and reducing emissions of toxic and polluting substances into the atmosphere. Moreover, polyurethanes are known as “tailor-made” products with properties resulting from a wide diversity of raw-materials which can be combined in different ways during the synthesis.

In recent years, our research group has been involved in the development of polyurethane-polyurea aqueous dispersions for various applications. With this work we intend to review this theme and describe the most recent developments. Characterization of industrial dispersions will be presented and examples of synthesis will be described.

1 Synthesis of aqueous polyurethane dispersions: general concepts

The industrial production of PUDs is nowadays a well established technology. There are two main synthetic routes to produce PUDs: the acetone process (a former process developed by Bayer AG) and the pre-polymer process (developed as an alternative response to the patented acetone process). A schematic representation of the two processes, putting into evidence their similarities and differences, is shown in Figure 1.

The acetone process can be described as comprising five main stages: (1) formation, in bulk, of an isocyanate terminated pre-polymer from the reaction of a diisocyanate (aromatic or aliphatic) and a macrodiol (usually a polyester or polyether α,ω-diol); (2) pre-polymer dilution in acetone in order to suppress any viscosity constraints and also to dissolve the hydrophilic diamine; (3) chain extension. In this step, the hydrophilising diamine assumes a double role, i.e., it acts simultaneously as an internal emulsifier and a chain extender; (4) dispersion. Phase inversion is promoted by adding water to the previously generated polymer acetone solution; and (5) acetone removal to achieve a solvent-free product.

The described acetone process presents some advantages; it avoids viscosity constraints by using a low boiling point solvent, acetone, which will be easily removed at the end of the synthesis and can be further recycled and reused in the process. Moreover, it is described as a reproducible process yielding final products with good performance. The main drawback of this process is related to the associated costs. Owing to the use of large amounts of acetone,

* Corresponding author. Tel + 351-273 303 089. E-mail: barreiro@ipb.pt

it requires a high reactor volume and, in general, explosion-proof equipment. Moreover, acetone needs to be distilled and dried before recycling (Dieterich, 1981; Gertzmann et al., 2007).

The pre-polymer process can be described as comprising four main stages: (1) formation, in bulk, of an isocyanate terminated pre-polymer from the reaction of a diisocyanate (aliphatic), a macrodiol (usually a polyester or polyether α,ω-diol) and a hydrophilising diol. Since the hydrophilising diol is not soluble, neither in the pre-polymer mixture nor in acetone, it requires other co-solvents which are in general highly polar and low volatility components. In general, the co-solvent will remain in the final product; (2) neutralization of the internal emulsifier acid groups using a tertiary amine; (3) dispersion. Phase inversion is promoted by adding water to the previously produced pre-polymer and (4) chain extension, usually using a short diamine. If viscosity constraints are encountered during the process, acetone is added to dilute the medium. If so, the last stage will correspond to its removal. These steps (dilution and acetone removal) can be viewed as optional and are directly related to the chemical system used. As an example, polyester based formulations have higher viscosity than the counterpart polyether based formulations.

Comparatively to the acetone process, the pre-polymer process has one major advantage, i.e., it requires none or only small amounts of acetone. As main disadvantages, it uses other co-solvents that might be difficult to remove and will remain in the final product. Chain extension is carried out in heterogeneous medium in opposition to the acetone process that uses a homogeneous medium (acetone solution before dispersion). This could lead to incomplete isocyanate conversion (inaccessible isocyantes entrapped inside polymer particles) and consequently to a lower final molecular weight polymer (Dieterich, 1981).

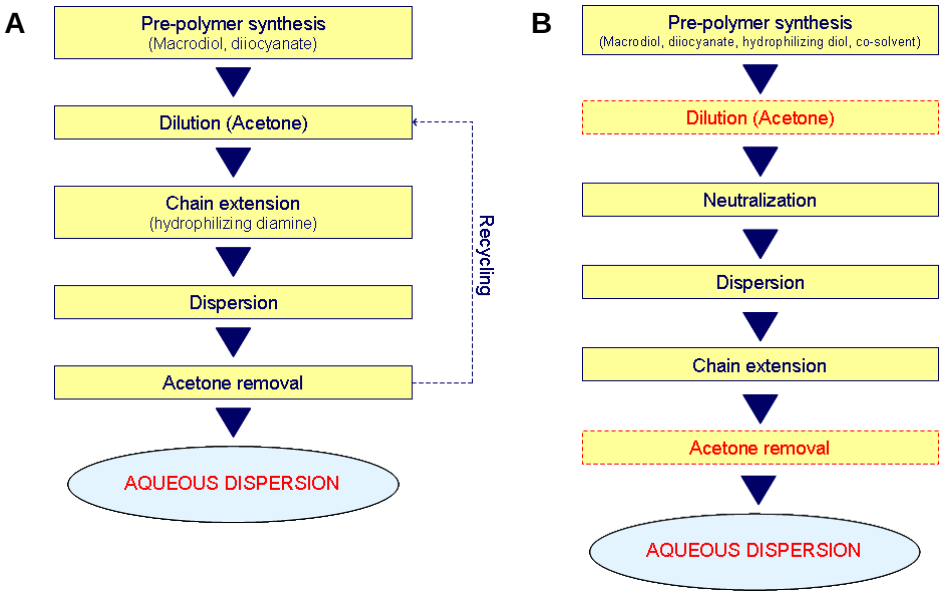

Figure 1 Schematic drawing of the acetone (A) and prepolymer (B) processes.

The chemical system associated to the pre-polymer process is rather complex and it involves polyols (mainly a polyester or polyether α,ω-diol), aliphatic diisocyanates to hinder isocyanate consumption due to water reactivity, hydrophilising diols that will act as internal emulsifiers, co-solvents to dissolve the hydrophilising diol and suppress process viscosity constraints, neutralizing agents to activate the ionic groups present in the internal emulsifier, chain extenders (mainly di- or tri- amines) to increment the molecular weight. Moreover catalysts are also added during pre-polymer synthesis.

Table 1 shows a set of typical chemical components used in the pre-polymer process and Table 2 presents a basic recipe for the synthesis of a polyurethane dispersion adapted from Kim Jung Hyun 's group research work (Cheong et al., 2002). This recipe uses a typical NCO/OH ratio of 1.7, a relative degree of neutralization of 100% and a chain extension degree of 100%. Typical used process temperature conditions are: 70 – 90 ºC during pre-polymer synthesis, 35 – 50 ºC during the neutralizing stage and 25 – 35 ºC during dispersion phase. The extension reaction is usually performed atroom temperature (around 25 ºC).

Our laboratory set-up for aqueous polyurethane production is shown in Figure 2. It comprises a reaction vessel of 500 ml, a mechanical stirrer, a silicone bath, a nitrogen inlet and controlled feed addition. Reaction temperature is controlled inside the reactive mixture by means of a thermocouple.

Table 1 Examples of typical chemical components used in the pre-polymer process

Component	Examples
Polyol	*Polyesters:* polyadipates, polycaprolactones (PCL) *Polyethers:* Polypropylene glycol (PPG), Polyethylene glycol (PEG), Polytetramethylene ether glycol (PTMG) *Others:* Polycarbonates (PC), acrylics
Isocyanates	*Aliphatic diisocyanates:* Dicyclohexylmethane Diisocyanate (HMDI), Isophorone Diisocyanate (IPDI), Tetramethylxylylene Diisocyanate (TMXDI)
hydrophilising diol	Dimethylol propionic acid (DMPA)
Co-solvents	*hydrophilising diol dissolution medium*: N-metil-2- pyrrolidone (NMP) *Viscosity control:* Acetone
Neutralizing agent	Triethylamine (TEA)
Chain extenders	Diethylene triamine (DETA), Hydrazine Monohydrate (HYD), Ethylenediamine (EDA)
Catalysts	Dibutyltin Dilaurate

Table 2 Basic recipe for the synthesis of polyurethane dispersions (*in Cheong et al*.)

Component	Amount (mol/g)
Polyhexamethylene adipate (polyol)	0.065 (130.0)
IPDI	0.176 (39.2)
DMPA	0.039 (5.2)
NMP	0.079 (7.8)
TEA	0.039 (3.9)
EDA	0.073 (4.4)

2 Considerations about the pre-polymer process face to the present environmental policies

The pre-polymer process, at present, is being forced to readapt due to ongoing developments, partly motivated by process constraints, raw materials restrictions and the need to obtain a true solvent-free product. Allied to this fact it is worth mentioning the upcoming of European REACH legislation, which is expected to have a considerable influence on the PUD industry. Most of the industrially produced PUDs use dimethylol propionic acid (DMPA) as the internal emulsifier. DMPA is sparingly soluble in the reactive mixture and needs to be previously dissolved in an organic solvent. The chosen solvent must fulfil a series of criterions: dissolve DMPA, be inert towards isocyanates and be miscible in water. Additionally it must present low odour and low cost. Alternatives to the traditionally

used option (N-methyl-2-pyrrolidone, NMP) include ketones, cyclic ethers, amines and amides.

NMP has one major problem; it has a high boiling point, near 200 ºC, and thus remains in the final product. The upcoming product restrictions refer that all products containing more than 5% (w/w) of NMP will be considered toxic from June 2009 onwards (Mestach and Goossen, 2007) and at present almost all commercially available PUDs have NMP contents from 5-15 %. In this context, the NMP-free concept is gaining a growing importance, particularly for PUD industry which uses the pre-polymer process.

1. Silicone bath
2. Reactor vessel with lid including thermocoulple, condenser, nitrogen and feed inlets
3. Mechanical stirrer
4. Peristaltic and vacuum pumps
5. Condenser for acetone recover
6. Computer for control and data registration

Figure 2 Bench scale set-up for preparing aqueous polyurethane dispersions.

Some new markets for PUD, where restrictions are even more specific, such as adhesives for food contact, are justifying also additional studies. In this case, besides the absence of solvents, the raw materials must be carefully chosen to avoid toxicity, component migration and noticeable smell. Moreover, there is a lack of protocols to characterize these issues (Petrie, 2007).

In USA, Food and Drug Administration (FDA) regularizes the allowed reactants through the elaboration of positive lists. Reactants allowed to be incorporated in the synthesis of PUD adhesives for indirect food contact are catalogued in the 21CFR 175.105 positive list. In the European Union (EU) context, since 1989 the legislation has been harmonized and the main restrictions were assembled in one directive: the “Plastics Directive”, 2002/72/EC. It is worth to mention that adhesives are not yet treated as an individual regulated group (Petrie, 2007). A summary of the existing limitations considering PUD production in general using the EU directive 2002/72/CE and FDA positive list 21CFR 175.105 are shown in Table 3.

3. New challenges to PUD formulators

Owing to the described restrictions PUD formulators are obliged to readapt and test alternatives to the traditional pre-polymer process:

NMP free concept. Presently, there are some alternatives to achieve the NMP-free concept. Among them we may refer the direct NMP replacement by an equivalent solvent, DMPA replacement by an equivalent hydrophilising diol but with better solubility in the reactive mixture, and replacement of the macrodiol by one of the commercially available new macrodiols with incorporated ionic groups in the molecular backbone (Gertzman et al., 2007).

NMP direct replacement. For direct NMP replacement some alternatives could be envisaged, namely, using dimethylsulfoxide (DMSO) or N-ethyl-2-pyrrolidone (NEP). DMSO has one major disadvantage related to the presence of strong odour that intensifies as a result of exothermic decomposition (formation of dimethylsulfide). NEP was been recently

commercially announced as a directly obvious alternative to NMP. Nevertheless it presents as a drawback the fact of being a new product, which is at present too expensive and insufficiently studied. Other possible NMP substitutes are ketones (acetone or methyl ethyl ketone (MEK)). Ketones have an additional benefit: their low boiling point allows an easy removal by vacuum distillation from the final product. However, DMPA presents low solubility in ketones and its incorporation will require large volumes of solvent. As a reference, 1 g of DMPA needs 250 ml acetone to solubilise.

DMPA replacement. Another alternative will be the direct DMPA replacement by an equivalent hydrophilising diol but with higher solubility in the reactive mixture, such as dimethylolbutanoic acid (DMBA). DMBA is more soluble both in acetone and in the relevant macrodiols than DMPA (Gertzmann, et al., 2007). Even so, DMBA has two main problems; it is a relatively new product, more expensive and the properties imparted to the developped products, which are still under study, may often not be better.

Macrodiols with incorporated ionic groups. It is also feasible to replace DMPA by macrodiols with incorporated ionic groups in the molecular backbone (Gertzman et al., 2007). These products are already available in the market. However, two major disadvantages are their high viscosity and high cost.

DBTDL replacement. Another important question in PUD industry is the changing of hazard classifications now labelling tin catalysts as toxic instead of harmful. This issue will have a great impact in PUD industry since the most applied catalyst is a tin based one (dibutyltin dilaurate, DBTDL). DBTDL is used worldwide mainly because it presents excellent catalytic effect and is selective towards hydroxyl reaction with isocyanates. A direct alternative is the use of amines, but the recent established restrictions also pose limits to these compounds. New alternatives are being made available in the market, among them the most effective to PUD synthesis are zinc and bismuth carboxylates and zirconium complexes. But again, there is a lack of studies about their catalytic performance in PUD synthesis. Comparatively to the presently used catalysts they are rather expensive (Extance, 2007).

Table 3. PUD component limitations face to EU directive 2002/72/CE and FDA positive list 21CFR 175.105

Component		Directive 2002/72/CE	FDA
Diisocyanate	Dicyclohexylmethane Diisocyanate	QM(T)=1mg/Kg (free NCO)	21CFR 175.105
	Isophorone Diisocyanate		21CFR 175.105
	Tetramethylxylylene Diisocyanate		
Poliol	Polycaprolactone	Without limitations	NR
	Polypropylene glycol		21CFR 175.105
	Polyethylene glycol		
	Polytetramethylene ether glycol		
Catalyst	Dibutyltin Dilaurate	NR	Only allowed as Polyurethane catalyst
Internal Emulsifier	Dimethylol propionic acid	QM(A)=0.05 mg/6dm^2 (free DMPA)	21CFR 175.105
	Dimethylolbutanoic acid	NR	21CFR 175.105
Neutralizing Agent	Triethylamine (TEA)	NR	21CFR 175.105
Chain Extender	Diethylene triamine	LME=5 mg/Kg	21CFR 175.105
	Hydrazine Monohydrate	NR	NR
	Ethylenediamine	LME=12 mg/Kg	21CFR 175.105
Co-Solvent	N-ethyl-2-pyrrolidone	NR	NR
	Dimethyl sulfoxide	NR	NR
	Acetone	Without limitations	21CFR 175.105
	N-metil-2- pyrrolidone (NMP)	NR	NR

NR- not referred, QM(T)- Maximum total amount, QM(A)- Maximum amount allowed, LME- Specific Migration Limit

4 Examples of PUD characterization – typical technical data

The characterized PUDs were kindly supplied by Bayer Material Science and Alberdingk Boley GMB. The relevant properties according to the characterization presented in the technical data sheet were performed and shown in Table 4.

PUDs were described in terms of solids content and pH, viscosity (measured with a Visco Star Fungilab viscometer of concentric cylinders, equipped with an Electro Temp heating/refrigerating bath) and Mean Particle Size and Particle Size Distribution (analyzed by laser dispersion using a Coulter LS230 instrument).

Table 4 Characterization of a commercial PUD

Properties	**Sample**			
	PUD1	PUD2	PUD3	PUD4
Solid Content (%, w/w)	50.5	41.0	40.8	36.6
Viscosity (mPa.s)	46.5	24.4	17.1	61.6
pH	7.0	7.6	7.4	7.7
Mean Particle Size (nm)				
Volume distribution	113	107	115	107
Number distribution	56	103	110	103

PUD 1 (Dispercoll U56), PUD2 (Alberdingk U3251), PUD3 Dispercoll XP2578) and PUD4 (Bayhydrol XP2593/1)

5 Conclusions

Over the past few decades, polyurethane-polyurea aqueous dispersions (PUDs) have developed a solid reputation for high performance applications, particularly in the field of adhesives and coatings. The industrial production of PUDs is nowadays a well established technology. There are two main synthetic routes to produce PUDs: the acetone process (a former process developed by Bayer AG) and the pre-polymer process (developed as an alternative response to the patented acetone process).

PUD industry in general and the pre-polymer process in particular, are facing some challenges due to the emerging new markets and environmental restrictions. According to FDA and EU legislation, substitutes for some of the traditionally used raw materials need to be found and implemented. A strong effort should be done in terms of both the optimization of the systems already implemented and the search for new ones. This will be achieved by means of basic, technological and economical research.

Keywords: Chemical Reaction Network, Regression, Stoichiometry.
Topic: Systematic methods and tools for managing the complexity.

Abstract

The aim of this work is a move towards the automated determination of chemical reaction networks, from batch process data. In this paper it is demonstrated how, in principal, this may be achieved using simple systematic mathematical and statistical analyses of the process data. Initially a global ordinary differential equation (ODE) model structure, capable of representing an entire set of possible chemical reactions, is specified and decoupled. Regression analyses are then used to reduce the ODE model structure to a subset of reactions. Rationalisation procedures that exploit the basic rules of reaction chemistry and a number of mathematical principals, often employed in biological systems theory (BST), are incorporated to ensure consistent chemical reaction networks are obtained. The methods are demonstrated using a simulated case study. It is concluded that it is possible to successfully determine chemical reaction networks, and their associated rate constants, from batch process data.

Introduction

The primary objective of this paper is to present an incremental approach to network identification. The method is based upon the use of composition and the rate of heat evolution ($\mathbf{q_R}$) data. Where $\mathbf{q_R}$ data may readily be obtained from a reaction calorimeter. During early process development in the fine chemical industry reaction calorimeters are used for systematic and quick characterization of the relevant kinetic and thermodynamic reaction parameters. $\mathbf{q_R}$ represents the sum of individual heats of reaction multiplied by the rates of reaction and may therefore be used to obtain kinetic data (see Wright *et al*, 1993 and Zogg *et al*, 2004).

This paper is split into seven stages a) the kinetic models are specified as decoupled ODEs, b) simulated batch process data is generated to demonstrate the techniques, c) singular value decomposition (SVD) is used to estimate the number of reactions occurring, (N_R), d) given N_R and the $\mathbf{q_R}$ data, regression procedures are applied to reduce the number of concentration terms to a subset of N_R terms, e) multiple linear regression (MLR), based on the composition data, is then used to obtain parameter estimates, thus, determine the concentration terms that are influential on the individual ODEs, f) as each ODE is considered separately a rationalisation procedure is applied to ensure consistent chemical reaction network equations are obtained that preserve system stoichiometry and g) the isothermal rate constants are estimated and the network is constructed.

As opposed to the rationalisation strategy described in Burnham *et al* (2008), the strategy here is to use topological features of the reaction network that may be obtained from the elemental matrix (particularly the atomic matrix). These topological features provide mathematical constraints that may be used to determine whether the estimated model parameters (and stoichiometries) are consistent with the atomic matrix and, given the event that they are not, constrain them to be. It is also possible to check that the (constrained) estimated model parameters (and stoichiometries) are consistent with the process data.

Kinetic models

Assuming batch, isothermal, operation, the (1 x N_R) vector of reaction step rates (RSRs) at any specified time instant, t, $\mathbf{r_r}$, may be defined by (1).

$$\mathbf{r_r} = \mathbf{Kr} \tag{1}$$

Where **K** is a diagonal matrix of the rate constants, **r** is a (1 x N_R) vector of relevant concentration terms, at the same specified time point. Assuming mass action kinetics and elementary reactions the concentration terms may be specified as the products of the concentrations of the reacting species, in the respective reaction, raised to a power equal to their order of reaction. For example, consider the Van de Vusse reaction scheme (Van de Vusse, 1964) involving three reactions and four chemical species, (2). Thus, **r** would be given by (3).

$$x_1 + x_1 \rightarrow x_2 \qquad x_1 \rightarrow x_3 \rightarrow x_4 \tag{2}$$

$$\mathbf{r} = \begin{bmatrix} x_1^2 & x_1 & x_3 \end{bmatrix} \tag{3}$$

Further, the species rate expression (SRE), which defines the rate of change of concentration of the species i due to reaction, can be expressed as the sum of the RSRs that are associated with the reaction steps in which species i is involved, multiplied by the stoichiometric coefficient of species i in that reaction step. Thus, for n species, a (1 x n) vector of the SREs, $\mathbf{r_s}$, may be defined by (4).

$$\mathbf{r_s} = \mathbf{VKr} \tag{4}$$

The (n x N_R) stoichiometric matrix **V** describes the topology of a chemical reaction network. The stoichiometries of the chemical species in the reactions, which make up the network, provide the entries of the stoichiometric matrix. For a network with n species and N_R chemical reactions, the stoichiometric relationships, which are assumed to be time invariant, are given by (5a). Where $v_{i,l}$, i = 1, …, n, l = 1, …, N_R, are the stoichiometric coefficients for the i^{th} species in the l^{th} reaction. For the reaction scheme given by (2), the stoichiometric matrix is then given by (5b).

$$\mathbf{V} = \begin{bmatrix} v_{1,1} & v_{1,N_R} \\ & \\ v_{n,1} & v_{n,N_R} \end{bmatrix} \qquad \mathbf{V} = \begin{bmatrix} -2 & -1 & 0 \\ 1 & 0 & 0 \\ 0 & 1 & -1 \\ 0 & 0 & 1 \end{bmatrix} \tag{5}$$

For any reaction step it can be noted that $v_{i,l} > 0$ represents a product formed by that reaction step, $v_{i,l} < 0$ represents a reactant consumed by that reaction step. $v_{i,l} = 0$ may represent either a catalyst or a species not involved in that reaction step.

For a batch, isothermal reactor, the total rate of heat evolution due to reaction per unit volume is $\mathbf{q_R}$, this may be equated to the sum of individual heats of reaction multiplied by the rates of reaction (7) where **h** (1 x N_R) is a vector of the individual heats of reaction, and for the reaction scheme given by (2) these are arbitrarily assigned in (8).

$$\mathbf{q_R} = \mathbf{hKr} \tag{7}$$

$$\mathbf{h} = \begin{bmatrix} -8e^4 & -1e^4 & -1e^5 \end{bmatrix} \tag{8}$$

It is possible to specify a set of possible concentration terms that may be used to define the structure of the RSRs/SREs. If it is assumed that a) the reactions are at most the result of bimolecular collisions and the total reaction order is no greater than two, b) the concentration terms are of integer order with respect to each species concentration and c) there are no terms consisting of purely zero order elements. Then, given the n species, a set of all of the possible concentration terms that may appear in the RSRs, S_C, are given by (9).

$$S_C = \left\{ [x_h],\ [x_h][x_j] \right\}, \quad h = 1,\cdots,n;\ \ j = h,\cdots,n \tag{9}$$

Where the total number of possible concentration terms, n_c, is given by (10).

$$n_c = 2n + \frac{n(n-1)}{2} \tag{10}$$

Thus, the vector **r** may become $\hat{\mathbf{r}}$, (11), which is a vector of all of the possible concentration

terms defined by (9).

$$\hat{\mathbf{r}} = \begin{bmatrix} [x_1] & [x_2] & \cdots & [x_n] & [x_1]^2 & [x_1][x_2] & \cdots & [x_n]^2 \end{bmatrix} \quad (11)$$

For the reaction scheme given by (2), $\hat{\mathbf{r}}$ may be defined as (12).

$$\hat{\mathbf{r}} = \begin{bmatrix} [x_1] & [x_2] & \cdots & [x_4] & [x_1]^2 & [x_1][x_2] & \cdots & [x_4]^2 \end{bmatrix} \quad (12)$$

Parameter estimates are obtained for each possible concentration term (term in $\hat{\mathbf{r}}$) for each SRE in (4). Therefore, a (n x n_c) matrix $\boldsymbol{\Theta}$ of parameters may be defined, where $\boldsymbol{\Theta}$ is an estimate of **VK** and, for $\hat{\mathbf{r}}$ defined as (12), is given by (13).

$$\boldsymbol{\Theta} = \begin{bmatrix} \theta_{0,1,1} & \theta_{0,2,1} & \cdots & \theta_{1,1,1} & \cdots & \theta_{4,4,1} \\ \vdots & & & & & \vdots \\ \theta_{0,1,4} & \theta_{0,2,4} & \cdots & \theta_{1,1,4} & \cdots & \theta_{4,4,4} \end{bmatrix} \quad (13)$$

As the SREs represent the rate of change of species concentration, (4) may be rewritten as (14), a general set of ODEs which represents the entire set of possible chemical reactions. Where $\dot{\mathbf{x}}$ is a vector of the rates of change of species concentrations at a specified time instant. It should be noted that for the reaction scheme given by (2), ideal parameter estimation would give the non zero estimates $\theta_{0,1,1}$= -k_2, $\theta_{1,1,1}$= -2k_1, $\theta_{1,1,2}$= +k_1, $\theta_{0,1,3}$= +k_2 $\theta_{0,3,3}$= -k_3 and $\theta_{0,3,4}$= +k_3.

$$\dot{\mathbf{x}} = \boldsymbol{\Theta}\hat{\mathbf{r}} \quad (14)$$

Further the rate of heat evolution (7) may be rewritten as (15), where correct parameter estimation would provide the estimates $\varphi_{0,1}$=$\Delta H_{R2}k_2$, $\varphi_{0,3}$= ΔH_{R3},k_3 $\varphi_{1,1}$=$\Delta H_{R1}k_1$.

$$\mathbf{q_R} = \boldsymbol{\Phi}\hat{\mathbf{r}} \quad (15)$$

Generating process data

For reaction scheme (2), it was assumed that it was only possible to alter the initial concentrations of the reactant x_1. Four simulated batch experiments were performed, where the levels of initial concentration of x_1 were chosen to be equidistant between 0.25 and 1.00 moldm^{-3}. Note that the volume of each batch is specified as 1 litre and that the reactions take place in an inert solvent. The kinetic rate constants were specified as k_1 = 0.00100 min^{-1}mol^{-1}dm^3, k_2 = 0.00685 min^{-1} and k_3 = 0.00248 min^{-1}. Eleven concentration measurements of each species were generated, for each simulated batch experiment, by numerical integration of the true system ODEs, that represent the SREs, using the initial reactant concentrations specified above. The total simulation period was specified as 1200 mins and measurements of all species were recorded every 120 mins. In this case no simulated measurement error was added to the signals. For the last batch (initial concentration of x_1 at 1.0 moldm^{-3}), the simulated concentration data and the fits of this data are given by figure 1. The rate of heat evolution data, $\mathbf{q_R}$, was also generated, using (7) given (8), at the same sampling times, refer to figure 2.

Estimating the number of reactions

It is known that $\mathbf{r}$ may be estimated as $\hat{\mathbf{r}}$, (11) but only N_R of the set of n_c concentration terms in $\hat{\mathbf{r}}$ are relevant. Methods to calculate the actual number of reaction steps from measured process data have been suggested in the literature e.g.Hamer (1989) and Bonvin and Rippin (1990) have demonstrated that the number of reactions may be obtained from a SVD analysis (Lawson and Hanson, 1974) of the matrix of the process data.

Based on the work of Burnham *et al* (2008), the fist derivatives of the concentration profiles were calculated and compiled to give the matrix $\dot{\mathbf{X}}$ which represents the rate of change of concentration of all species at all measured time points. $\dot{\mathbf{X}}$ was decomposed using SVD, to obtain the eigenvalues of $\dot{\mathbf{X}}$. The cumulative percentage variance represented by each eigenvalue was found, and the number of largest eigenvalues which represent a summed

variance larger than a fixed threshold of 95% was then determined. This corresponded to the first three eigenvalues which accounted for 98.78% of the variation, hence $\hat{N}_R$ is three.

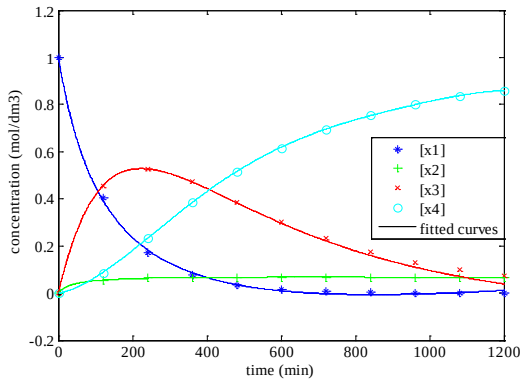

Fig. 1: Measured concentration values for the last batch of data

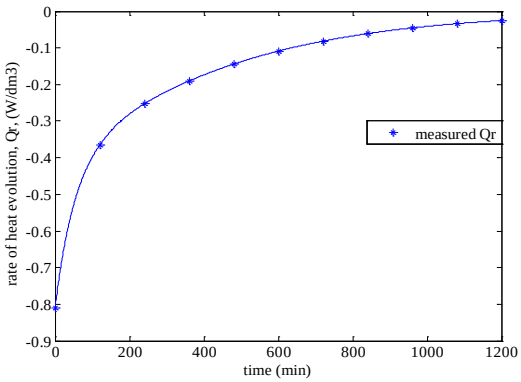

Fig. 2: Simulated rate of heat evolution measurements

Determining the concentration terms

From (7) it is known that $\mathbf{q_R}$ is proportional to all of the relevant N_R concentration terms. Thus, it is believed that the $\mathbf{q_R}$ data will be helpful in determining the relevant N_R concentration terms through regression analysis. Best subsets regression allows a number of models containing different predictors (and different numbers of predictors) to be compared. Hence, it is possible to compare the models comprised of all possible combinations of $\hat{N}_R$ terms from the set of n_c concentration terms, regressed against the $\mathbf{q_R}$ data. It is usually not feasible to model each combination of predictors individually; alternatively, a statistical algorithm is used to produce summary statistics for the possible combinations of predictors. Hence, this procedure does not produce a regression equation but identifies the best combination of $\hat{N}_R$ concentration terms that describe the variability in the $\mathbf{q_R}$ expression.

To determine the best set of predictors, commonly, the adjusted R^2 value and Mallows' *C-p* statistic (Mallows, 1973) are used. Given, that $\hat{N}_R$ was estimated to be three, the number of predictors for the regression models was specified as three. Best subsets regression of all combinations of three of the fourteen concentration terms defined by (12) against the $\mathbf{q_R}$ experimental data were generated. Based on the adjusted R^2 value and the Mallows' *C-p* statistic, $\mathbf{q_R}$ was taken to be proportional to the set of terms, $[x_1]^2$, $[x_1]$, $[x_3]$. Thus $\hat{\mathbf{r}}$ is given by (16).

$$\hat{\mathbf{r}} = \begin{bmatrix}[x_1]^2 & [x_1] & [x_3]\end{bmatrix}^{\mathsf{T}} \tag{16}$$

Obtaining estimates for the coefficients of Θ

Multiple linear regression (MLR) of the three concentration terms against $\dot{\mathbf{X}}$ was executed, in order to estimate $\boldsymbol{\Theta}$, thus, obtain estimates for $\mathbf{V}$ and $\mathbf{K}$. With use of the t-statistics and p-values it was possible to identify that a number terms were insignificant at the 95% level with p-values ≥ 0.05. These were removed from the models and the models were again regressed. This was repeated until only terms significant at the 95% level (p-values ≤ 0.05) remained. This gave an estimate for $\boldsymbol{\Theta}$ shown by (17), along with adjusted R^2 values for the respective SRE models.

$$\hat{\boldsymbol{\Theta}} = \begin{bmatrix} -0.00162 & -0.00699 & 0.00000 \\ 0.00092 & 0.00000 & 0.00000 \\ 0.00000 & 0.00676 & -0.00244 \\ 0.00000 & 0.00000 & 0.00248 \end{bmatrix} \quad \begin{aligned} adjR^2 &= 100\% \\ adjR^2 &= 99.1\% \\ adjR^2 &= 100\% \\ adjR^2 &= 100\% \end{aligned} \tag{17}$$

A posteriori application of mass conservation for rationalisation

If all the chemical species involved in a chemical reaction network have been characterised they may be expressed in terms of an atomic matrix, **A**, (18a). The n columns represent the reacting species and the rows represent the N_A distinct atoms (or molecular groups) in the chemical system ($a_{f,i}$, f = 1, …,N_A, i = 1, …n, $a_{f,i}$ is the number of atoms of the f^{th} type in the i^{th} chemical species). For reaction scheme (2), for example, the atomic matrix may be arbitrarily chosen to be (18b). In the case where it is not possible to characterise all chemical species it is possible to replace the atomic matrix, **A**, with a (1 x n) vector of the species' relative molecular masses (RMMs) if these are known.

$$\mathbf{A} = \begin{bmatrix} a_{1,1} & \cdots & a_{1,n} \\ \vdots & \ddots & \vdots \\ a_{N_A,1} & \cdots & a_{N_A,n} \end{bmatrix} \qquad \mathbf{A} = \begin{bmatrix} 2 & 4 & 2 & 2 \\ 6 & 12 & 6 & 6 \\ 1 & 2 & 1 & 1 \\ 1 & 2 & 1 & 1 \end{bmatrix} \tag{18}$$

As atoms are conserved during a chemical reaction, any composition change must obey (19).

$$\mathbf{AV} = \mathbf{0} \tag{19}$$

Therefore if $\hat{\mathbf{\Theta}}$ is correctly identified, (20) is true.

$$\mathbf{A}\hat{\mathbf{\Theta}} = \mathbf{0} \tag{20}$$

Thus it is possible to check whether the $\hat{\mathbf{\Theta}}$ (17) provides a mass balanced solution, consistent with **A** (18b). The magnitude of the values obtained was comparable to that of the specified rate constants. Thus it is still somewhat ambiguous as to whether (or not) $\hat{\mathbf{\Theta}}$ in (17) provides a mass balanced solution. It is possible to calculate an improved estimate for $\hat{\mathbf{\Theta}}$, which adheres to the constraint given by (20). This is achieved by projecting $\hat{\mathbf{\Theta}}$ onto the null space of **A**, through a projection matrix, $\mathbf{P_A}$ size (n x n), associated with the null space of **A.** $\mathbf{P_A}$ is given by (21), where **I** is an identity matrix size (n x n). Refer to Lawson and Hanson (1974). Given (21) an improved estimate for $\hat{\mathbf{\Theta}}$, $\hat{\mathbf{\Theta}}_{\mathbf{P_A}}$, which adheres to the constraint given by (20) may be calculated, (22).

$$\mathbf{P_A} = \mathbf{I} - \mathbf{A}^{+}\mathbf{A} \tag{21}$$

$$\hat{\mathbf{\Theta}}_{\mathbf{P_A}} = \mathbf{P_A}\mathbf{A} = \begin{bmatrix} -0.0018 & -0.0070 & 0.0000 \\ 0.0009 & 0.0001 & 0.0000 \\ 0.0000 & 0.0068 & -0.0025 \\ 0.0000 & 0.0000 & 0.0025 \end{bmatrix} \tag{22}$$

Also, it is possible to perform target factor testing, Bonvin and Rippin (1990), on each of the estimated stoichiometries from $\hat{\mathbf{\Theta}}_{\mathbf{P_A}}$ to test whether (or not) it is consistent with the measured data.

Obtaining the chemical reaction network

Given that it may be assumed that $\hat{\mathbf{\Theta}}_{\mathbf{P_A}}$ is an accurate estimate, therefore, from $\hat{\mathbf{\Theta}}_{\mathbf{P_A}}\mathbf{r}$ it may be deduced that species x_1 reacts with itself to form x_2, that species x_1 rearranges to form x_3 and that species x_3 in turn rearranges to form x_4. This gives the chemical reaction network defined by (23).

$$x_1 + x_1 \rightarrow C_1 x_2 \qquad x_1 \rightarrow C_2 x_3 \qquad x_3 \rightarrow C_3 x_4 \tag{23}$$

Also given that $\hat{\mathbf{\Theta}}$ has been projected onto the null space of **A**, it is possible to identify the stoichiometry of the products of each reaction step (each column in (22) was standardised). This suggests that C_1 = C_2 = C_3 = 1, leading to correct estimation of the stoichiometric matrix. It is then possible to accurately estimate the kinetic rate constants, achieved by the repeated simulation (numerical integration) of the ODEs that represent the SREs whilst adjusting the kinetic parameters using an optimisation algorithm, until the simulation closely

matches the experimental data. The BatchCAD software package (1995-2004) was used to fit the kinetic rate constants and heats of reaction (24).

$$\hat{K} = \begin{bmatrix} 0.00101 & 0 & 0 \\ 0 & 0.00679 & 0 \\ 0 & 0 & 0.00246 \end{bmatrix} \qquad \hat{\mathbf{h}} = \begin{bmatrix} -8e^4 & -1e^4 & -1e^5 \end{bmatrix} \qquad (24)$$

The correct stoichiometric matrix, the actual individual heats of reaction specified for simulation and accurate estimates for **K** with percentage errors of 0.99%, 0.88% and 0.81% respectively, have been obtained.

Conclusion

This paper proposes a method for the determination of chemical reaction networks, their associated rate constants and heats of reaction. This is achieved through an incremental strategy to analyse composition and heat of heat evolution data. The procedure is demonstrated to be successful, through a worked example of the Van de Vusse chemical reaction network, consisting of four chemical species and three reaction steps, Van de Vusse (1964).

The majority of methods in the literature, are based on system perturbations around stationary states, thus do not lend themselves to batch experimentation often performed in chemical laboratories. In comparison the techniques proposed here are based solely on the analysis of process data obtained from batch reactors. Another advantage of the method proposed is that it is not necessary to have any prior knowledge about the reaction stoichiometry; in fact, given that a number of kinetic assumptions are valid, the stoichiometries may be deduced from the estimated models. Furthermore. the presented analyses are relatively simple from a mathematical viewpoint and use concepts and tools that will be familiar to most researchers and engineers, for example curve fitting and regression analysis.

The use of the rate of heat evolution data for determining reaction networks should be applied with caution as one or more of the reaction step(s) may not exhibit any heat evolution ($\Delta H_{Rl} = 0$) or the heat evolution of one reaction step may be significantly less than that of another ($\Delta H_{Rl} << \Delta H_{Rl+1}$). Therefore it may not be possible to obtain all of the relevant concentration terms from analysis of the rate of heat evolution data.

Topic: Systematic methods and tools for managing complexity.

Abstract

Like most real-world problems, the design of multipurpose batch facilities involves multiple objectives, however the existing literature on the subject has been mainly centered on mono-criterion objectives (Barbosa-Povoa, 2007). Therefore, the multi-objective optimisation is a modeling approach that requires further study when applied to such facilities. The best way to deal with various goals simultaneously is to define the efficient frontier which offers the optimal solutions found by multi-objective optimization. The inspection of the efficient frontier allows the decision maker to select the most satisfactory solution depending on the relative worthiness of each objective. In this work, the detailed design of multipurpose batch facilities with periodic mode of operation, as proposed by Pinto et al. (2005), is extended with the incorporation of economic aspects, which are targeted as multi-objectives within an optimization approach. This allows the identification of a range of plant topologies, design facilities and storage policies that minimize the total cost of the system, while maximizing production, subject to total product demands and operational restrictions. The ε-constraint method is employed to handle the multi-objective optimization, which has as its major advantage the fact that it can be used for any arbitrary problem with either convex or non convex objective space. An example, where different situations are evaluated, is solved to test the model applicability.

1 Introduction

In multipurpose batch facilities, a wide variety of products can be produced via different processing recipes by sharing all available resources, such as equipment, raw material, intermediates and utilities. Sometimes this type of facilities operates under conditions of relatively stable production demands, over extended periods of time. In such situations it is profitable to establish a regular periodic operating schedule, in which the same sequence of operations is carried out repeatedly, thus simplifying the operation and control of such facilities. The periodic mode of operation applied to the design/schedule of multipurpose-batch plants has been so far centered on mono-criterion objectives (Barbosa Povoa, 2007). Some published work is next reviewed.

Fuchino et al. (1994, 1995) studied the design problem of multipurpose batch plants under a periodic operation through an evolutionary design method. Voudouris and Grossmann (1996) proposed a method for integrating scheduling and design for a special class of multipurpose batch processes. A novel representation for periodic schedules is proposed that has the effect of aggregating the number of batches for each product. Heo et al. (2003) addressed the periodic scheduling, planning and design of batch plants. A non linear model is proposed

* To whom correspondence should be addressed. Tel.: +351-214233507. Fax: +351-214233568 e-mail: apovoa@ist.utl.pt

that was linearized using a separable programming method. Finally, Castro et al. (2005) presented a continuous general mathematical formulation based on the RTN process representation. A periodic operation is assumed where the cycle time value is optimized simultaneously with the rest of the design variables.

The existing literature does not explore the application of the multi-objective optimization to the design of multipurpose facilities. Frequently, real-world problems involve multiple objectives and the multi-objective approach is a form of modeling such realistic situations conferring the resulting models characteristics that will allow them to act as potentially powerful decision making tools. On the basis of the Pareto-optimum surface, decision makers will be able to select any given solution depending on the relative worth of each objective.

In the present paper the work of Pinto et al. (2005) is generalized so as to account for a multi-objective decision context where more than one economic objective is considered. This early work presents a generic and detailed formulation for the optimal design and retrofit of multipurpose batch facilities operating in a periodic mode for a single mono-criterion objective. A multi-objective approach based on the ε-constraint is now explored. This method has the advantage of suiting any arbitrary problem, i.e. with either convex or non convex objective spaces. The final results allows the identification of a range of plant topologies, facilities design and storage policies associated with a scheduling operating mode that minimizes the total cost of the system, while maximizing the production, subject to total product demands and operational restrictions.

An example is solved to test the model applicability where different situations are evaluated.

2 Design Problem

The optimal plant design can be obtained by solving the following problem:

Given:

- Process description, through a RTN representation;
- The maximal amount of each type of resource available, its characteristics and costs;
- Time horizon of planning and cycle time;
- Demand over the time horizon (production range);
- Task and resources operating cost data;
- Equipment and connection suitability;

Determine:

- The amount of each resource used;
- The process scheduling;
- The optimal plant topology as well as the associated design for all equipment and connectivity required.

Mixed storage policies, shared intermediated states, material recycles and multipurpose batch plant equipment units with continuous sizes, are allowed. In terms of operation mode, a periodic operation is considered where the concept of cycle time T is used. This is taken as the shortest interval of time at which a cycle is repeated, where the cycle represents a sequence of operations involving the production of all desired products and the utilization of all available resources.

Since all cycles are equal, the problem is formulated over a single cycle where it is guaranteed that the operation of the plant is the same at the beginning and at the end of the cycle. The execution of a task is allowed to overlap successive cycles and, since a cycle is repeated over the time of planning, its execution is modeled by wrapping around to the beginning of the same cycle. To do so, the wrap-around operator as defined by Shah et al. (1993) is used:

$$\Omega(t) = \begin{cases} t & if\ t \geq 1 \\ \Omega(t+T) & if\ t \leq 0 \end{cases}$$

When this is applied, for instance to the variable $N_{k,\Omega(t-\theta)}$ for t–θ ≤ 0, it leads to an identical equipment resource allocation which will start at time t–θ +T.

In terms of modeling, a discretization of time is used, where the cycle time is divided into T intervals of equal duration. The start of the cycle is defined as time t=1, and the end as t=T+1. The latter coincides with the starting point of the next cycle. A planning horizon (H) is assumed which is divided into n equal cycles of duration (T). A cycle is divided into a number of elementary time steps of fixed duration (δ), as shown in Figure 1.

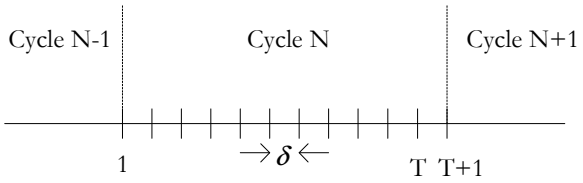

Figure 1-Time discretization for a single cycle

Based on the above problem description and considering the discretization of time, a model was developed using the RTN representation.

3 Multi-objective Optimization

In general those models requiring a single objective, have a clear, quantitative way to compare alternative feasible solutions. In many applications a single objective is sufficient to model realistically the actual decision process. However, decisions become much more problematical when dealing with complex engineering designs, where more than one objective is at stake. For such cases, as referred above, a multi-objective optimization model is required to capture all the possible perspectives. This is the case of batch plants design, addressed in this work, where two objectives are under consideration – maximization of revenue (that is, production) and minimization of cost. Contrary to common practice, where these are usually assigned equal weights and merged into a single index such as profit, revenue and cost are now handled separately since the desired trade-off between them is meant to be open to the decision maker. The multi-objective optimization can be generically represented as:

$$\begin{aligned} &Maximize\ f_m(x) && m = 1,2,...,M; \\ &s.t. \\ &\quad g_j(x) \leq 0 && j = 1,2,...J; \\ &\quad h_k(x) = 0 && k = 1,2,...,K; \\ &\quad x_i^{(L)} \leq x_i \leq x_i^{(U)} && i = 1,2,...,n. \end{aligned}$$

where M identifies the objective function $f(x) = (f_1(x), f_2(x),\ldots,f_m(x))^T$ and J and K are, respectively, the number of inequality and equality constraints. A solution will be given by a vector X of n decision variables: $X=(x_1, x_2,\ldots, x_{n-1}, x_n)^T$

However, no solution vector X exists that maximizes all objective functions simultaneously. A feasible vector X is called an optimal solution if there is no other feasible vector that increases one objective function without causing a reduction in at least one of the others. It is up to the decision maker to select the best compromising solution among a number of optimal solutions in the efficient frontier. There are several methods to define this frontier, but one of the most popular methods is the ε-constraint, which is very useful since it overcomes duality gaps in convex sets.

Using the ε-constraint, the above formulation becomes:

$$
\begin{aligned}
&Maximize\ f_u(x)\\
&s.t. \quad f_m(x) \le \varepsilon_m \quad m = 1,2,...,M \ and\ m \ne u\\
&\qquad g_j(x) \le 0 \quad j = 1,2,....;\\
&\qquad h_k(x) = 0 \quad k = 1,2,...,K;\\
&\qquad x_i^{(L)} \le x_i \le x_i^{(U)}
\end{aligned}
$$

where ε_m represents an upper bound of the value of f_m. This technique suggests handling one of the objectives and restricting the others within user-specified values. First the upper and lower bounds are determined by the maximization of the total revenue and minimization of the cost, respectively. Next, varying ε, the optimization problem (maximization) is implemented with the objective function being the total revenue and the cost being a constraint varying between its lower and upper bounds.
Once obtained, the efficient frontier allows the decision maker to select any solution depending on the relative worthiness of each objective.

4 Example

The presented method is applied to the design of a multipurpose batch plant that must produce [0; 170] tons of products S5, [0; 166] tons of S9 and S10, [0; 270] tons of products S6 and [0; 143] tons of products S11. Three raw materials, S1, S2 and S7, are used over the horizon of 24 h. The products S5 and S6 are both intermediate and final products. There are six main reactors available (R1 to R6), and nine dedicated vessels. In terms of equipment suitability, only reactors R1 and R2 may carry out two processing tasks, T1 and T2, while each storage vessel and reactors R3, R4, R5 and R6 are only dedicated to a single state/task. Task T1 may process S1 during 2 hours in R1 or R2; task T2 may process S2 during 2 hours in R1 or R2; task T3 may process during 4 hours in R3; task T4 processes during 2 hours in R4; task T5 may process S6 during 1 hour to produce the final product 0.3 of S11 and 0.7 of S8 in R5, and finally task T6 processes during 1 hour S8 in reactor R6 to produce the final products S9 and S10. The connections capacity range from 0 to 200 [m.u./m^2] at a fix/variable cost of 0.1/ 0.01 [10^3c.u.]. The capacity of R1, R2, R5 and R6 range from 0 to 150 [m.u./m^2] while the others range from 0 to 200 [m.u./m^2] (where m.u. and c.u. are, respectively, mass and currency units).

The problem described is solved and the obtained efficient frontier shown in figure 2, which forms the boundary of the feasibility region defined by the values of the two objectives. Every efficient point lies along the depicted boundary because no further progress is possible in one objective function without degrading the other. This is an alternative way to plot solutions of multi-objective models. For the case under study the objective value space is represented with cost and revenue axes. In the efficient frontier are visible some optimal plant topologies. A, B, F and G represent points where there is a topology change caused by the addition or replacement of one or more main equipment units in relation to the previous topology. In figure 2 are shown these different topologies and the corresponding final products. In table 1 are presented, for each point assigned, the final products and their quantities. Table 2 presents the main equipment optimal design, in terms of capacities, for points A to G. For point G, the optimal scheduling is shown in figure 3. It is visible the multi-task nature of equipment R1, since it performs not only T1 but also T2. All the other processing equipment units are single-task dedicated.

5 Conclusions

The plant topology, equipment design, scheduling and storage policies of multipurpose batch plants are addressed in this paper, considering simultaneously production maximization and cost minimization - a multi-objective optimization. The model was developed as a MILP and the multi-objective method used was the ε-constraint. The obtained efficient frontier defined the optimal solutions, allowing the identification of a range of plant topologies, facilities design and storage policies that minimize the total cost of the system, while maximizing production, subject to total product demands and operational restrictions. The proposed methodology allows the decision makers to evaluate the relationship between revenue and cost of given batch facilities, thus enabling them to develop an adequate business strategy.

Keywords: Supply chain management, optimal planning, uncertainty
Topic: Systematic methods and tools for managing the complexity

Abstract

In this paper, we study the supply chain planning decisions under uncertainty on product portfolios demand and prices. A supply chain centralized managing strategy is adopted for the multi-period planning problem, where the supply chain operational decisions, at the actual period, take into consideration both contracted and uncertain products' demand and/or prices. The operational decisions on supply, production, transportation, and distribution are evaluated in face of a defined supply chain economical performance objective (e.g. global operating costs/ profit realized) for different demand and price behaviours.

A general model, based on the work of Amaro and Barbosa-Póvoa (2008), is proposed that considers the supply chain topology, operability and market demand/price uncertainty while accounting for product recovery through the integration of reverse material flows and remanufacturing operations. A Mixed Integer Linear Programming formulation (MILP) is developed for each planning scenario and the optimal solution is reached using a standard Branch and Bound (B&B) procedure. The final results provide details on the supply chain partners production, transportation and inventory at each planning period while accounting for demand/price uncertainties.

The model applicability was tested on a real industrial case involving a pharmaceutical supply chain.

1 Introduction

Nowadays enterprises face important economical challenges. The trade-off between quality, price and service levels is definitively a key to success in a worldwide scale. Thus, enterprises need to provide high quality products around the world at the right time, in the right quantity and at the lowest prices. Supply chain structures have, in this area, an important role in the fulfilment of such goals in global markets (Varma et al, 2007). Therefore, the supply chain planning is one of the areas that needs a special care and should be optimized so as to enhance the desired operational efficiency.

Planning problems involve usually medium to large time horizons and accordingly, decisions on future events are frequently taken based on more or less accurate forecasts. Therefore, uncertainties regarding product demands and prices, amongst other supply chain conditions, need to be accounted for in planning decisions (Guillen *et al*, 2007).These sources of uncertainty depend on the products demand pattern and are at least partially explained by the demand to price dependency.

Moreover, customers' demand behaviour is influenced by distinct sources of uncertainty other than price forecasts. Different contributions have been proposed so far to enhance different uncertainty aspects (Guillen et al., 2006). Almost all the proposed methodologies

* Corresponding author. Tel + 351-239-798700. E-mail:user1@eq.uc.pt

agree on the fact that the complex demand behaviour can not be fully explained by deterministic measures and therefore some stochastic parameters are required to explain customers' subjective nature as well as some market patterns'.

In the present work, the demand behaviour is characterized by a set of polynomial functions representing the demand to price dependencies, according to the products considered. The demand uncertainty induced by price changes (i.e. different probabilistic price forecasts) is modelled through a set of planning scenarios with a probability of occurrence corresponding to the price forecasts. In each one of these scenarios the demand uncertainty is considered through the demand to price elasticity coefficient. The influence of market scores over the optimal planning solution is also considered. The elasticity to price coefficient observed for each product family, at each market place, is analysed and mutually compared in order to identify the embedded market characteristics.

On the other hand, the economical flows raised at each planning period are converted to a common time point, in order to be comparable. This conversation corresponds to the actualization of the economical flows based on a defined average market rate (Gupta et al, 2004). In fact, the strategy implemented to actualize economical flows is an actual and largely discussed subject, although it is not the scope of this study. Some literature contributions as the one of Gupta et al. (2004) based on real option values (ROV), or the corporate value evaluations proposed by Puigjanner (2008), promise important advantages against the commonly used net profit value (NPV) methodology. The major difference in between is essentially due to the market rate considerations and to the entailed financial assumptions. Our approach considers regular *cash-flows* (i.e. resulting from equally spaced periods) subject to an actualization, defined by a 2% constant market rate, done to each planning period and economical flow. The actualized planning profit (APP) is considered as the problem economical goal.

2 Problem Characterisation and Modelling Approach

The proposed contribution considers a close-loop supply chain, SC, with a centralized managing strategy defined over a multi-period. The supply chain decisions, at each period, take into consideration the supply chain topology, its operability and market demand/price uncertainty, while accounting for product recovery through the integration of reverse material flows and remanufacturing operations (see figure 1).

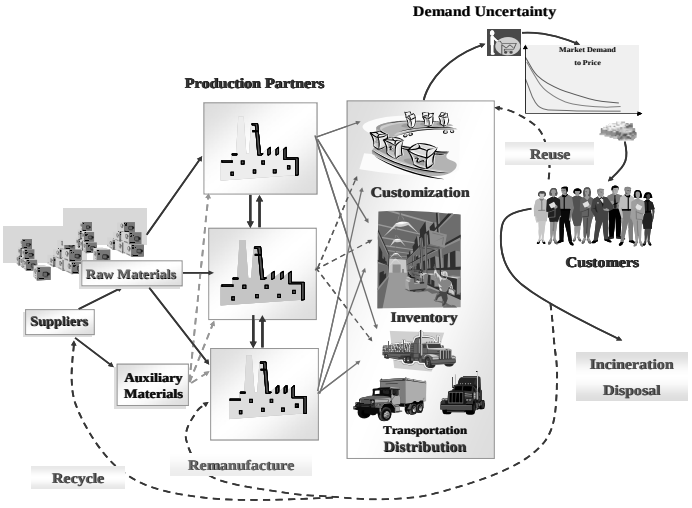

Figure 1.- Closed loop supply chain, SC.

Under an uncertainty environment this contribution studies how medicine portfolios' and marketplaces influence the SC economical performance. A general formulation is develop

and the final results provide details on the supply chain partners production, transportation and inventory levels, at each planning period, while accounting for demand/price uncertainties. The supply chain planning problem can be stated as follows:

Given the supply chain:

- planning horizon;
- topology structure (i.e. partners geographical location; suitability to process, store, receive and deliver products; the corresponding capacities and processing times);
- connectivity network (i.e. transportation capacities, suitability and transportation times);
- materials' network (i.e. available materials and SC location) and the recovery policy (i.e. products' recycling and remanufacture capacities and suitability);
- markets network (i.e. market locations and scoring; demands and prices; demand to price elasticity to each suitable product and marketplace);
- Price forecasts to each final product and its probability of occurrence during each planning period and the actualization rate of economical flows during the planning horizon or per planning period;

Determine:

- the optimal allocation of products production, recovery, transportation, delivering, receipts and storage and the associated timings;
- the economical performance of the supply chain as well as of each SC partner under each demand and price uncertainty scenario;

So as to: Maximize the actualized Global Planning Profit, APP, under a defined partnership structure subject to demand and price uncertainty.

Modelling Consideration

The proposed SC planning formulation is summarized in table 1. A discrete time approach of the planning horizon is considered. The model is based on the works of Amaro and Barbosa (2007, 2008) and considers the following assumptions:

- the profit at each planning period is actualized based on a fixed market rate;
- Products demand patterns' follow a polynomial form $\hat{D}_{st} = \hat{D}_s^0 \left(\hat{p}_{st} \right)^k$, where *k* represents the constant elasticity to price coefficient (i.e. logarithmic derivative of demand to price) and $\hat{D}_s^0$ represents the demand value observed for each product s, when it is sold at the lowest suitable market price $\left(\text{i.e.} \quad \hat{D}_s^0 = \hat{D}_{st}\big|_{Min_t(\hat{p}_{st})}, \quad \forall s \right)$. This represents a demand upper bound for all products, s, with a demand to price elasticity less than 1 (i.e. having a negative k value); and a demand lower bound to all products having an elasticity coefficient greater than 1.
- a price forecast is considered for each final product and planning period;
- the price of final products is considered unchanged till the planning period where forecasts indicate a given probability of price changes (defined as a percentage of the current price);
- the probabilistic occurrences of products price variations' are independent events modelled as a scenario approach with a defined probability of occurrence: three scenarios are considered as representative of both optimistic, pessimistic and unchanged price situations within a risk analysis strategy (Tsikaris et al. (2001). This can however be generalised for a N, number of scenarios;

- demand uncertainty is represented according to the price elasticity coefficient defined for each medicine family.

Table 1. Summary of SC Planning Formulation.

Objective Function: Actualized Planning Profit,
$APP\left(u(\hat{D});PS\right)=\sum_{ip}\xi(ip)\quad\sum_{Sc}\Upsilon(Sc)\left(\sum_{t=1}^{H_p}\frac{GPP_t}{(1+\overline{r})^{t-1}}\right)$
Scenarios: $\left(\Upsilon(Sc_1),-x\%p\right);\left(\Upsilon(Sc_2),0\%p\right);\left(\Upsilon(Sc_3),+x\,p\%\right)$ with $\sum_i\Upsilon(Sc_i)=1$ Constraints: Processing and Recovery Transportation; Supply; Deliver; Store, to all or some SC partners;
Variables: Integer – assignment of tasks and flows to resources; Continuous – capacities, demands, supplies.

Case Study

A real pharmaceutical SC is studied (figure 2). This involves three industrial plants (I1 and I2, located in Portugal and I3 in Spain) with a distribution channel supported by five warehouses (WH1, WH2 and WH3 in Portugal and WSH1 and WSH2 in Spain) involving seven distribution points (i.e. warehouses, airport AP and seaport SP).

GL_{u2}: O.F.= 6666910;	ΔGL_{u2}-Rc=-552449

Figure 2.- Pharmaceutical supply chain and results on the uncertainty scenarios studied.

The pharmaceutical chain supplies the European and African markets with three manufactured product families: injection, soft-table and oral suspension medicines. These involve the formulation of four intermediate medicines that are subject to three types of customizations, resulting into eleven final product medicines. The medicines distribution is ensured by three transportation structures, with different capacities and number of transportation resources. The SC planning problem was solved for a three months horizon of planning with weekly periods (12th periods).

As referred above, the developed study comprises two major scopes: i) the effect of demand uncertainty due to price; and ii) the influence, under an uncertain scenario, of market scores on the optimal products portfolios'. To illustrate each one of these model developments a set of operational scenarios was defined. Firstly, the optimal planning solution, without demand uncertainty was determined (i.e. reference case, Rc) and the actualized planning profit obtained. This is compared with those resulting from the integration of a demand pattern

submitted to price uncertainties (i.e. u1 and u2 cases). A set of cases was studied using two price scenarios denoted by *u1 (represent 80% probability of a 5% increase on the actual medicines price, 20% probability of a 5% decrease on products price and a null probability of a constant price) and *u2 (20% probability of a 5% price increase, 80% probability of a 5% products price decrease and again a null probability of unchanged price values). Due to the lack of space, only the results achieved to soft-tablet medicines are shown. These consider both probabilistic behaviours occurring at the 8th period, till the end of the planning horizon.

Moreover, the SC structure comprises ten geographical positions covering three customer markets': Portuguese (PG) and Spanish (SP), as country-side for production partners; other EC markets (EC) and the African positions. Having these market specificities the goal is to identify the behaviour of the SC planning profit for: **i)** each single market; and **ii)** the combined effect of uncertainty due to its simultaneous occurrence at more than a market place. In cases EC, PG and SP, two different uncertain conditions, (EC_{u1},EC_{u2}); (PG_{u1},PG_{u2}); (SP_{u1},SP_{u2}), are analysed for price uncertainties occurring at a single and specific market (i.e. EC, SP and PG markets). Finally, cases IB and GL comprise uncertainty scenarios for the Iberian (IB) market (i.e. Portugal and Spain) and for the whole European market (GL).

As it can be observed in figure 2 the demand reduction caused by a highly probable price increase, scenarios u1 for EC, PG and SP cases, is covered by the unitary profit change. This is partially explained by the increment on stock existences and since the time frame to the end of planning horizon is small the storage costs does not have a significant contribution. On the other hand, for scenario u2, the demand increase caused by the price reduction is not enough to overcome the income decrease and a global profit reduction is observed when compared to u1, having as reference the Rc case. It is also important to note that soft-tablet medicines have an elasticity coefficient higher than the one observed for injection and oral suspensions, but these are not the top of the demanded medicines.

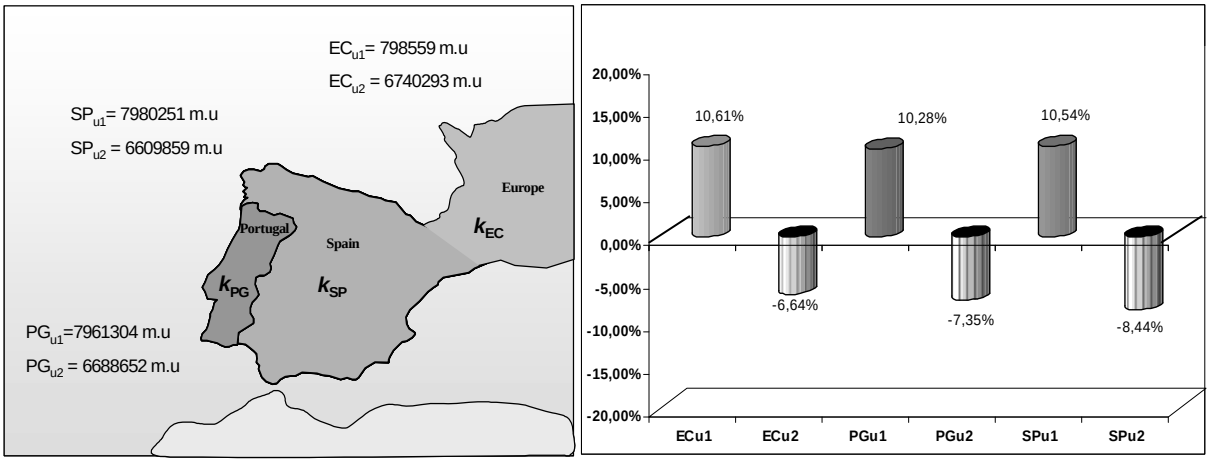

Figure 2 – Planning results for both uncertainty scenarios at EC, PG and EC markets.

Although, the effect of the same type of uncertainty is not the same for all the markets considered. For the uncertainty scenario due to a most probable price reduction almost all markets behave similarly, but the less profitable (PG) is also the less sensitive to price increase since it presents the lower percentage deviation (-6.64% at scenario u2) from the constant demand behaviour (i.e. scenario Rc). Concerning the profitable cases (EC and SP) these have lower demand to price elasticity coefficients than the PG case and larger medicine demands. Thus, their performance is less sensitive to price reduction than to the demand reductions. The later increases the level of handled stocks and a globally less profitable solution is raised.

The influence of market scores on the chain global planning profit under an uncertain environment was also explored. The uncertainty conditions defined above are assumed.

When analyzing figures (3a) and (3b) it can be seen that the effect of price uncertainties influences differently the optimal planning profit, as above, and the combined effect of market's uncertainties is also more visible for u1. This is explained essentially by the increase of handled medicine inventories' and to the cumulative effect of demand reduction.

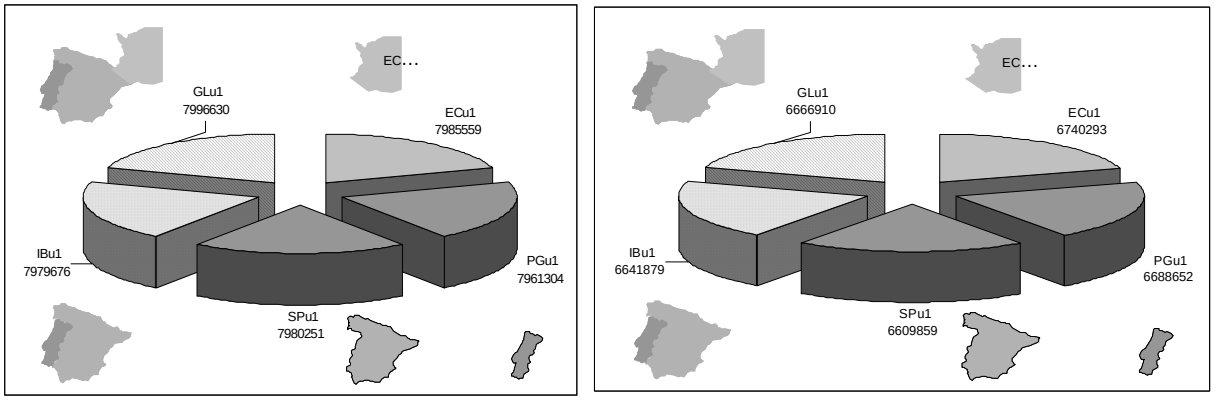

Figure 3- Global planning analysis for (a) u1 and (b) u2 uncertainty scenarios.

The model was implemented in GAMS/CPLEX on a Pentium III. The statistics of the model involve 22275 continuous variables, 8856 integer/binary variables and 44512 equations. The problems were solved on average after 8000 CPU seconds for a relative gap of 2.5%.

Conclusions

This paper presents the optimal planning of a generic supply chain where detailed aspects involving the supply chain production, storage and transportation are considered. The planning is performed under market demand/price uncertainty while accounting for product recovery through the integration of reverse material flows and remanufacturing operations. An actualized profit is considered as well as demand and price uncertainties related to each product, by the elasticity to price coefficient. The influence of market scores on the allocation of product portfolios' and supply chain operations was studied.

The formulation applicability was tested on a real industrial case involving a pharmaceutical supply chain. Some interesting results where achieved but improvements should be further explored. Namely, the relation among demand to price elasticity coefficients, products and markets can be extended. Also, price uncertainties should be explored to larger planning horizons with different periods of occurrence in order to capture the cumulative effect of demand uncertainties induced by price changes.

Topic: Systematic methods and tools for managing the complexity.

Abstract

The aim of the present work is to develop and validate a nonlinear dynamic model of a pilot-scale continuous distillation process for the simulation of the dynamic behaviour of a real continuous distillation plant at the Chemical Engineering Department of ISEL, in the absence and in the presence of faults. The model of the overall pilot scale distillation plant is derived from fundamental principles including mass and energy balances for the individual systems such as the distillation column sections, the condenser, the heated reboiler, the feed pre-heater, the reflux valve, the bottom product control valve and the PID regulatory level controller. The complete dynamic model for the separation of a non-ideal binary liquid mixture of ethanol/water was developed within Matlab®/Simulink environment and was validated against experimental data collected from the plant under normal operating conditions in the absence and in the presence of faults showing a good agreement with the experimental results. Thus, this non-linear dynamic model is well-suited to be used for the implementation of Fault-Tolerant Control strategies in real time.

1 Introduction

Distillation columns are probably among the most common process units within the chemical industry (Kister, 1990). Industrial distillation columns are complex systems which exhibit nonlinear dynamic behaviour, so the development of models for control strategies is usually based on nonlinear models (Abdullah et al., 2007). In recent years, one of the major challenges in developing an effective model based control strategy is to generate a dynamic model which is used to describe the process under consideration. At present, most industrial controllers use a linear process model such as first-order-plus-time-delay models, and the linear model is applied to the estimation of the linearity for the dynamic range of the process (Abdullah et al., 2007). Satisfactory performance of these linear models is generally achieved over a narrow operating range, so the development of nonlinear process models is tremendously essential for the design of controllers that are capable of dealing with the unavoidable nonlinearity and complexity of nonlinear processes.

The steady-state analysis is not sufficient for the development and testing of control schemes. Nevertheless, very few dynamic modelling and simulation studies have been carried out and validated on real distillation columns (Can et al., 2002).

Many sophisticated model based control algorithms have been developed under the assumption that all system components will not fail. Once a failure occurs, the system performance will degrade and may lead to divergence, generating dangerous situations, particularly when the failure occurs in the control loops.

The demand for increased efficiency, in various branches of industry, such as chemical industry leads to an increased degree of automation of the production process. In order to meet this demand, while at the same time maintaining or improving the quality and safety, it is necessary that the (complex) control system is fault tolerant. This means that the effects of failures, such as component failures, actuator or sensor failures, on the quality and safety of the production process are minimized.

An important class of approaches to design fault tolerant control systems, includes the so-called Model Based Fault Detection and Isolation part (Calado et al., 2001) and a Controller Reconfiguration part. A key step in designing these two parts is the development of a mathematical model for the system.

It is well known that the ultimate judgment of the model quality is through model validation under normal operating conditions. However, the literature has been relatively sparse on studies concerned with model validation using process data under normal operating conditions.

In this work, a nonlinear dynamic model of a pilot-scale continuous distillation process is developed for the simulation of the dynamic behaviour of an experimental continuous distillation column at the Chemical Engineering Department of ISEL. This model is valide in both the absence and the presence of system faults. The complete model includes mass and energy balances for the individual systems such as the distillation column sections, the condenser, the heated reboiler, the feed pre-heater, the reflux valve, the bottom product control valve, and the PID regulatory level controller. The complete dynamic model is developed within Matlab®/Simulink environment and is validated against experimental data collected from the plant under normal operating conditions, in the absence and in the presence of faults, for the separation of a binary liquid mixture of ethanol/water.

2 Experimental Distillation Process

A photograph and a schematic overview of the pilot scale continuous distillation column are presented in Figure 1. This continuous distillation column is used to separate a liquid binary mixture of water and ethanol (10-20%) into a distillate product with ethanol (75-88%) and bottom product with (92-98%) water (mole fractions).

The column structure is made of several glass sections supported by an external steel framework. The glass is enfolded with proper isolation material to guarantee minimal heat loss into the surroundings. The column internals used for distillation are two structured packing sections (type 1900) with 1000 mm height and 4.3 mm inside diameter. Each structured packing is equivalent to a number of 30 equilibrium stages.

The liquid feed mixture is pre-heated using a 1200 W ON/OFF electrical heater element, which is actuated by an automatic controller, and enters the column at the feed stage with volumetric flow rate (Fv), ethanol molar fraction (xF) and temperature (TF). Ethanol evaporates along the distillation process, going upwards throughout the column section above the feeding point. Distillate ethanol leaves the top section of the column with a molar fraction (xD) and flow rate (D) into a water cooled condenser. A fraction of the condensed distillate is fed back into the top of the column at a rate determined by the actuation of a solenoid valve (freflux). The liquid mixture travels

downwards through the section below the feed into the reboiler. Here part of the mixture changes phase from liquid to vapour upon the action of two 2000 W electrical ON/OFF heater elements, which are controlled by an automatic controller. The water rich mixture leaves the bottom section of the column with a molar fraction (xB) at flow rate (B) and goes through a condenser before being stored in the product tank.

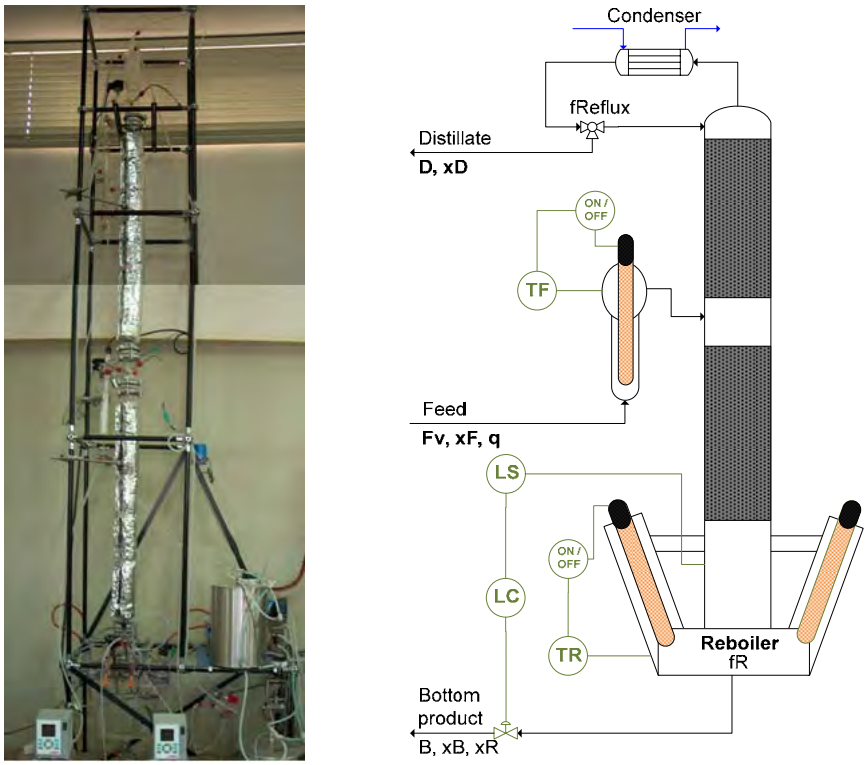

Figure 1 – Pilot scale distillation column at Chemical Engineering Department – ISEL.

The column measurement instrumentation consists of two types of sensors: temperature thermopars type Kv (e.g.TF or TR), and pressure sensors (e.g. LS). These sensors gather the online information about temperature and pressures at different points in the column. The measured signals are fed into the digital controller in real time using the National Instruments FieldPoint 2000 system. All the signal conditioning operations and the network communications are carried on using this modular distributed I/O system. The actuators consist of: heater elements, valves and peristaltic pumps. These devices are operated by an automatic digital control system, which interfaces with the actuators through the FieldPoint I/O bus. This system handles the network communications and the device actuation in the control process. The digital controllers were designed and run over LabView software. An automatic level control (LC) system was implemented at the reboiler.

3 Mathematical Model and implementation

Mathematical model

The mathematical model developed for the pilot scale distillation column includes global and component transient mass balances along the column trays, and is based on the well established simplifying assumptions and steady-state behaviour of both trayed and packed columns, which can be modelled using a staged equilibrium model (Skogestad, 1997). Several modifications were considered to develop the model according to the characteristics of the pilot scale distillation unit and of the non-ideal binary mixture (Skogestad, 2003). The set of ordinary differential equations obtained

was solved numerically using “ode15s” Matlab® solver. The heat lost along the column is taken into account as parameter HL (heat loss), which corresponds to the fraction of vapour condensed in each tray. With the introduction of this parameter in the model, liquid (L) and vapour (V) flows are allowed to change along the column influencing tray efficiencies. So, by using L/V ratio, the tray efficiency (Ef_i) is defined by the following equation:

$$Ef_i = \left(1 - \frac{1}{\left(L/V\right)_i + 1}\right)^{ef}$$

where $\left(L/V\right)_i$ is the liquid and vapour ratio in tray *i* and *ef* its influence in tray efficiency.

By including parameter Ef_i, the number of theoretical stages are fixed to the number indicated by the column manufacturer (60). The feed tray is considered the middle (31) tray, since the column has two equal sections, as described above. With this approach, instead of adjusting the real number of theoretical plates and feed position, the efficiency of the column is allowed to vary when dynamic changes occur without the need of changing other parameters.

It is important to note that the binary mixture used (ethanol-water) is highly non-ideal, which means that the relative volatility cannot be used. Therefore, vapour-liquid activity coefficients are used.

Model Inputs

Since the main objective is to simulate the dynamic behaviour of the real distillation column described above, the Matlab®/Simulink model inputs are the same used in the real column: the volumetric feed flow rate (Fv), the ethanol molar fraction of the feed (xF) and its temperature (TF), the time fraction that Reboiler is turned on at maximum power (fR) and the fraction of time that reflux valve is fully open (fReflux). These five variables are converted into the following variables: refluxed liquid (Lr), vapor generated in the reboiler (Vs), distillate flow rate (D), bottom flow rate (B), molar feed flow rate (F) and the liquid fraction in the feed (q).

Model implementation

The dynamic model was implemented in Matlab®/Simulink. The Simulink diagram is shown in Figure 2. With this model it is easy to implement perturbations/faults in the input variables and also to implement control loops or model-based control strategies. The Simulink diagram includes three main blocks (Figure 2). In the first and second blocks the inputs are processed and converted into the input variables used in the block of the column nonlinear model implemented in Matlab. This block has three outputs: distillate (xD) and bottom (xB) ethanol compositions and reboiler holdup. As in the real distillation column, a level control loop is also implemented in the model to keep the reboiler holdup constant when dynamic changes occur in the column.

4 Model validation

The developed model has three parameters for the fitting of the column steady states and other four parameters for adjusting the dynamic behaviour. These parameters were tuned by fitting the model to experimental data that resulted from 12 different steady states and 5 dynamic responses to step disturbances in the inputs. The quality of the fittings can be evaluated by the parity plot obtained for the different steady states in the column. The inputs supplied to the experimental column were designed as a series of persistently exciting steps that drive the column in transient regime. Some examples of dynamic responses are shown in Figure 3.

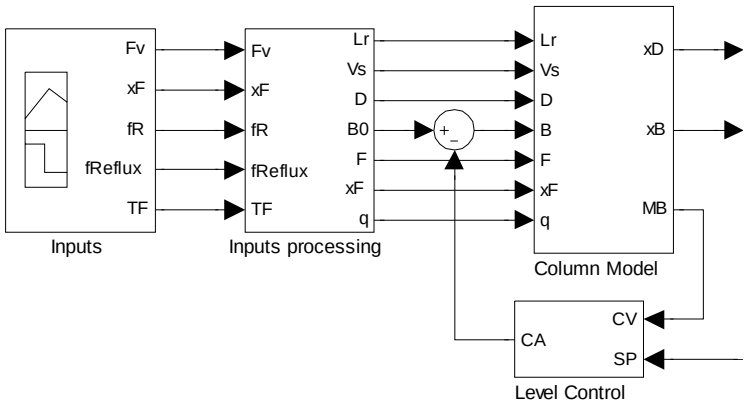

Figure 2 – Simulink diagram for the distillation column nonlinear model.

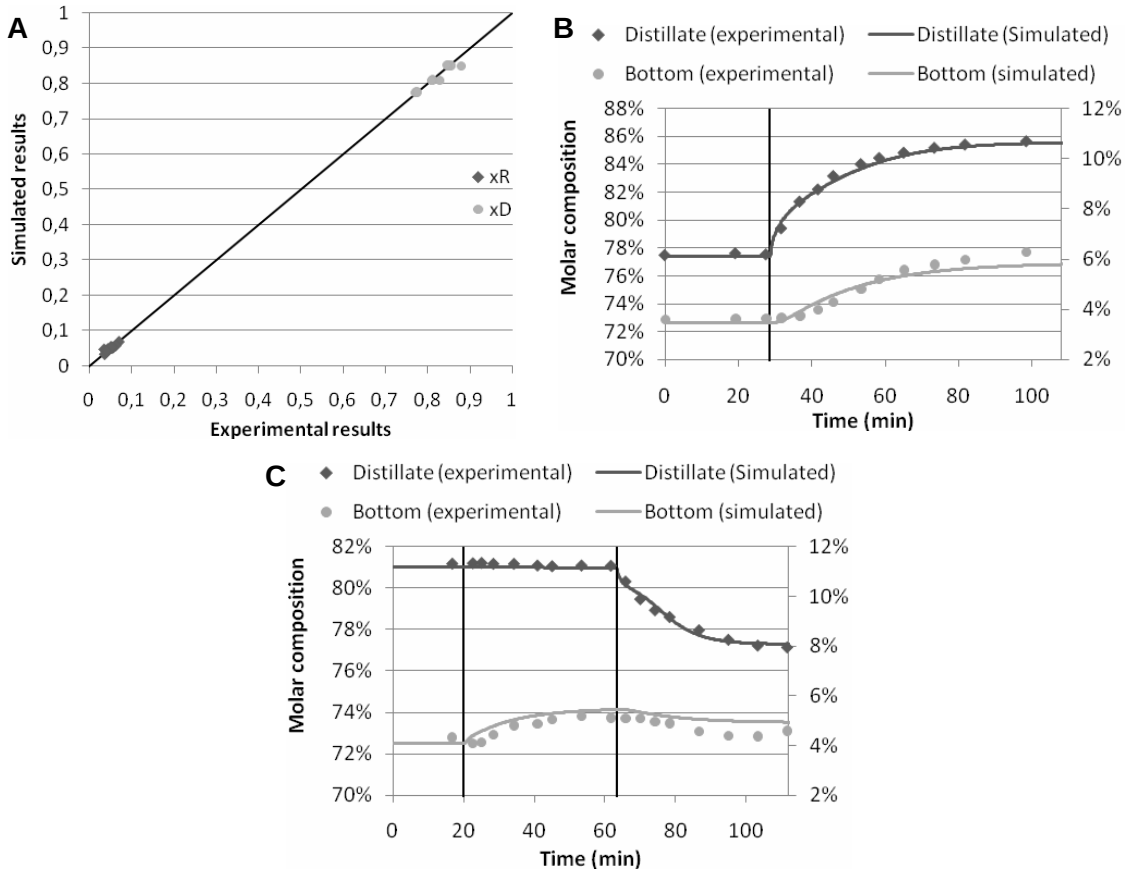

Figure 3 – A) Parity plot for the distillate (xD) and bottom (xR) ethanol compositions. B) Dynamic response of the column to a step abrupt change in reflux ratio (+600%). C) Dynamic response of the column to a step abrupt change in the feed rate (+50% at t=20 min) followed by a step change in reflux ratio (-60% at t=65 min).

5 Results and Discussion

From the results presented in Section 4, we can conclude that the model is capable of describing both the steady states and the dynamic behaviour of this real distillation column. Further, since the online measurements available experimentally are some tray temperatures and not the compositions, we added to the model the conversion between the predicted compositions and certain stage temperatures. Figure 4, also shows a good agreement between the experimental temperatures and those predicted by the model.

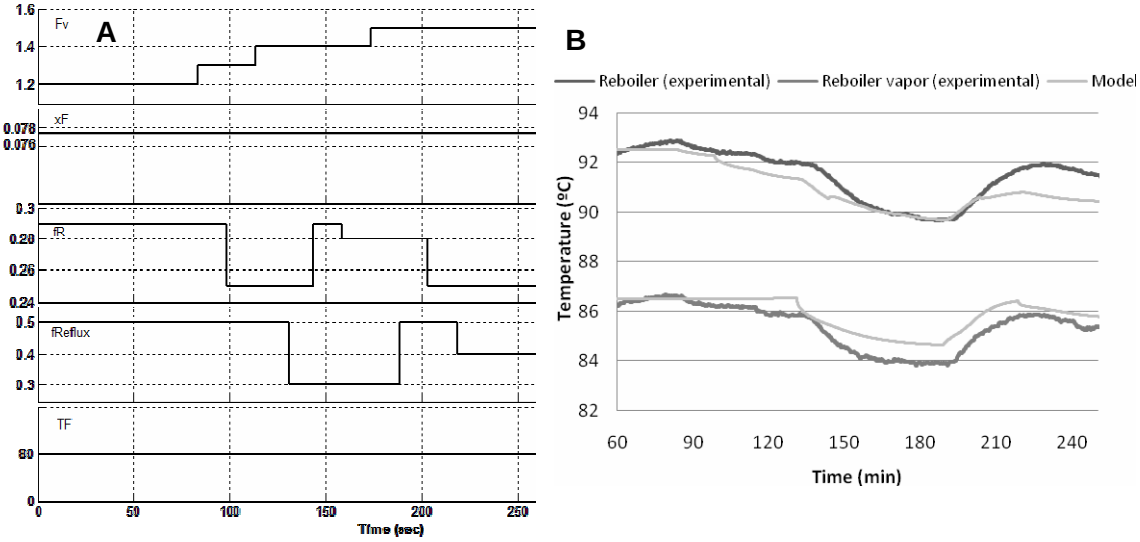

Figure 4 – A) Sequence of multiple steps in the model inputs that were designed to drive the column in transient regime. B) Simulated and real temperatures obtained for the Figure 4A inputs.

6 Conclusions

A simulator for a real a pilot scale continuous distillation process was developed, which implements a detailed nonlinear mathematical model in Matlab®/Simulink simulation environment. This simulator can predict both the steady-state and the dynamic behaviour of this pilot scale distillation column at the Chemical Engineering Department of ISEL, for the separation of a non-ideal binary liquid mixture of ethanol/water, in the absence and in the presence of faults. The model developed was validated against data collected from the plant for the separation of a non-ideal binary liquid mixture of ethanol/water, showing a good agreement with the experimental results.

Thus, this dynamic model is well-suited to be used as a reference model for the implementation of Fault-Tolerant Control strategies in real time.

Abstract

Previous work (**Silva, 2006; Silva and Oliveira, 2007**) described a systematic methodology for the design of free-radical polymer products based on discontinuous operation. This design problem is characterized by considerable complexity, high dimensionality, nonlinear behaviour of the physical models, and multi-objective nature. To avoid most of these limitations, a two-step methodology was introduced, where the problem is initially reformulated in terms of the decision variables used. Here, additional aspects of the application of the methodology to particular cases are considered, and modifications proposed to enhance its practical application. A particular problem addressed is the residual amount of initiators present is the final product. The application is demonstrated with the batch suspension polymerization of vinyl chloride, one of the most used thermoplastics.

1 Introduction

Previous work in the optimization of polymeric materials addressed the search of operating conditions that improve productivity, resulting from minimum time formulations (**Silva and Oliveira, 2002**) and the effects of constraining the variance of the chain length distribution of the final product (**Silva, 2006**). In a systematic approach to polymer design, additional aspects need also to be considered; namely, it must be possible to rigorously control the size distributions (moments and shape) and to completely determine the operating conditions (*e.g.* temperature, concentrations), processing agents, such as suitable initiators (which ones, how many, in what concentrations, when to add) and other additives like suspension or chain transfer agents.

The resulting design problem is characterized by considerable complexity, high dimensionality, highly nonlinear behaviour of the physical models, multi-objective nature and the need to perform discrete design decisions. To tackle most of these limitations, a two-step methodology was recently introduced (**Silva, 2006; Silva and Oliveira, 2007**). Initially the problem is reformulated in terms of the decision variables used, namely the reaction temperature and the initiation reaction rates, aiming to seek an extreme of a performance criterion (e.g., minimize the reaction time). Given that the initiation reaction rate profile is independent of the set of initiators used, the choice of suitable initiators may be considered in a second step, and formulated as an algebraic MILP problem. This later step leads to the set of initiators and their respective addition policies, which minimize the cost of obtaining the initiation profile obtained in the first step of the methodology. As demonstrated previously, this sequential approach significantly diminishes the overall problem complexity, and allows the systematic optimization of the major aspects related to the batch production of free-radical polymer products.

2 Improving the base methodology

A relevant aspect in the industrial practice of free-radical polymerization is the control of the residual amounts of initiators that are present in the final product, after the end of the operation. This must be considered not only due to the potential extra costs incurred, but also because of a number of additional criteria, including product quality, health and environmental factors.

During the application of the first step of the methodology previously presented the maximum concentrations of initiators cannot be directly constrained, since the decision variables used are still independent from a particular choice of initiators. Therefore, to assure that excessive residual concentrations of initiators are not obtained at the end of the operation, both steps of the methodology need to be simultaneously considered.

2.1 Problem statement

In some of the previously studied cases, a swift rise in the initiation reaction rate was observed at the end of the operation, while applying the first step of the methodology (**Figure 1**). This is due to the fact that the design problem was formulated as a minimum time problem. This objective is decreased when, at the final stage of the operation, we are able to increase the initiation reaction rate while also increasing the probability of the occurrence of termination of the active chains.

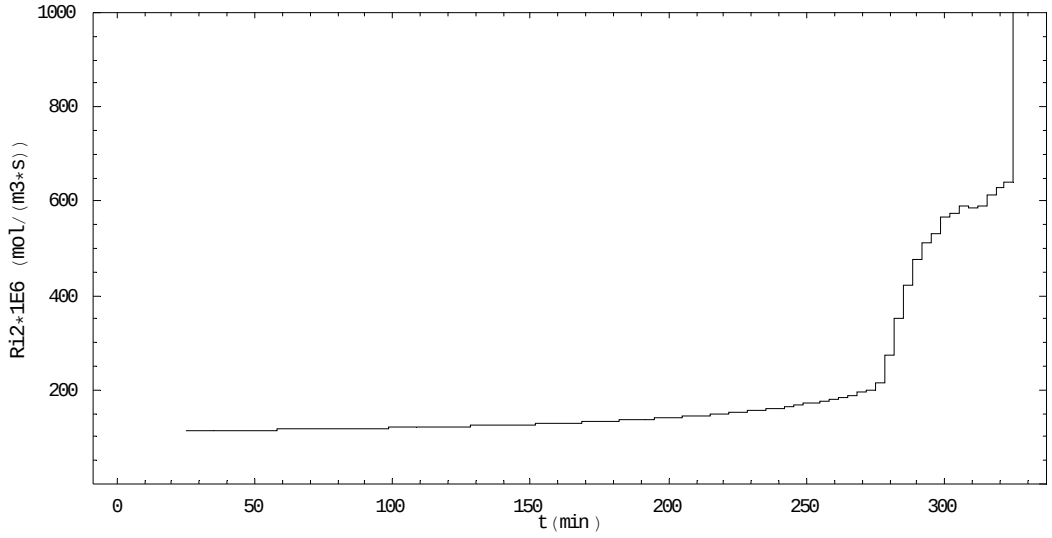

Figure 1 – Graphical representation of the initiation reaction rate profile in the polymer rich phase, with constraints only in the $\overline{M}_n$ (Initial case).

However, an increase in the initiation reaction rate during the final stages of the operation, such as the one observed in **Figure 1**, may lead to undesirable situations from a practical standpoint. If the temperature is kept approximately constant, excessive quantities of initiators might need to be added in the later stages of the operation, causing higher residual concentrations of these species. Additionally, it might be necessary to use excessive quantities of fast initiators, with the subsequent increase of operational costs. In a practical application, the temperature profile can also be changed during the last operational phase to mitigate this problem, but this effect might not be sufficient. Therefore, a more direct control of the residual concentration of the initiators is required, to enhance the applicability of the systematic design methodology.

2.2 Problem solution

Considering the particular application to the batch suspension polymerization of vinyl chloride, we started by comparing different initiation reaction rate profiles obtained close to standard operation conditions, in order to infer the typical values relative to this product. For this purpose, an optimization problem was prepared, where the objective function was the minimization of the final time (t_f), in case study I, with two typical initiators specified (one fast and the other slow).

Case Study I: Preliminary runs

This case study consists in the minimization of t_f, selecting the concentrations of two initiators at the beginning of operation and the addition policies of these species. The only constraints imposed were the desired numeric average molecular weight, $\overline{M}_n$ (in all situations presented in this work, the constraint $0.98 \leq \overline{M}_n \leq 1.02$, was used, with normalized values). **Figure 2** presents the addition profiles determined this way.

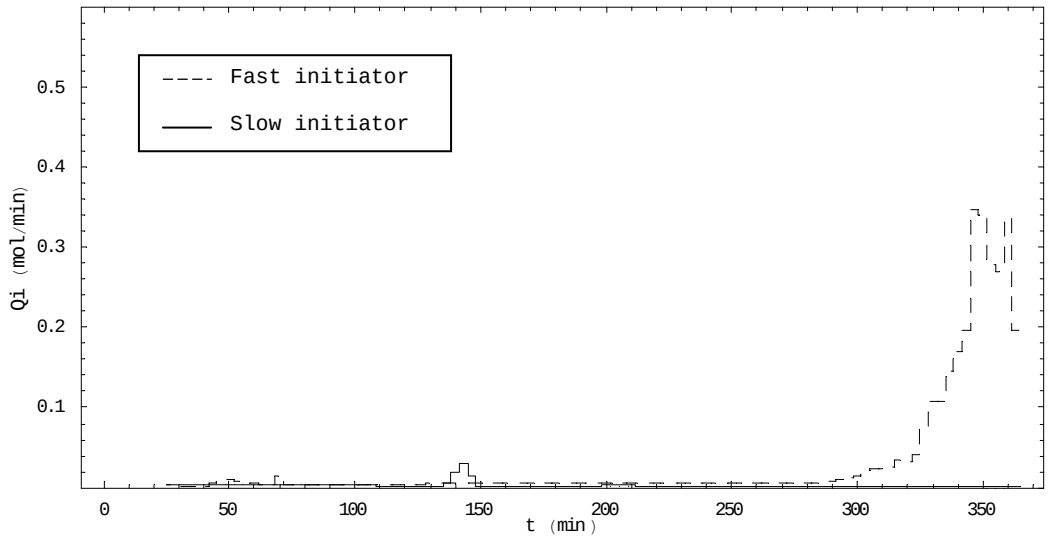

Figure 2 – Graphical representation of the addition profiles of initiators determined in case study I.

The solution of this problem also produced the values of 0.10 x 10^{-3} mol/kg_{VCM} for the fast initiator and 2.38 x 10^{-3} mol/kg_{VCM} for the slow one, as quantities of the initiators to be added at the beginning; the residual concentrations of initiators added to a total value of 1.15 x 10^{-3} mol/kg_{VCM}. This last value is close to the one obtained in typical operation, considering just the initial addition of initiators (10^{-3} mol/kg_{VCM}). **Figure 3** presents the initiation reaction rate calculated from the above results. Here, a slight rise in the initiation reaction rate when the operation is close to its end is visible. This means that if upper limits in the initiation rate, with linear shape and small slope, are imposed on the initiation reaction rate profile during the first optimization phase, then low (i.e., acceptable) residual concentrations of initiators may be expected at the end of operation. This can be easily specified in the first step of the systematic design methodology for polymer design.

Case Study II: Application of the first step of the design methodology

The objective in this case study is the minimization of t_f having as decision variable the initiation reaction rate profile (the temperature is maintained constant and equal to 55ºC). The previous constraint is applied regarding the final value of $\overline{M}_n$. After the critical

conversion (i.e., when the monomer rich phase is depleted) the initiation reaction rate now has as an upper limit corresponding to a straight-line with a specified slope (0.1, 0.05 and 0.01 mol / (m^3.s.min)). **Figure 4** shows the initiation reaction rate profiles determined in each situation. As can be observed, with successively lower slopes the duration of the operation presented increases slightly; this is in agreement with the initial observations. Applying the restriction with slope 0.01 resulted in the largest increase in operation time (6.4%). With these scenarios, we proceed to the following step of the methodology.

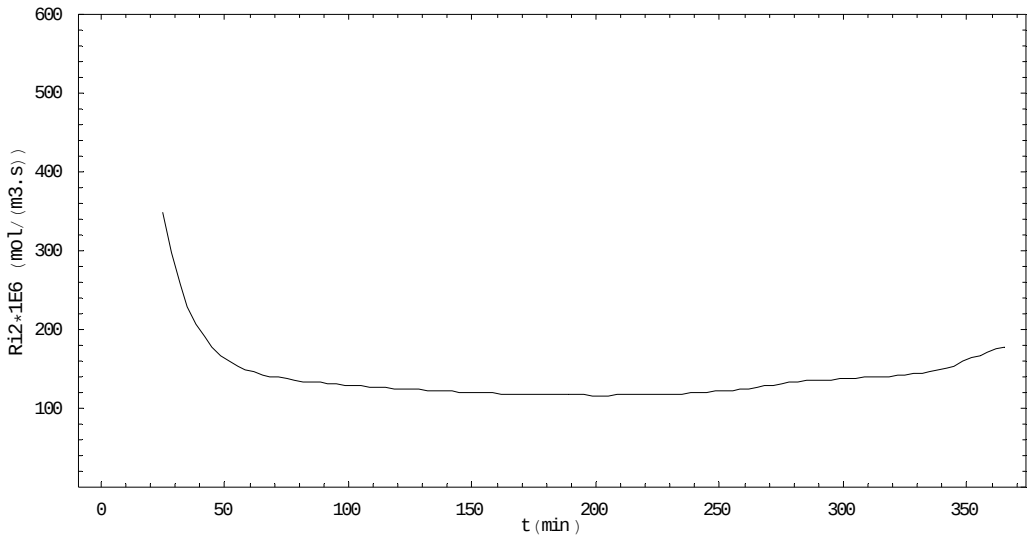

Figure 3 – Graphical representation of the initiation reaction rate profile determined in case study I.

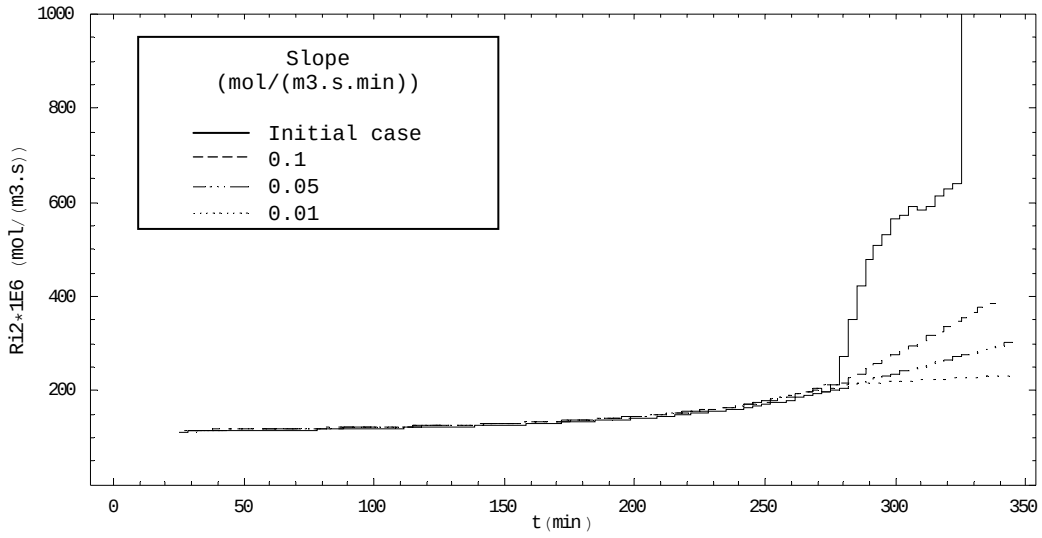

Figure 4 – Graphical representation of the initiation reaction rate profiles for case study II.

Case Study III: Second step of the design methodology

The objective in the second step of the methodology is to minimize the costs associated with the initiators used, considering the set of species and their addition policies as decision variables. Additionally, a good fit between the initiation reaction rate profiles of this and the first step of the methodology was imposed. Table 2 presents the relative costs and dissociation constants of the set of initiators made available to the optimization framework.

With this data (which will be referred to as set *A*), the optimization problem determined the results presented in **Table 3**.

Table 2 – Relative costs and inititation reaction rate constants of the set of initiators available (**Sanches e Myers, 1996; Akzo Nobel Chemicals BV, 2000**).

* monetary cost units.

Table 3 – Results obtained by applying the second step of the methodology.

Initiator data cost	*Slope* (mol/(m^3.s.min))	*Total cost* (m.c.u.)	*Residual concentration of initiators* (mol/kg_{VCM})	*Initiators selected*
A	Initial case	24.58	2.81×10^{-4}	i17
	0.1	21.96	9.40×10^{-5}	i17
	0.05	21.65	7.26×10^{-5}	i17
	0.01	21.41	5.81×10^{-5}	i17
B	Initial case	36.90	1.60×10^{-3}	i10, i14, i17
	0.1	26.67	1.44×10^{-3}	i10, i14, i17
	0.05	25.65	1.34×10^{-3}	i10, i14, i17
	0.01	24.71	1.41×10^{-3}	i10, i14, i17

When smaller slopes were used as upper limits, a reduction in the residual concentration of initiators was observed, together with a smaller total cost associated (a decrease of 13.8% in the total cost was observed with slope 0.01, compared to the initial case). This is due to the fact that in situations with higher slopes greater quantities of initiator must be added during the operation. As the slope of the constraint is decreased, the residual quantities of initiators at the end of the operation also tend to present lower values.

From the available set of initiators, the program initially chose only i17. In **Table 2** it can be noticed that not only is this the fastest initiator, but that also it presents a relative low cost. Therefore initiator i17 becomes the natural choice. To assess the ability of the methodology to produce alternative solutions, a second analysis was performed, penalizing this time the choice of fast, low cost, initiators (set *B*). In this situation the solution is different (**Table 3**). The total cost also decreases with the slope (39.6% for the restriction with slope 0.01, relative to the initial case). This is due to the additional penalization that fast initiators have in this scenario. Although the residual concentrations have slightly increased in this situation, they are still reduced, when compared the situations with an upper limit to the initial case, and in the acceptable range.

With the cost data set *A*, in all scenarios, a substantial decrease in the initiators residual concentrations can be observed, when compared to the base case (10^{-3} mol/kg_{VCM}).This demonstrates the capacity of the methodology to make careful choices of the initiators, in the presence of diverse sets of objectives and constraints. Likewise, the residual concentrations regarding situation *B* are similar to the value considered to be acceptable (10^{-3} mol/kg_{VCM}), and can be reduced even further, if necessary. Thus, it is possible to state that the systematic optimization methodology for polymeric materials design applied is sufficiently flexible to accommodate the generality of objectives and restrictions found in the industrial production of this category of polymers.

3 Conclusions

With this work we aimed at improving a systematic methodology for polymeric material optimization. Namely, it was intended to consider the residual concentrations of initiators. The path followed was searching for aspects of the methodology that could be readily changed by the user, while trying to achieve residual concentrations suited to the case studies. Here, the temperature was kept constant, in order to study independently the behaviour of the initiator addition policies.

A possible way of reducing the initiator residual concentrations was identified. This is based on imposing an upper limit to the initiation reaction rate profile, in the later stages of operation, during the first step of the methodology. From this procedure, a reduction in the residual concentration of initiators will also occur. This is obtained while reduced costs with initiators are also verified, when compared to the situations without restrictions on the initiation reaction rate profiles. Smaller slopes in the upper limit will result in larger operation times, which need to be verified, but have usually small effects, in industrial applications.

Abstract

A scatter search-based algorithm for global dynamic optimization in chemical engineering is presented. It is designed to overcome typical difficulties of non-linear dynamic systems optimization such as noise, flat areas, non-smoothness and/or discontinuities. It balances between intensification and diversification by coupling a local search procedure with a global search and makes use of memory to avoid simulations in previously explored areas. Its application to three dynamic optimization case studies proves its efficiency and robustness, showing also a very good scalability.

1 Introduction

Dynamic optimization appears in many industrial applications to optimize a pre-defined performance index (e.g., profitability) subject to some specifications over a time interval. Objective functions and/or constraints formulated from mathematical models describing industrial processes are usually highly nonlinear, which often causes non-convexity. Besides, non-smoothness and discontinuities can be present, thus the use of global optimization methods is needed for many dynamic optimization problems (Banga et al., 2005). In recent years, a special class of stochastic global optimization methods called metaheuristics have appeared as efficient optimization techniques.

Scatter search is a population-based metaheuristic introduced by Glover (1977) which combines a global phase with an intensification method, usually a local search (Laguna and Martí, 2003). Our scatter search-based algorithm has been written in Matlab under the name *SSm*. This study goes beyond a simple exercise of applying scatter search to dynamic optimization problems, but presents innovative mechanisms to obtain a good balance between intensification and diversification in a short-term search horizon. In many instances, dynamic optimization problems are non-convex and multimodal, thus the use of global optimization techniques becomes crucial for solving them (Banga et al., 2005). The application of our algorithm for solving nonlinear optimization problems arising from chemical and biological systems has provided excellent results (Egea et al., 2007; Rodríguez-Fernández et al., 2006).

This paper is organized as follows: Section 2 states the problem of dynamic optimization. Our algorithm is depicted in Section 3. Section 4 presents the three case studies used in this paper for our experiments as well as the results obtained. The paper finishes with some conclusions.

2 Dynamic Optimization: Problem Statement

The general dynamic optimization problem has the following mathematical form:

*Corresponding author. Tel. +34-986-214473. E-mail: julio@iim.csic.es

$$\min_{\mathbf{u}(t),\mathbf{v},t_f} C\left(\mathbf{x}(t_f),\mathbf{z}(t_f),\mathbf{u}(t_f),\mathbf{v},t_f\right) \tag{1}$$

subject to the system dynamics:

$$\mathbf{F}\left(\dot{\mathbf{x}}(t),\mathbf{x}(t),\mathbf{z}(t),\mathbf{u}(t),\mathbf{v},\mathbf{t}\right)=\mathbf{0} \tag{2}$$

$$\mathbf{x}(0)=\mathbf{x}_0,\mathbf{u}(0)=\mathbf{u}_0,\mathbf{z}(0)=\mathbf{z}_0 \tag{3}$$

where $\mathbf{x}(t)\in\mathbf{X}\subset\mathbb{R}^n$ and $\mathbf{z}(t)\in\mathbf{Z}\subset\mathbb{R}^m$ are the vectors of differential and algebraic states respectively; $\mathbf{u}(t)\in\mathbf{U}\subset\mathbb{R}^p$ is the vector of control (input) variables; $\mathbf{v}\in\mathbf{V}\subset\mathbb{R}^q$ are time invariant parameters; t is the time (and t_f is the final time); C is a functional to be minimized; $\mathbf{F}$ is the set of differential-algebraic equations describing the systems dynamics; finally, $\mathbf{x}_0$, $\mathbf{z}_0$, and $\mathbf{u}_0$ are the values of the respective vectors at the initial time t_0. Equality and inequality constraints may be imposed. Some of them must be satisfied over the whole process time (path constraints), while others must be only satisfied at the end of the process (endpoint constraints). The control variables and/or the time-invariant parameters may be subject to lower and upper bounds.

In this work we will consider the CVP approach (Vassiliadis et al., 1994) using the Piecewise Constant approximation, PC (i.e., zero order polynomial) with fixed-length time intervals. Different number of intervals will be used for each problem in order to check the scalability of the different optimization methods.

3 Scatter search algorithm for dynamic optimization of chemical and bio-processes

***Diversification Generation Method*:** *SSm* begins by generating an initial set of diverse vectors in the search space. The method makes use of memory taking into account the number of times that every decision variable appears in different parts of the search space (Glover et al., 2003).

Initial *RefSet* formation: For building the initial *RefSet*, after generating the set of diverse solutions, a subset of high quality and diverse points is selected. The first step consists in evaluating all diverse vectors and select some of them in terms of quality. The *RefSet* is completed with the remaining diverse vectors by maximizing the minimum Euclidean distance to the included vectors in the *RefSet*.

***Subset Generation* and *Solution Combination* methods:** After the initial *RefSet* is built, its solutions are sorted according to their quality and we apply the *Subset Generation Method*. In our implementation, it consists in selecting all pairs of solutions in the *Refset* to combine them. To avoid repeating combinations with the same pair of solutions, we use a memory term which keeps track of the pairs previously combined. Regarding the *Solution Combination Method*, we use a type of combination based on hyper-rectangles (Ugray et al., 2005), which enhances the diversification. Depending on their position in the *RefSet* every pair of combined solutions may generate from two up to four new solutions.

Updating the *RefSet*: As recommended by Laguna and Martí (2005), we update the *RefSet* considering the quality of the elements. This strategy may cause convergence to sub-optimal solutions or stagnation of the search in flat areas. To avoid these effects, we have implemented two filters (Egea et al., 2007) which restrict the incorporation of solutions that contribute only slight diversity to the *RefSet*

***Improvement Method*:** The *Improvement Method* consists in a local search, selecting the initial points by means of different filters. In this work, we have considered a gradient-based method (Exler and Schittkowski, 2007) and a direct-search method (Lagarias et al., 1999). In applications related to chemical and bioprocess engineering, we often face time-consuming evaluation problems or complex topologies which can make the local search inefficient. This implies that the application of the *Improvement Method* should be restricted to a low number of promising solutions. Here we use merit and distance heuristic filters introduced by Ugray et al. (2005) to avoid performing local searches from poor quality solutions or from solutions which are likely to provide already found local minima.

***RefSet* Rebuilding:** Due to the memory term which avoids combinations between *RefSet* members previously combined, the optimization procedure may stop if no new solutions enter the *RefSet* in a given iteration. Advanced scatter search designs overcome this problem by resorting a mechanism to partially rebuild the *RefSet*. The method is usually the same as that used to create the initial *RefSet*, in the sense that it uses the max-min distance criterion for selecting diverse solutions. We propose an alternative strategy to maximize the number of search directions. In this strategy, the vectors refilling the *RefSet* are chosen to maximize the number of relative directions defined by them and the existing vectors in the *RefSet* (Egea et al., 2007).

Intensification strategies: One of the filters mentioned above may prevent the search from focusing on intensification, especially during the first iterations. To allow combinations between high quality solutions (which do not apply to enter the *RefSet* because of the distance filter) and *RefSet* members, we store the solutions which can not enter the *RefSet* but have a better function value than the second *RefSet* member. These stored solutions are then combined with the best *RefSet* solution, increasing the probability of obtaining high quality solutions by combination in early stages of the search (Egea et al., 2007). Another advanced strategy (the *go beyond* strategy) to enhance the intensification of the search has been implemented in our algorithm. It consists in exploiting promising directions (Egea, 2008).

4 Computational experiments

In this section, a set of bioprocess dynamic optimization problems will be used as case studies to test the performance of the algorithm proposed in this work. A set of different state-of-the-art global optimization methods has been selected to compare their results with those obtained with the algorithm proposed in this study: *CMAES* (Hansen et al., 2003), *DE* (Storn and Price, 1997), *SRES* (Runarsson and Yao, 2000), *DIRECT* (Jones, 2001) and *OQNLP* (Laguna and Martí, 2002). Regarding stochastic solvers, a total number of 10 runs were performed for each problem.

4.1 Case studies

4.1.1 Fed-batch reactor for ethanol production

This system is a fed-batch bioreactor for the production of ethanol (Banga et al., 1997). The objective is to find the feed rate which maximizes the yield of ethanol. Table 1 presents results for every solver with the different levels of discretization considered. Table 2 compares the best result obtained by our algorithm for this problem with those found in the literature. Figure 1 presents the optimal control profile for the highest level of discretization.

4.1.2 Fed-batch fermenter for penicillin production

This problem deals with the dynamic optimization of a fed-batch fermenter for the production of penicillin (Banga et al., 1997). The optimal control problem is to maximize the total amount of penicillin

4.1.3 Drying operation

In this section we consider a food convective drying problem, similar to the one formulated by Banga and Singh (1994). The aim is to dry a cellulose slab maximizing the retention of a nutrient. The dynamic optimization problem associated with the process consists of finding the dry bulb temperature along the time to maximize the nutrient retention at the final time. Table 4 presents results for every solver with the different levels of discretization.

4.2 Executive summary of results

In this section we provide a summary of the results obtained in this work by making use of the performance profiles methodology (Dolan and Moré, 2002). Following Auger and Hansen (2005), we define the success performance FE for a solver on a specific problem by:

		CMAES	DE	glcDirect	OQNLP	SRES	SSm
$\rho = 10$	**Best**	**0.20002**	**0.20003**	0.19979	0.19875	0.20001	**0.20003**
	Mean	0.19710	0.19683	-	-	0.19894	0.19694
	Worst	0.19108	0.18939	-	-	0.19579	0.18742
$\rho = 20$	**Best**	0.19997	0.19913	0.19329	0.15483	0.19989	**0.20010**
	Mean	0.19696	0.19608	-	-	0.19878	0.19687
	Worst	0.19298	0.19185	-	-	0.19728	0.19326
$\rho = 40$	**Best**	**0.19952**	0.19859	0.18848	0.15102	0.19001	0.19788
	Mean	0.19751	0.19442	-	-	0.18796	0.19618
	Worst	0.19522	0.19103	-	-	0.18623	0.19311

Table 4: Results for the drying process problem

$$\mathsf{FE} = eval_{mean} \cdot \frac{\#\text{all runs}(10)}{\#\text{successful runs}} \tag{4}$$

where a run is considered successful if it obtained the optimal solution with a relative error $\leq 0.1\%$ (in our problems, we consider it as the best solution found by any of the solvers). With this definition the best success performance FEbest is given by the lowest value of FE for every problem. Figure 2 shows the empirical distribution function of the success performance FE/FEbest over all the problems.

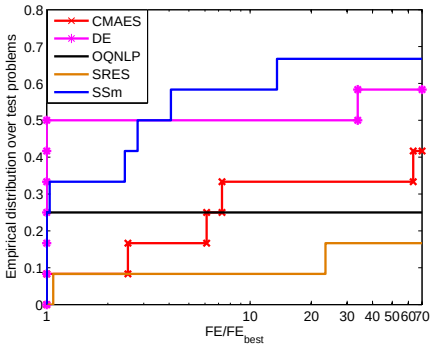

Figure 2: Performance profiles

As shown in the performance profiles, *SSm* solves the highest percentage of problems compared with the rest of solvers tested.

Conclusions

We have developed a scatter search-based methodology which intends to be effective for solving global optimization problems from the biotechnological and food industries. The procedure treats the objective function as a black box, making the search algorithm context-independent. We have expanded and advanced knowledge associated with the implementation of scatter search procedures. We have tested the proposed methodology over a set of dynamic optimization problems from the biotechnological and food industries. In order to have an idea about their efficiency, they have been compared with other state-of-the-art global optimization methods. The results obtained showed that the proposed methodology is adequate for the kind of problems intended to solve. In all cases our algorithm was competitive, providing the best solution among the tested solvers in many of the examples. It is to note that the algorithm's behavior is not affected by the problem size since it provides excellent results for every level of discretization considered in this study.

Keywords: Bio-ethanol process, direct optimizing control, NMPC.
Topic: Systematic methods and tools for managing the complexity.

Abstract

In this work, the integration of real-time optimization and control for optimal operation of a continuous bio-ethanol process is investigated, providing a first insight into a plantwide control methodology for bioprocess applications. The results obtained are compared to the open loop behavior of the process, showing the importance of incorporating an optimization-based control strategy to the traditional pH and temperature control.

1 Introduction

During the last years, significant improvements have been done in the bio-ethanol industry in order to make it economically more competitive. However, the economical feasibility of the bio-ethanol industry is still questioned, and therefore much effort should be oriented to the optimization and control of the process. In the same way, as argued by Engell (2007) for chemical processes, the purpose of control should be to achieve optimal process operation despite the presence of uncertainties. Thus, optimization and control are not considered anymore as isolated tasks but as tasks that should be combined in order to operate the chemical or biochemical process at maximal productivity, which is the real purpose of any production plant. In the last years, many works related to the real-time dynamic optimization of chemical processes coupling dynamic optimization and Nonlinear Model Predictive Control, have been reported in chemical process applications (Engell., 2007; Manenti and Rovaglio, 2007). However, to the authors' knowledge no applications on the bio-ethanol process taking into account more than one process unit have been presented. On the other hand, the problem of optimal process operation should be addressed from a plantwide perspective. Independently of the kind of process (chemical or biochemical), it is clear that the interactions between different operating units affect the dynamic behavior of the whole process (and therefore the productivity), and that in real operation these interactions cannot be neglected especially if the process contains recycle loops. Specifically for bioprocesses, optimal operation is a compromise between several facts: i) a proper environment for the microorganisms should be guaranteed; ii) the production of the main metabolite should be maximized; iii) inhibition factors should be avoided or minimized. In this work, the real-time dynamic optimization problem for the bio-ethanol process (including saccharification, fermentation, cells recycle and a first separation step) is addressed from two perspectives: direct finite horizon optimizing control (Engell, 2007) and dynamic optimization involving real time optimization coupled with NMPC (Kadam et al 2003).

2 Description of the Process

The process shown in Figure 1 corresponds to the so called extractive alcoholic fermentation studied by Costa et al (2001). The raw material entering into the process is liquefied starch, which is broken down into monosaccharides (glucose) by means of enzymatic action. The

* Corresponding author. Tel + 49-30-31426905. E-mail: ochoa@mailbox.tu-berlin.de

output stream of the saccharificator is fed into a fermentor in which ethanol production is carried out by the action of *Saccharomyces cerevisiae*. After the fermentation stage, stream F_4 is fed into a filter in which all the yeast are retained to be recycled into the fermentor through stream F_9. The yeast-free stream F_6 is mainly a mixture of starch, glucose, ethanol, water and some CO_2. This stream is fed into a flash vessel which operates under vacuum conditions to separate in the top a mixture of CO_2, ethanol and water. After that, the mixture is fed into a condenser in which all the remaining CO_2 is released. The condensate (F_{16}) is a mixture ethanol – water that is mixed with a portion of the liquid leaving the bottom of the flash resulting the stream F_{17}, which will be used as feed for the purification stage (distillation and molecular sieves).The process has been simulated using Simulink, assuming that pH, temperature and the liquid volumes on the tanks are regulated by means of internal control loops. Besides, it is considered that the dynamics on the yeast filter, the flash vessel and the condenser are much faster than the dynamics on the saccharification and fermentor tanks, and therefore they were simulated by using a steady state model. The saccharification and fermentation stages were modeled by unstructured non-linear dynamic models obtained from the corresponding mass balances for starch, glucose, enzymes, ethanol, cells, and CO_2.

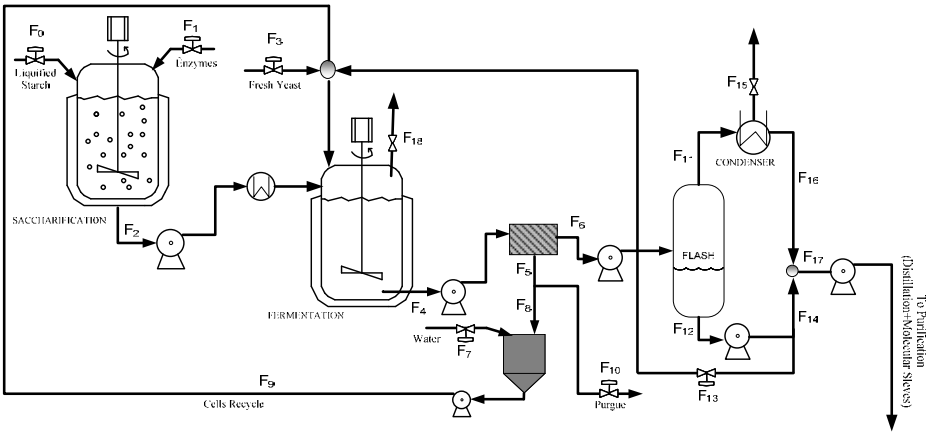

Figure 1. Bio-ethanol Process: Saccharification- Fermentation- Cells Recycle- First Purification step.

3 Optimization-based Control: Two-layer Integrated Dynamic Optimization and Control Vs Direct finite Horizon Dynamic Optimization

The challenge of controlling a plant for reaching optimal operation has been addressed from two main frameworks. The first one is the two-layer integrated optimization and control framework (two-layer approach) and the second corresponds to the direct optimizing framework (one-layer approach). Figure 2 shows the structure of these two approaches.

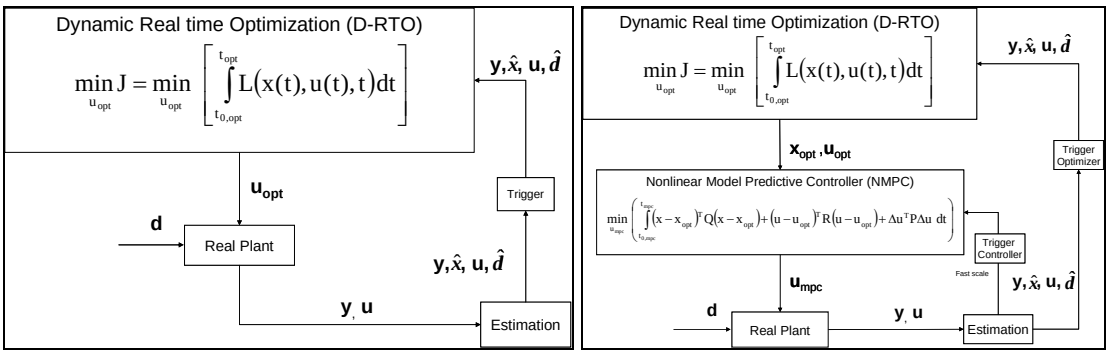

Figure 2. Dynamic Optimization based Control: One-layer (left) vs. Two-layer (right) approach.

As can be seen in Figure 2, the approaches have very much in common, actually the only different aspect is that in the one-layer approach, the input variables applied to the real plant (u_{opt}), are given by the optimization layer; whereas for the two-layer framework, the inputs applied to the real plant (u_{mpc}) are calculated by a control layer (usually containing a NMPC

controller); that uses as set points, the optimal values of the states given by the optimization layer (x_{opt}). In the following a description of each block presented in Figure 2 is given:

- D-RTO layer: This layer consists on a dynamic real time optimization problem in which the objective function is usually an economical function that should be maximized. The decision variables of the optimization problem are the manipulated variables (u_{opt}). Although the Bio-ethanol process shown in Figure 1 has six available manipulated variables (F_0, F_1, F_3, F_7, F_{10}, F_{13}) for controlling the plant, only three of these variables (F_0, F_1, F_{13}) are taken as decision variables during the optimization problem, because the remaining are used in an internal control loop proposed in Section 4.1.
- Real Plant: For the case of the bio-ethanol process considered in this paper, the real plant is the Simulink model mentioned before; in which the main disturbance (d) considered is the starch input concentration to the process (S_0).
- Estimation Block: In order to find the optimal operating point at each time, it is necessary to estimate the main state variables ($\hat{\boldsymbol{x}}$) that cannot be measured directly on the process; this can be done by using software sensors which employ the information of the available measurement variables (y). In this work, we assume that all the state variables and the disturbances ($\hat{\boldsymbol{d}}$) are known at every sample time during the process.
- Trigger: This block acts like a switch for re-calling the optimization layer. A trigger can work based on a time criteria (that means that the optimization is called periodically at a predetermined frequency) or based on the disturbance dynamics. A controller trigger is also used in the two-layer approach for re-calling the control-layer, whose re-calling frequency should be faster than that of the optimization-trigger. Due to the slow dynamics on the process, and after making a balance between performance and computational time, for the example presented in this work, it is used a re-calling frequency of 0.5h for the optimization-trigger and 0.2h for the controller-trigger.
- Control layer: This layer usually consists on a NMPC, in which the optimal values given by the optimization layer are used as set points for the controller. The NMPC solves an optimization problem, in which the objective function is usually composed of three terms: a penalization of the deviation of the main state variables from their set points (x_{opt}), a term that prevents large changes on the manipulated variables from one sample time to the next, and a term that constraints the manipulated variables to a small envelope around the reference trajectories (optimal values for the manipulated variables, u_{opt}, given by the optimization layer). In the present work, the cost functional of the NMPC considers the deviation of the ethanol concentration in the fermentor (E_4) from its optimal value calculated by the optimization layer ($E_{4,opt}$), and a penalization term for avoiding large changes between each sample time and the next.

$$\min_{\boldsymbol{u}_{opt}} J = \min_{\boldsymbol{u}_{opt}} \left[\Phi\left(\boldsymbol{x}(t_{opt})\right) + \int_{t_{0,opt}}^{t_{opt}} L\left(\boldsymbol{x}(t), \boldsymbol{u}(t), t\right) dt \right]$$

Subject to:

$$0 = \boldsymbol{f}_{opt}(\dot{\boldsymbol{x}}_{opt}(t), \boldsymbol{x}_{opt}, \boldsymbol{u}_{opt}(t), \hat{\boldsymbol{d}})$$

$$\boldsymbol{x}(t_{0,opt}) = \hat{\boldsymbol{x}}_{0,opt}$$

$$\boldsymbol{g}(\boldsymbol{x}_{opt}(t), \boldsymbol{u}_{opt}(t), \hat{\boldsymbol{d}}) = 0$$

$$\boldsymbol{h}(\boldsymbol{x}_{opt}(t), \boldsymbol{u}_{opt}(t), \hat{\boldsymbol{d}}) \le 0$$

$$x^{l} \le x_{opt}(t) \le x^{U}$$

$$\boldsymbol{u}^{l} \le \boldsymbol{u}_{opt}(t) \le \boldsymbol{u}^{U}$$

$$\min_{u_{mpc}} J_{NMPC} = \min_{u_{mpc}} \left(\int_{t_{0,mpc}}^{t_{mpc}} \left(x - x_{opt}\right)^{T} Q \left(x - x_{opt}\right) + \left(u - u_{opt}\right)^{T} R \left(u - u_{opt}\right) + \Delta u^{T} P \Delta u \, dt \right)$$

Subject to:

$$0 = \boldsymbol{f}_{mpc}(\dot{\boldsymbol{x}}_{mpc}(t), \boldsymbol{x}_{mpc}, \boldsymbol{u}_{mpc}(t), \hat{\boldsymbol{d}})$$

$$\boldsymbol{x}(t_{0,mpc}) = \hat{\boldsymbol{x}}_{0,mpc}$$

$$\boldsymbol{g}(\boldsymbol{x}_{mpc}(t), \boldsymbol{u}_{mpc}(t), \hat{\boldsymbol{d}}) = 0$$

$$\boldsymbol{h}(\boldsymbol{x}(t), \boldsymbol{u}_{mpc}(t), \hat{\boldsymbol{d}}) \le 0$$

$$\boldsymbol{x}^{l} \le \boldsymbol{x}_{mpc}(t) \le \boldsymbol{x}^{U}$$

$$\boldsymbol{u}^{l} \le \boldsymbol{u}_{mpc}(t) \le \boldsymbol{u}^{U}$$

Figure 3. Mathematical statement of the Optimization layer (left) and the Control layer (right).

Figure 3 shows the general formulation of the optimization and control layer problems, where f_{opt} and f_{mpc} represent the nonlinear process models used in the optimization and control layers respectively. The objective function used in the D-RTO problem is composed of the Mayer term (Φ) which is related to the state of the process at the final time and the Lagrange term (L) which represents an economical function related to the dynamic behaviour of the state variables during the transition from the initial optimization time ($t_{0,opt}$) to the final optimization time (t_{opt}); whereas g and h are the equality and inequality constraints of each optimization problem; and the super-indexes l and U indicate the lower and upper bounds for the states and manipulated variables. Basically, both layers (the optimization and the control

one) consist on a constraint nonlinear optimization problem, which differs mainly on the nature of the objective function, being an economic and a performance objective function for the D-RTO and the NMPC blocks respectively. Finally, the terms Q, R and P are weighting matrices of proper dimensions, which can be seen as tuning parameters for the NMPC.

4 Optimization-based Control for the Bio-ethanol process

The problem of controlling the bio-ethanol process for obtaining optimal operation at each sample time is addressed by applying the two frameworks described in Section 3. It is important to remark that the whole process has six available input variables that can be used as manipulated variables (control degrees of freedom). However, only three of them are taken as decision variables in the optimization layer, because the other three manipulated variables are used in an internal control loop. In this section, it will be first explained the mentioned internal control loops and after that, the results obtained by applying the one and two layer approaches (including the internal control loops) are presented and compared.

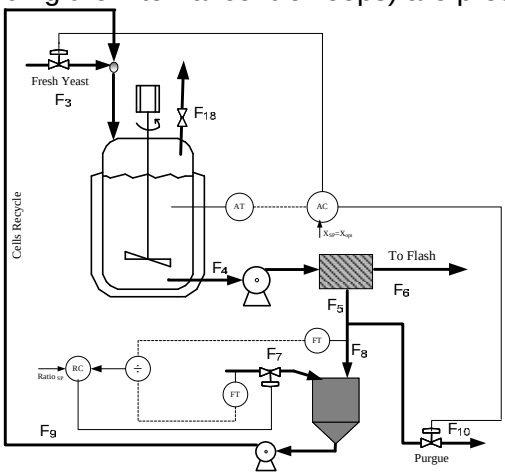

Figure 4. Internal Control loop for the Bio-ethanol Process.

4.1 Internal Control Loops for the Bio-ethanol Process

The internal loops proposed in this work comprise a split-range controller for keeping the biomass concentration in the fermentor at its optimal value and a ratio controller for achieving a suitable viscosity in the biomass recycle slurry. The biomass control loops proposed in this work are treated as independent because i) an optimal biomass concentration should be always guaranteed, in order to avoid a misuse of the substrate (which can be quickly consumed for cells maintenance and growth instead of metabolite production) if a higher concentration than the optimal is available; also, if the biomass concentration is below the optimal, a slower metabolite production rate will occur, affecting the productivity of the process; and ii) the yeast is only involved in the fermentation, filter and cells recycle loop. Figure 4 shows the proposed control loops in which the set point for the biomass in the fermentor (X_{opt}) comes from the optimization layer (tracking control); whereas the set point for the ratio controller (fixed set-point) was calculated following the suggestions given by Maiorella et al (1983), for achieving a suitable viscosity in the biomass recycle slurry.

4.2 Two-layer vs. One-layer Optimizing Control for the Bio-ethanol process

The dynamic optimization problem for both approaches was solved by the direct sequential approach using the Metropolis Monte Carlo-simulated annealing optimization method as presented in Ochoa et al (2007). The process begins at steady state. At time t=5h, a step disturbance on the starch feed concentration occurs (20% reduction). At the same time the optimization layer is called, which calculates the values of the manipulated variables that maximize the following objective function (which only considers the Lagrange term):

$$J_{opt} = w_1 \int_t^{t+\Delta t} E_{17} F_{17} dt - w_2 \int_t^{t+\Delta t} F_0 S_0 dt - w_3 \int_t^{t+\Delta t} F_4 dt + w_4 \int_t^{t+\Delta t} E_4 dt \quad (1)$$

The first term in (1) represents the productivity of the process, the second term penalizes the consumption of raw material, the third term penalizes the energy consumption and the last term incorporates a quality constraint as soft constraint, and Δt is the optimization interval. As previously mentioned, in the one-layer approach, the manipulated variables calculated for the optimization layer are directly applied to the process, and the optimization layer is recalled every 0.5 hours (trigger), in the meanwhile the process kept the manipulated variables at the optimal values given by the last optimization routine. In contrast, in the two-layer framework the optimal values for the manipulated variables are used into the model of the process for calculating the corresponding values for the state variables (i.e. $E_{4,opt}$ which is the "optimal" value for the ethanol concentration in the fermentor); this information is sent to the control layer for minimizing the objective function given by (2). The solution of the optimization problem for the NMPC (optimal values for the manipulated variables F_0, F_1, and F_{13} that minimizes (2) is applied to the process, and the control layer is recalled every 0.2h.

$$J_{NMPC} = \int_{t_{0,mpc}}^{t_{mpc}} Q(E_4 - E_{4,opt})^2 dt + \int_{t_{0,mpc}}^{t_{mpc}} P\,\Delta F_0^{\,2} dt \qquad (2)$$

Figure 5 compares the results of the one and two-layer approaches to the open loop policy. All three frameworks were run considering the biomass internal control loops proposed in Section 4.1 by using a proportional control law (biomass set point was given by the optimization layer in the first two cases, whereas for the open loop case, the set point was the initial steady state). As shown in Figure 5, the one and two-layer approaches have good response to the disturbance, maintaining the ethanol concentration in a higher value when compared to the open loop policy, in which a fast decrease in the ethanol concentration took place. This behaviour can be explained after a careful analysis of biomass dynamics. In the open loop case, in which no optimization was carried out after the disturbance, the biomass was kept in a high value (close to its original steady state), which resulted in a high cells' population using most of the glucose for maintenance and growing tasks (primary cell's tasks) instead of ethanol production. In contrast, the one and two-layer frameworks kept the biomass concentration at a lower value, consuming less substrate in maintenance and growth and reaching a suitable condition leading to higher ethanol concentrations.

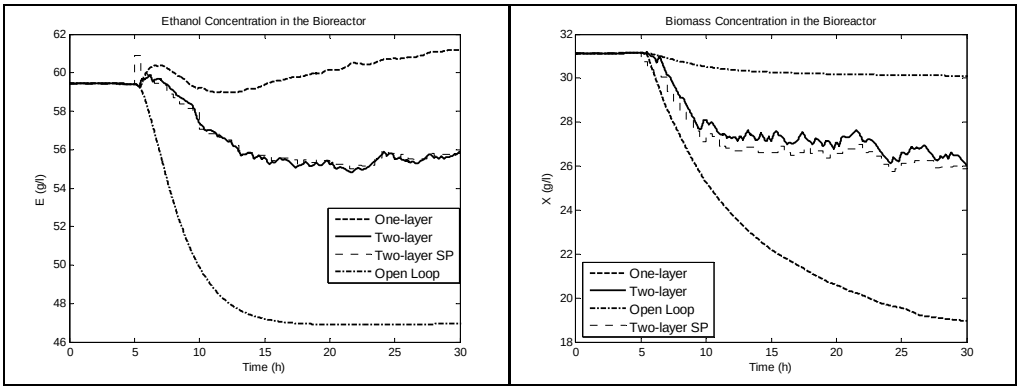

Figure 5. Results one-layer v.s. two-layer: Ethanol (left) and Biomass (right)

On the other hand, the ethanol concentration obtained with the one-layer approach was higher than that obtained with the two-layer during the whole process. To explain this fact, it is necessary to analyze the starch input flow (F_0, main manipulated variable) profiles applied to the process in both cases (Fig. 6). After the disturbance, the first action of the NMPC controller, trying to track the ethanol set point given by the optimization layer, was to reduce F_0 leading to an increase in ethanol concentration in the bioreactor due to a reduced dilution effect. However, by doing this, the process was driven to a condition of less substrate availability and consequently to lower ethanol production compared to the one-layer approach, which increased F_0 after the disturbance. After this short but relevant difference in starch feeding profile, the optimal operation profiles of the state variables in the process (e.g. ethanol and biomass) became completely different for both approaches.

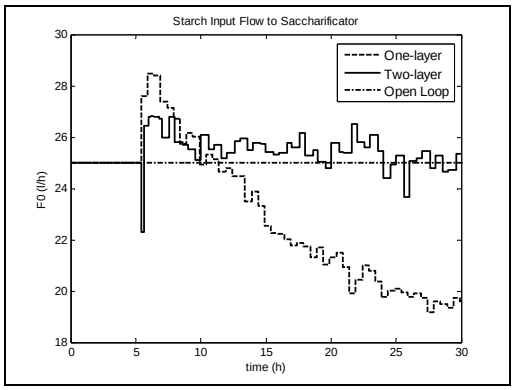

Figure 6. Results one-layer vs. two-layer: Starch Input Flow

At this point some important remarks should be done. First, the success of the one-layer approach depends strongly on the accuracy of the model used on the optimization-layer. Second, the one-layer approach has a certain “dead period” (0.5 h in this case) in which the control system does not have any feedback from the real process measurements. If a disturbance takes place during this “dead period”, it may drive the process to a condition of poor performance, and this will not be corrected until the following optimization task is triggered. In this sense, the two-layer approach seems to be a better choice because the NMPC-layer (which uses a simpler model of the process) acts in a feedback fashion more frequently than the optimization-layer. However, as can be seen in the bio-ethanol example, the objective function of the NMPC-layer is more a performance-type objective than a productivity one, and thus, it is possible that the results obtained are optimal in terms of tracking control but not in terms of productivity. Therefore, much effort should be oriented to the development of a two-layer strategy in which the NMPC takes into account the productivity of the whole process and not only the tracking of a set of variables.

Conclusion

The results presented in this work, demonstrate that the integration of optimization and control in a real-time framework is a very promising approach for achieving optimal operation (higher productivity, good disturbance rejection, increased profit, etc.) in bioprocesses from a plantwide control perspective. The two-layer and one-layer approaches were applied to the bioethanol process combining the use of two internal control loops for tracking the optimal biomass concentration. In a further study, optimization-control integration will be applied to the complete bioethanol process (including distillation and adsorption). Finally, it is important to highlight that there is a need of controlling the process for tracking the optimal operating conditions that lead to maximum productivity, instead of maintaining a predefined operating point calculated by using a steady state model of the process under nominal conditions.

Keywords: Metabolic flux analysis, on-line, adaptive, polyhydroxybutyrate, mixed microbial cultures
Topic: Systematic methods and tools for managing the complexity

Abstract
In this work, an on-line adaptive metabolic flux analysis (MFA) algorithm was developed and applied to the polyhydroxybutyrate (PHB) production by mixed microbial cultures (MMC). In MMC the main source of perturbation is the population dynamics which may cause variability in the energetic and stoichiometric parameters and therefore in the metabolic fluxes. An observer-based estimator (OBE) applied to the central MFA equation was proposed to solve this problem. The role of the OBE was to adjust the values of the unknown parameters such that the concentrations of the intracellular metabolites were forced to converge to zero. The estimator was implemented to the PHB process operated in a sequencing batch reactor (SBR) equipped with the on-line respirometric and titrimetric analysis. The O_2 and CO_2 fluxes were estimated directly through the experimental data. The macroscopic fluxes of acetate, PHB and sludge production was estimated through the on-line measurements and a projection of latent structures (PLS) model constrained by the carbon balance previously validated with off-line data. The proposed algorithm proved to converge exponentially with errors of the metabolites concentration always below 1 mmol/l by adjusting on-line the network parameters associated to biosynthesis. The estimates of the unknown fluxes passed the consistency index test for experimental error as low as 1%.

Introduction
Metabolic Flux Analysis (MFA) is a technique that uses data of some measured fluxes, normally substrate uptake and end-product formation rates, to determine the unknown fluxes of a metabolic network. The calculations required to this analysis are based on the pseudo-steady-state hypothesis to intracellular metabolites (Stephanopoulos et al, 1998). One of the several applications of MFA in metabolic engineering is the on-line estimation of the flux distribution of cells cultivated in bioreactors (Kim et al, 2008; Zhang et al, 2005).

In present work, on-line MFA is applied to polyhydroxybutyrate (PHB) production by mixed microbial cultures (MMC). The metabolic network adopted in this work was previously described (Dias et al, 2005). The main challenge in the MMC process control is the time-varying population composition which indirectly causes dynamics in the metabolic network. Same examples of this dynamic behavior are the undesired production of extracellular polymeric substances (EPS) (Dias et al., 2008a) and the oxidative phosphorylation efficiency (P/O ratio) oscillations that may occur over culture selection process (Dias et al., 2008b).

To deal with the time-variability of the metabolic network parameters, an on-line adaptive algorithm is proposed. The algorithm is based on the application of the observer-based estimator (OBE) (Bastin and Dochain, 1990; Oliveira et al., 2002) to the central MFA equation, whereby the role of the OBE is to force the concentrations of intracellular metabolites to converge to zero by adjusting the values of unknown parameters. The consistency of the on-line adaptive metabolic flux distribution (MFD) calculations was verified through the Chi-squared (X^2) test (Wang and Stephanopoulos, 1983).

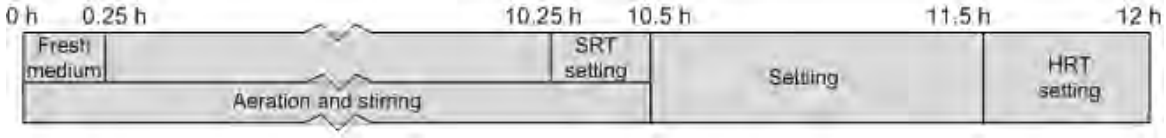
Materials and Methods

Experimental set-up and culture conditions

The set of 4 experiments were performed in a Sequencing Batch Reactor (SBR) with a working volume of 1.5 l controlled by a BIOSTAT B unit (Sartorius Biotech). Several probes were connected to the reactor in order to measure on-line temperature, pH, dissolved O_2 and dissolved CO_2. The reactor inlet and outlet gas flow was measured with mass flowmeters and the outlet gas composition in O_2 and CO_2 was detected by a gas analyzer. An analytical balance was used to monitor the weight of the acid solution used to control the reactor pH during the SBR experiments. The SBR cycles and operational conditions are summarized in Table 1.

Table 1- SBR cycles and operational conditions

SBR cycles conditions			
			


Operating conditions			
Hydraulic Retention Time (HRT) (h)	24	Aeration rate (ml/min)	400
Sludge Retention Time (SRT) (d)	10	Stirrer speed (RPM)	600
Temperature (ºC)	24		

Metabolic network and metabolic constraints

The metabolic network adopted for the PHB and EPS production can be described by a set of six metabolic reactions (expressed in a carbon-mole basis) which are compiled in Table 2:

Table 2- Metabolic model for PHB and EPS production by mixed microbial cultures

Acetate uptake (R_{Ac})
$CH_2O + ATP \rightarrow CHO_{0.5} + 0.5 \cdot H_2O$
Biomass growth and EPS synthesis (R_{EPS+X})
$Y_{Ac-CoA/(EPS+X)} \cdot CHO_{0.5} + Y_{N/(EPS+X)} \cdot NH_3 + K_{EPS+X} \cdot ATP \rightarrow (EPS + X) + \left(Y_{Ac-CoA/(EPS+X)} - 1 \right) \cdot CO_2$
Catabolism (R_3)
$CHO_{0.5} + 1.5 \cdot H_2O \rightarrow CO_2 + 2 \cdot NADH_2 + 0.5 \cdot ATP$
PHB production (R_{PHB})
$CHO_{0.5} + 0.25 \cdot NADH_2 \rightarrow CH_{1.5}O_{0.5}$
Maintenance (R_5)
$ATP \rightarrow m_{ATP}$
Oxidative phosphorylation (R_6)
$NADH_2 + 0.5 \cdot O_2 \rightarrow H_2O + \delta \cdot ATP$

Additionally to these reactions, R_{CO2} and R_{O2} were defined as fluxes and the steady-state balances of intracellular metabolites (Ac-CoA and ATP), redox, oxygen and total carbon were derived as metabolic constraints. Therefore, to calculate all network fluxes at least three fluxes has to be measure on-line.

In this study five fluxes were available on-line. R_{CO2} and R_{O2} were provided by on-line measurements while the on-line estimation of acetate, PHB, sludge concentration and their respective fluxes were obtained by a projection of latent variables (PLS) model constrained by the carbon balance (Dias et al, 2008a).

On-line adaptive MFA implementation

The central MFA equation was defined as $\mathbf{0} = \mathbf{A} \cdot \mathbf{v}$, where **A** is the stoichiometric coefficients matrix of the metabolic reactions and **v** the vector of fluxes.

The matrix **A** was derived as a function of the time-varying parameters and split into the matrix $\mathbf{A_b}$ and $\mathbf{A_n}$ for the subset of known ($\mathbf{v_b}$) and unknown ($\mathbf{v_n}$) metabolic fluxes. To solve the system, an adaptive MFA system was developed by applying an observer-based estimator (Bastin and Dochain, 1990) to the central MFA equation. The system involves a vector of intracellular concentrations ($\mathbf{c_i}$), the matrices described above, a vector of unknown time-varying parameters ($\boldsymbol{\theta}$) and tuning matrices $\boldsymbol{\Omega}$ and $\boldsymbol{\Gamma}$. The tuning parameters were defined to control the stability and the speed of convergence and were defined according to the rules proposed by Oliveira et al. (2002). The on-line adaptive MFA system is defined as follows:

$$\frac{d\Delta\mathbf{c}_i}{dt} = \mathbf{A_b}(\boldsymbol{\theta}) \cdot \mathbf{v_b} + \mathbf{A_n}(\boldsymbol{\theta}) \cdot \mathbf{v_n} + \boldsymbol{\Omega} \cdot \left(\mathbf{0} - \Delta\mathbf{c_i}\right)$$

$$\frac{d\boldsymbol{\theta}}{dt} = \boldsymbol{\Gamma} \cdot \left(\mathbf{0} - \Delta\mathbf{c_i}\right)$$

$$\mathbf{v_n} = -\mathbf{A_n^{\#}}(\boldsymbol{\theta}) \cdot \mathbf{A_b}(\boldsymbol{\theta}) \cdot \mathbf{v_b}$$

This problem was implemented in a MATLAB™ program. The matrix **A** and **v** were derived according to ATP, Ac-CoA, redox, O_2 and carbon balances.

$$v_b = \left[R_{CO_2}, R_{O_c}, R_{PHB}, R_{EPS+X}, R_{m_{ATP}}\right]^T;\ v_n = \left[R_{Ac}, R_4, R_6\right]^T$$

$$A_n = \begin{bmatrix} 0 & 0 & -Y_{Ac-CoA/(EPS+X)} & -1 & 0 \\ -\sigma_2 & 0 & \sigma_{EPS+X} & \sigma_{PHB} & 0 \\ 0 & 0 & -K_{EPS+X} & 0 & -1 \\ 0 & -1 & -1 & -1 & 0 \\ -2 & 0 & 0 & 0 & 0 \end{bmatrix};\ A_b = \begin{bmatrix} 1 & -1 & 0 \\ -\sigma_{Ac} & 0 & 0 \\ -1 & 0.5 & \delta \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{bmatrix}$$

The matrix $\boldsymbol{\theta}$ comprises the unknown parameters related to the biomass and EPS biosynthesis:

$$\theta = \begin{bmatrix} Y_{Ac-CoA/(EPS+X)} & \sigma_{EPS+X} & K_{EPS+X} \end{bmatrix}^T$$

The tuning matrices $\boldsymbol{\Omega}$ and $\boldsymbol{\Gamma}$ contain $\boldsymbol{\zeta}$ and $\boldsymbol{\tau}$, which are the natural periods of oscillation and damping coefficients of the desired second order dynamical response, respectively, were defined as following:

$$\Omega = diag\left(2 \cdot \frac{\zeta}{\tau}\right) \text{ with } \dim(\Omega) = 4;\ \Gamma = \frac{1}{\tau^2} \cdot \begin{bmatrix} -\frac{1}{R_{EPS+X}} & 0 & 0 & 0 & 0 \\ 0 & -\frac{1}{R_{EPS+X}} & 0 & 0 & 0 \\ 0 & 0 & -\frac{1}{R_{EPS+X}} & 0 & 0 \end{bmatrix} \cdot e$$

The consistency of the measured fluxes was checked through the consistency index method (Wang and Stephanopoulos, 1983) whenever the MFA system is redundant. The redundancy matrix, $\mathbf{R} = \mathbf{A_b} - \mathbf{A_n} \cdot \mathbf{A_n^{\#}} \cdot \mathbf{A_b}$, was calculated for this propose. When $\mathbf{v_b}$ is fully consistent with the network stoichiometry and devoid of error, the equation $\mathbf{0} = \mathbf{R} \cdot \mathbf{v_b}$ is verified.

In this study, the equation $\mathbf{0} = \mathbf{R} \cdot \mathbf{v_b}$ is equivalent to the steady-state balance $\mathbf{e} = (0 - c_i)$. In general, this relation is not obeyed and the consistency index test, **h**, has to be performed. The index (**h**) is a statistical chi-squared (χ^2) test and was calculated using the following set of equations:

$$\mathbf{e} = -\mathbf{R} \cdot \mathbf{v_b};\ \mathbf{Y} = \mathbf{R} \cdot \mathbf{Y_b} \cdot \mathbf{R}^{\mathbf{T}};\ h = \mathbf{e}^{\mathbf{T}} \cdot \mathbf{Y}^{-1} \cdot \mathbf{e}$$

where **e** is the deviation from zero of $\mathbf{0} = \mathbf{R} \cdot \mathbf{v_b}$ and **Y** the variance-covariance matrix of the metabolic fluxes, **v**, calculated by the propagation of **Y** associated to the measured fluxes, $\mathbf{Y_b}$. The number of degrees of freedom required to choose the χ^2 value is given by the difference between the number of metabolic constraints (5) and the number of unknown fluxes (3). The network consistency fails whenever h > χ^2.

Results and discussion

Direct and indirect measurements used for on-line MFA

The cumulative fluxes of O_2 and CO_2 (R_{O2}, R_{CO2}) were measured directly through respirometry, while PHB and EPS+X fluxes (R_{PHB}, R_{EPS+X}) were estimated indirectly through a PLS model calibrated a priori with the off-line measurements (see Dias et al., 2008a, for details). The maintenance flux for acetate (R_5) was assumed to be known [m_{ATP} = 0.02 mol-ATP/(C-mol.h) (Beun et al., 2002)] and calculated by integrating the theoretical maintenance coefficient obtained by the material and energetic balances of intermediates (Dias et al., 2008b). Figure 1 shows schematically the metabolic network of the PHB production process while in Table 3 are presented the fluxes for R_{O2}, R_{CO2}, R_{PHB}, R_{EPS+X} and R_5 at five different process phases of one SBR experiment.

On-line estimation of the unknown metabolic parameters

The estimation of σ_{EPS+X}, $Y_{Ac-CoA/(EPS+X)}$ and K_{EPS+X} was carried out assuming full knowledge of the remaing metabolic parameters. The oxidative phosphorylation efficiency, δ, was set at 3 mol-ATP/mol-$NADH_2$ (Dias et al., 2008b), while the convergence to unrealistic values of the unknown parameters was prevented by keeping them within biological limits. The estimates of the metabolic parameters presented a high variability within and between the four SBR experiments. The short-term variability was caused by the shift between biomass synthesis and EPS production, while the long-term variability may be explained by the population dynamics. Table 3 compiles the results obtained for these parameters for 5 different process phases.

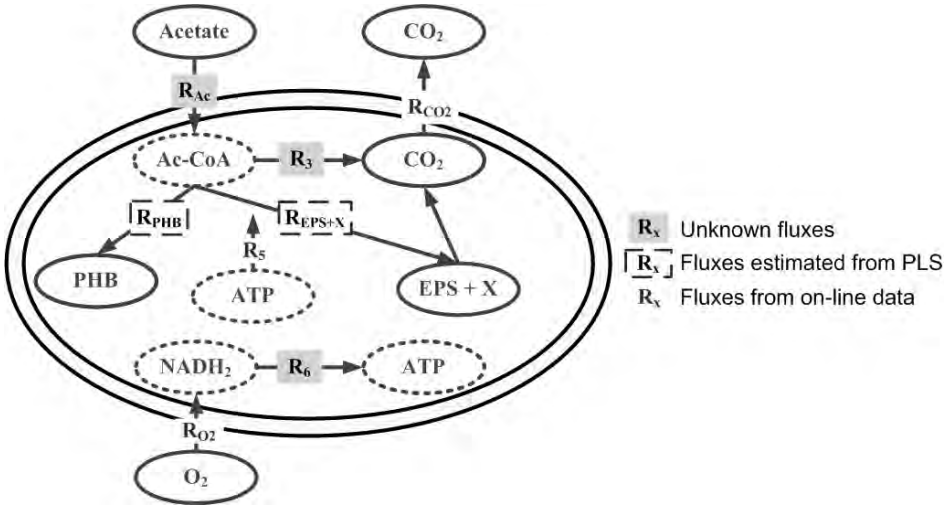


Figure 1 – Metabolic network of PHB and EPS plus biomass production process by MMC.

Table 3 – Values of cumulative fluxes, estimated (Est), expected or experimental (Exp) at five phases of one SBR experiment. Unknown time-varying parameters, consistency index and maximum (0-Δc_i) are also presented at the same SBR phases.

Metabolic fluxes

The unknown fluxes R_{Ac}, R_3 and R_6 included in matrix $\mathbf{v_b}$ were estimated and compared with their calculated and experimental values. The expected flux for R_{Ac} and R_6 were obtained directly from acetate and O_2 measurements while the expected R_3 was estimated through the carbon balance and the previous estimate of $Y_{Ac-CoA/(EPS+X)}$. The results obtained for 5 different SBR phases are presented in Table 3. In general, for all SBR experiments a good agreement between the expected and estimated fluxes were observed. Nevertheless, the cumulative $NADH_2$ in R_6 presented some no systematic variations which may be explained by the unknown ATP and redox balances or by time-varying P/O ratio. The introduction of additional metabolic constraints, not accounted by the model, has to be investigated in the future to enhance these last results.

Consistency analysis of the metabolic network

The consistency index test, **h**, was performed for all on-line samples assuming experimental errors below 1 %. The χ^2 coefficient was calculated for 95 % of confidence level and 2 degrees of freedom (number of redundant equations). Under these conditions, in nearly all samples, the estimated fluxes passed the χ^2 distribution test. The higher values for **h**, caused by the deviation from zero of the intracellular concentrations, were mainly due to the transition between the cell growth and EPS metabolism.

Conclusions

The main bottleneck of metabolic flux analysis in bioprocesses is the lack of information in metabolites balances, such as of ATP and $NADH_2$. In the PHB production process by MMC, there is two additional sources of uncertainty, namely the time-varying metabolic network, due to the population dynamics, and the lack of metabolic pathways for the EPS production. In this work, an algorithm that applies an observer-based estimator to central MFA equation was derived and validated for 4 SBR experiments. The algorithm showed an exponential convergence with residual intracellular concentrations always below 1 mmol/l. The consistency index, **h**, was also checked and passed in nearly all samples the χ^2 distribution test for experimental errors as low as 1 %. The ability of the algorithm to identify the shift

between biomass synthesis and EPS production demonstrated that its application for on-line monitoring and control of other biological systems may be very promising.

Keywords: Membrane Bioreactor (MBR), Modelling, PLS, 2D-fluorescence
Topic: Systematic methods and tools for managing the complexity

Abstract

In this work two membrane bioreactor (MBR) systems for wastewater treatment are monitored using 2D-fluorescence spectroscopy as fingerprints of the system status. Fluorescence maps can be correlated with the operational parameters using non-mechanistic methods, such as principal component analysis (PCA) and projection to latent structures (PLS), for performance monitoring and process optimisation. The 2D-fluorescence was used as a tool for monitoring MBR performance. It was found that the combination of the 2D-fluorescence data with selected performance variables capture additional information about the biological system state and substantially enhances MBR modelling and performance prediction.

1 Introduction

Membrane bioreactors are widely applied for wastewater treatment. However, the progressive membrane fouling due to deposition of cells and cell products on the membranes reduces the permeability of the system, resulting in substantial maintenance costs and shortening membrane life span. The major biofouling agents in MBRs are Extracellular Polymeric Substances (EPS), and thus EPS monitoring and control in MBR operation is essential. EPS contain large amounts of proteins and aromatic organic substances that possess natural fluorescence properties, making fluorescence a powerful technique to monitor their production in MBRs.

2D-fluorescence spectroscopy is a highly sensitive, selective and non-invasive technique that can provide rapid information about the composition of complex media such as biological systems. Due to the fact that all organisms contain natural intracellular fluorophores, such as aminoacids (e.g. tyrosine and tryptophan), vitamins, coenzymes and aromatic organic matter in general, fluorescence is a technique suitable to be used in bioprocess monitoring. Furthermore, since this technique is non-invasive, it can be used in situ and on-line without disturbing the biological system. The excitation-emission matrices (EEMs) obtained by scanning the spectra wavelengths can cover a wide diversity of natural fluorophores. The maps obtained from the EEMs can thus correspond to a fingerprint of the physiological status of a biological system.

The richness and complexity of information contained in EEMs should be taken into account when interpreting fluorescence results. Fluorescence fingerprints not only combine

* Corresponding author. Tel + 351-21-294-83-85. E-mail:jgc@dq.fct.unl.pt

physiological patterns of different microorganisms, but also reflect the variation in concentration of some substrate components and microbial by-products which possess fluorescence properties. In addition, some molecules can act as quenchers to fluorescence, by interacting with the excited fluorophores, resulting in alterations of fluorescence signal. Therefore, it is necessary to deconvolute the contextual information contained in the fluorescence maps. Using chemometrics, EEMs can be correlated with key operational and performance parameters of the studied system. When using chemometric modelling techniques, fluorescence spectra are viewed as multivariate descriptors of performance parameters and treated with statistical approaches such as Principal Component Analysis (PCA) and Projection to Latent Structures (PLS). The statistical models are obtained by this approach using on-line fluorescence maps and their corresponding process performance parameters measured for different operating conditions. Through these calibrated models, the EEMs obtained on-line can be used to monitor the status of the process, as well as for prediction, allowing rapid correction of operational parameters for process optimisation.

Fluorescence spectroscopy was previously applied for on-line monitoring of an extractive MBR for degradation of volatile organic compounds in aqueous media (Wolf et al., 2001). The biofilm formed at the membrane surface was monitored in situ using an optical fibre cable for delivering excitation light and capturing emission light. The EEMs obtained were analysed together with operational parameters using artificial neural networks (ANN) for system monitoring and modelling. 2D-scanning fluorometry together with ANN, as a nonlinear and non-mechanistic technique for deconvoluting fluorescence information, proved to be suitable for monitoring this complex biosystem.

In the present study, 2D-fluorescence is applied to monitor two pilot scale MBRs for domestic wastewater treatment, by measuring EEMs of the influent wastewater, the bioreactor mixed liquor and the permeate. The fluorescence maps obtained as fingerprints of the system are correlated with operating and performance parameters using PLS to create models able to predict the selected performance variables.

2 Methodology

In the current work 2D-fluorescence is applied to monitor a pilot scale MBR for domestic wastewater treatment located in a Wastewater Treatment Plant (Lavis, Italy) and a lab MBR in Caparica, Portugal, also with municipal wastewater. Both MBR systems consist in submerged hollow-fibre membranes immersed in a complex matrix containing suspended activated sludge and several products resulting from wastewater feeding and microbial activity, as well as biofilms attached to the membranes.

Fluorescence EEMs are measured in the wastewater feed, in the mixed liquor and in the permeate at the same time that samples are collected for further analysis of wastewater and mixed liquor (chemical oxygen demand (COD), nitrogen and suspended solids). Also transmembrane pressure (TMP), temperature and dissolved oxygen (DO) are measured on-line. All these data collected together with the operating parameters – imposed permeate flux (J), hydraulic retention time (HRT) and solids retention time (SRT) – are used to perform PLS models for each system.

PLS are used to maximize the co-variance between fluorescence maps, selected performance variables (e.g. TMP and COD removal) and operation conditions (e.g. aeration and influent COD).

To perform mathematical models, data needs to be previously processed. Since fluorescence EEMs have one value of intensity of emission for each pair of excitation/emission wavelength that have to be used as independent variables, EEMs have to be linearized and compacted using principal component analysis (PCA). EEMs compacting is needed to decrease the amount of variables described by fluorescence maps, colinearity and noise. Additionally, all data have to be standardized to ensure the same initial weight for all variables, and have to be split in training and validation sets. Standardization

was done by subtracting to each value the average of the corresponding variable and dividing by the standard deviation. Approximately 25% of the data is used to validate the models after the PLS training with the remaining data.

PLS models are developed for these systems in search for a correlation between inputs and outputs that would enable us to predict the systems behaviour. Operating conditions, wastewater characteristics and EEMs are used as inputs of the models. Permeate characteristics, sludge characteristics and membrane performance (measured as TMP) are the parameters predicted by these models (called outputs). PLS models are obtained as one linear correlation of all inputs to predict each output, permitting to infer about the contribution of each input parameter in the outputs behaviour, leading to a possible process optimization.

PLS models are trained using EEMs of either wastewater, sludge or permeate in distinct models, and all together in the same model to access the information contained in each kind of EEMs and their predicting capability. Additionally, changes are introduced in the operating conditions to cover a wider range of conditions used for model training and improve the predictability capacity of the resulting PLS models.

3 Results and Discussion

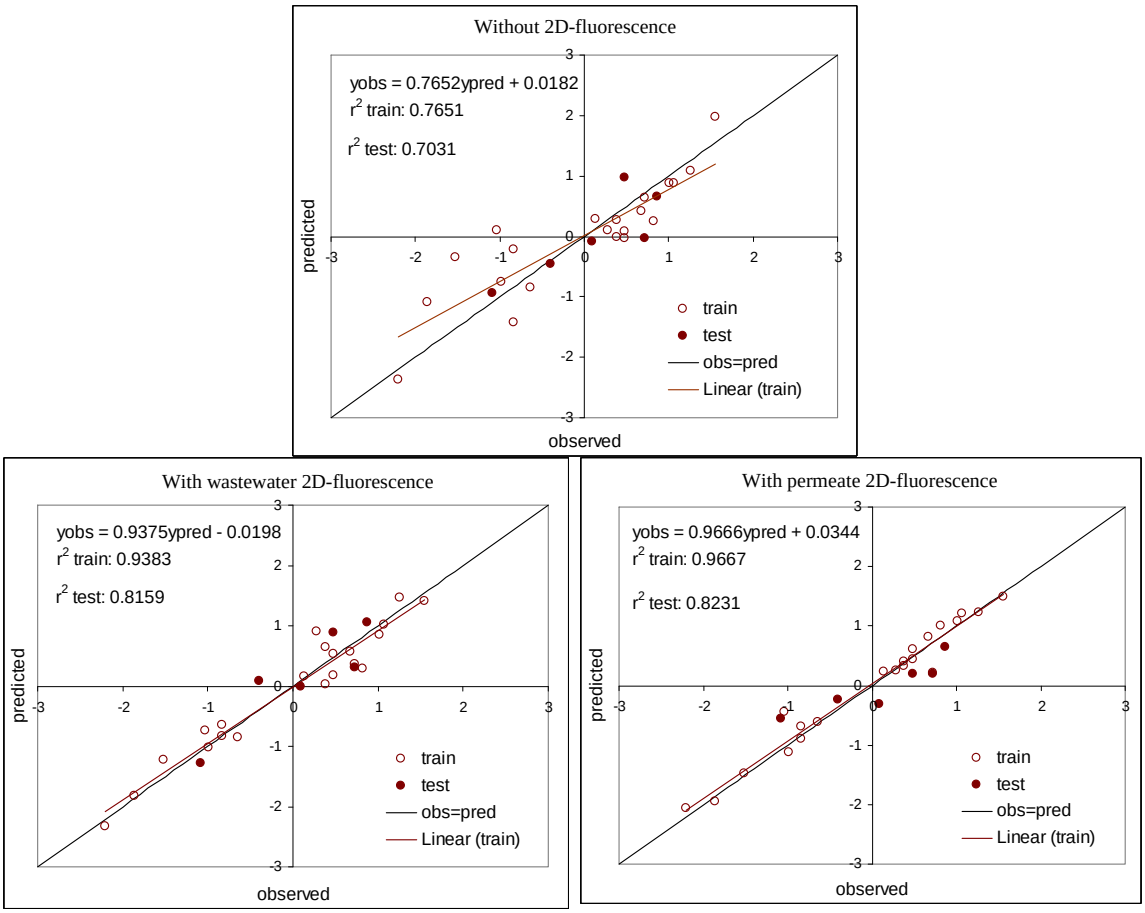

Figure1 – Normalized values of TMP predicted by PLS models against the experimental normalized values of TMP. The first plot shows predicted values by a PLS model without fluorescence information, the other two plots with a PLS model developed with wastewater EEMs and permeate EEMs, respectively.

PLS models obtained with data from the pilot MBR show that the combination of the EEM's additional information about the biological system state with the selected performance variables enhanced MBR modelling and performance prediction. Figure 1 shows that models

using EMMs as input together with analytical and performance data, have a better fitting of the training points for the TMP prediction. Also the validation points fit better in PLS models developed with fluorescence data.

Preliminary results suggest that strong correlated parameters (such as total suspended solids and volatile suspended solids or the information given by each of the three different EEM types) do not improve the information given to the model and can even increase noise, decreasing the predictive capacity of model. Additionally, it was found that fluorescence maps from sludge seem to capture more information about the system than the wastewater or permeate EEMs (data not shown), which is expectable as the information collected by the sludge reflect the biomass status and the microbial activity taking place in the activated sludge tank. Nevertheless different compacting methods of the EEMs are still being studied to ensure that none of the information contained in each type of EEM is lost.

In the future, PLS models and conclusions about the correlation between inputs and outputs obtained from models will be compared for both MBRs since they differ in scale, configuration, membrane manufacturer and wastewater fed.

Topic: Systematic methods and tools for managing the complexity

Abstract

A cost indicator for the design and multi-objective optimization of reactive distillation columns, designated capacity, was introduced in previous work by the authors. The question of this indicator's effectiveness as a measure of the actual column cost, is herein investigated over a number of designs by comparing it with the value obtained by means of conventional costing procedures. The results show that the level of accuracy obtained when using capacity is satisfactory and certainly acceptable for a preliminary design stage.

1 Introduction

Reactive distillation (RD) combines reaction and separation into the same physical shell. This combination can lead to both economic and environmental gains resulting from process intensification (Malone and Doherty, 2000; Taylor and Krishna, 2000) and therefore to systems with significantly greener engineering attributes (Malone *et al.*, 2003).

However the design of these systems can prove very complex and costly. Design should therefore be preceded by preliminary studies to assess first the potential adequacy of the technology. With this aim some work was developed to create a framework combining feasible regions and optimization techniques to the design and multi-objective optimization of complex reactive distillation columns, for reacting systems with variable degrees of relative volatilities (Filipe *et al.*, 2006; 2007; 2008b).

This led to the consideration of RD columns with distributed feeds, with many of them involving the combination of superheated and subcooled feeds. This combination provides a source or a sink of heat at specified trays of the columns, which favors reaction while reducing the total reactive holdup requirements.

To assess the impact of employing such combined feeds, a cost indicator, designated capacity, was introduced as a novel optimization objective criterion (Filipe *et al.*, 2006). This cost indicator, based on the capacity variables (Jobson *et al.*, 1996), was defined as the weighted sum of liquid and vapor internal flows divided by the total feed to the column.

Together with the total number of stages and reactive holdup this indicator was used to build the Pareto front that contains the efficient set of solutions. Considering the very large number of designs involved in the evaluation, an indicator was preferred to a detailed cost calculation.

Following a strategy of refining the Pareto optimal designs, some aspects related with the practical implementation of a few promising designs were investigated (Filipe *et al.*, 2008a) by means of a number of sensitivity tests on catalyst usage and feed quality. The advantage

* Corresponding author. Tel + 351 218 317 000. E-mail: rfilipe@isel.ipl.pt

of using combined feeds was confirmed, as well as the need for a careful selection of the feed qualities.

The capacity indicator proved valuable as an optimization criterion, not only because it is efficient in comparing thousands of different designs, but also because it effectively limits the range of the feed qualities used. However, some drawbacks have been identified in its formulation, namely it makes no distinction between reactive and non reactive trays and the RD effective capital and operational costs are not explicitly shown.

This work presents a study where the effectiveness of the proposed cost indicator is assessed and, in addition, the optimal solutions identified in previous stages of the design procedure are tested at an advanced level. The size (height and diameter) of the column, energy and catalyst demands are quantified in the Aspen Plus detailed model of some designs and the total cost of the column estimated using common cost correlations. These values can be correlated with the corresponding capacity values, thus allowing the estimation of new weights for the factors present in the initial capacity definition.

As an illustrative example, a system with ideal vapor liquid behavior is employed, i.e., the olefin metathesis system (wherein 2-pentene reacts to form 2-butene and 3-hexene). For this particular reactive system, the reactant boiling point falls between those of the two products, allowing for a wide range of feasible column designs.

2 Methodology

To develop this study, six different solutions belonging to the Pareto front relating reactive and capacity (cost indicator) previously generated (Filipe *et al.*, 2008b) were selected. The main assumptions for the optimization methodology developed in GAMS to achieve the Pareto fronts are: steady state operation, constant pressure, vapor-liquid equilibrium at every stage, kinetically controlled reaction occurring in the liquid phase, and negligible heat effects. For each design, the methodology applied determines the optimal locations for the catalyst, feeds and feed quality.

The selected set of solutions is used to initialize simulations in Aspen Plus, using the RadFrac model and the Ideal property method. All the design specifications, such as the number of stages, reboil ratio, distillate to feed ratio, location and quality of the feeds, as well as the reactive holdup distribution, are taken from the former optimization results. Aspen Plus does not support the direct specification of the feed quality. To overcome this, a design specification is implemented: the feed temperature is adjusted to provide the required energy for a change in the internal liquid flow according to the equation $L_n = L_{n+1} + q \bullet F$, where F is the feed flow, q the feed quality, and L_{n+1} and L_n the liquid entering and leaving the tray, respectively.

The capacity cost indicator previously defined (Filipe *et al.*, 2006) is based on the size of internal flows, feeds and number of stages, providing an expedient method for the evaluation of a large number of solutions. Equation 1 shows how to calculate the capacity for a column with N stages, where i = 1 refers to the condenser and i = N to the reboiler, V_2 is the vapor condensed at the total condenser, B is the bottom liquid flow and w_B and w_C are the weights for the boiling and condensing capacity, respectively. Both weights were set to unity during the optimization step.

$$Capacity = \frac{w_B\left(\sum_{i=2}^{N} V_i\right) + w_C\left(\sum_{i=2}^{N-1} L_i + V_2 + B\right)}{\sum_{i=1}^{N} F_i} \qquad \textbf{Eq. 1}$$

As many reported designs tend to be operationally unrealistic (e.g. very large number of feeds, too large or too small feed temperatures), some modifications of the optimal designs previously obtained were considered. Three different scenarios, A, B and C are defined by

modifying the original optimal design, for each of the selected 6 cases. In scenario A, the number of feeds is limited to two, while maintaining the amount of energy supplied by the feed streams to the column. Scenario B considers a more realistic adaptation, where the number of feeds is reduced to two and the feed quality value is bounded by an upper temperature of 650K and a lower of 298K. In this same scenario, the cooling requirements of the cold stream are reduced to zero. Moreover the elimination of unrealistic temperature conditions by increasing the temperature of the cold feeds, has only a slight effect on product purity as demonstrated previously (Filipe *et al.*, 2008a). Scenario C represents a departing approach from the previous ones, where the advantages of using subcooled and superheated feeds are not considered. Instead, feed conditions - dew and boiling points of the feed stream - usually found in industrially operating columns are assumed. The number of feeds is also reduced to two in this scenario and the behavior of the capacity is tested for a diverse range of feed qualities.

The total annual cost (TAC) is calculated as the sum of the annual capital cost and energy cost, using the correlations reported by Luyben (2000). Annual capital cost is assumed to be the capital investment divided by a payback period of 3 years. The column shell, trays, reboiler, condenser, heat exchangers for feeds and corresponding heating utilities, are considered in the calculations. The cost of the catalyst is not considered, as the capacity is supposed to include only capital and utilities cost, but it is accounted for in the multi-objective optimization methodology, in terms of the reactive holdup variable.

The olefin metathesis system is used, with the physical properties and reaction kinetics being taken from the literature (Okasinski and Doherty, 1998). The reaction is considered only to occur in the liquid phase with a negligible heat of reaction and ideal vapor-liquid equilibrium behavior at atmospheric pressure. The specifications for column operation are taken from Hoffmaster and Hauan (2006), where the goal is to convert a pure 2-pentene feed into product streams of 2-butene and 3-hexene with a purity of at least 98 mole percent using a feed flow of 2 kmol/h and a distillate to feed ratio of 0.5.

3 Results and discussion

The details for the selected cases are shown in Table 1. The number of stages ranges between 29 and 16, the reactive holdup between 3.2 and 8 and the capacity between 90.4 and 41. As discussed earlier (Filipe *et al.*, 2008b) the capacity increases with the number of stages (higher internal flows in larger columns) and, for the same design specification, higher product purities require higher capacities (increased residence time in the reactive trays). Column diameter changes only slightly within each scenario, while between scenarios a significant reduction is observed in C when compared to A and B, which is justified by its lower internal flows due to the feed qualities used.

Although the design specifications used in the optimization methodology required a purity of 98% in the products, the assumptions made at the optimization stage and the more rigorous calculations employed by Aspen Plus lead to different purities. In addition, the changes in the feed qualities also contribute to this effect. Product purity is greatly reduced in scenario C, especially in the columns with larger number of stages, where the reduction in the internal flows is more noticeable. This reduction in the internal flows, also revealed by the reduction in capacity, decreases the residence time in the reactive trays, thus deteriorating the specifications of the products.

Figure 1 depicts the variation of product purity with capacity for scenarios A and B. The dashed line indicates the specification used in the optimization methodology. It is noticeable that the adjustments made in the feed qualities increase the product purities in most of the designs at the expense of a penalty in capacity, which is always increased. This is a somewhat expected result as these scenarios are based in optimal designs where the reactive holdup and capacity had been minimized. In addition, contrary to the observed effect

for a single column, capacity is found not to increase with product purity while comparing different columns, since they correspond to different performance levels.

NT number of trays, NF number of feeds, FT feed tray, F amount of feed (%), q feed quality, Cap capacity, D_{col} column diameter, TAC total annualized costs.

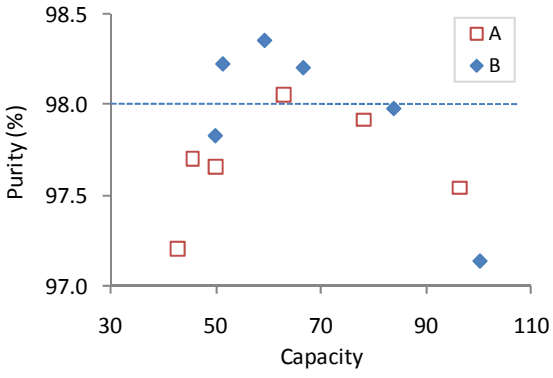

Figure 1 - Purity versus capacity for scenarios A and B

3.1. Comparison of capacity with total annualized costs

In Figure 2, the capacity, and the equipment and utilities costs are depicted for scenario B. All these variables decrease as the height of the column decreases (a high case number indicates a low number of stages). It is noticeable that capacity describes correctly the cost trend, while displaying greater sensitivity at the upper end of the cost curves.

In Figure 3 the variation of the total annual costs and capacity for case B are normalized, by dividing the value of each case by the average value of the six cases. It now becomes clearer that the deviation occurs at both ends of the cost curves. The calculated mean deviation is about 20%, thus capacity may be considered an acceptable cost indicator for an early stage conceptual process design. It is also advantageous when the design is not yet fully specified as only the knowledge of internal flows and feed flows is required. In addition, its calculation is straightforward, making it adequate for the comparison of very large number of designs.

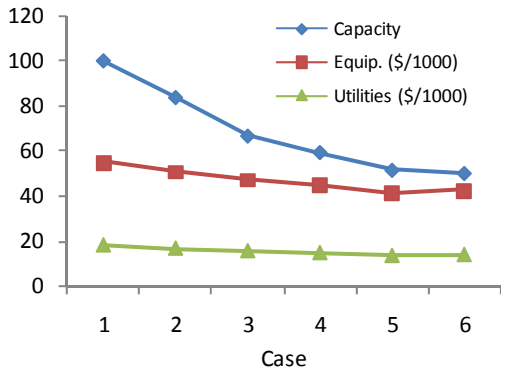

Figure 2 - Capacity, equipment and utilities cost for scenario B

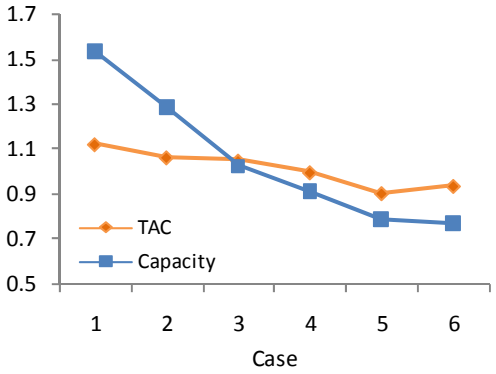

Figure 3 - Normalized capacity and TAC for scenario B

3.2. Capacity weights

The effect of weights w_C and w_B on the capacity cost indicator was assessed and it is concluded that no significant effects were noticed. The values for the individual boiling and condensing capacities (Figure 4) typically differ less than 5%, so the assumed values of $w_B = w_C = 1$, employed for the present study seem justified.

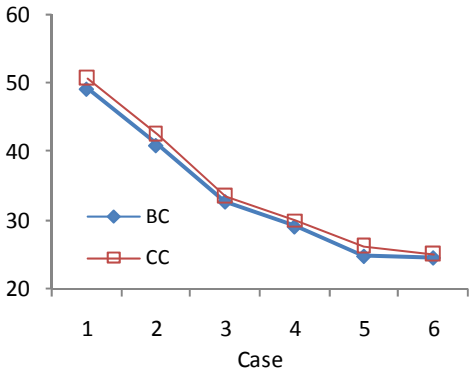

Figure 4 – Boiling capacity (BC) and condensing capacity(CC) for scenario B

4 Conclusions

This paper addresses the use of performance indicators for the design of reactive distillation columns. Specifically, the analysis of a cost indicator previously used in the classification and selection of several thousands of preliminary designs is addressed. The total annualized

costs are calculated and compared to capacity indicator values for several different designs derived from the optimal designs previously obtained from optimization runs performed in GAMS. The results show that capacity and costs have a common trend, within an average error of 20%, pointing to capacity as a suitable indicator for preliminary design analysis.

The influence of the weights used in the definition of capacity was also assessed with a view of improving its accuracy, but no significant improvements could be achieved as the individual capacity values are quite close.

On-going work aims to establish the effect of the weights during the optimization process and to further sophisticate the capacity indicator with a view to make it more selective in terms of the number and characteristics of the optimal preliminary designs.

Topic: Systematic methods and tools for managing the complexity

This work is based on the presentation recently awarded with the prize jEPSI at the 6th Workshop Anual de Engenharia de Processos e Sistemas, 12th March 2008 at Coimbra-Portugal, and intends to illustrate why a solid method for process development should be the result of the integration of "theory" (the models) and "practice" (experimental applications). Therefore, are presented some cases from the Simulated Moving Bed technology where developments based on model analysis led to the conception of practical applications, as well as some cases where the restructuration or operation of experimental/industrial units guided improvements in the previously used models, Figure 1.

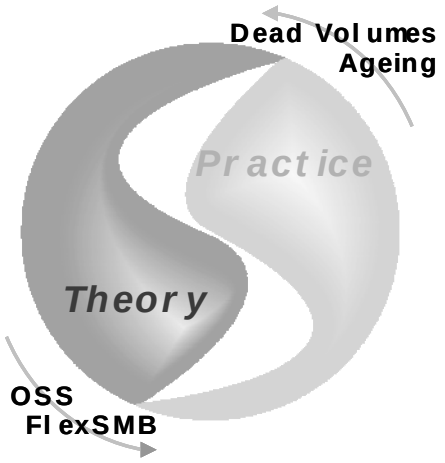

Figure 1 – From models to practice… and from practice to models.

Simulated Moving Bed technology

It is known that industrial-scale continuous adsorption processes are preferable to batch ones. The use of continuous chromatographic counter current operation in particular (here by called TMB, True Moving Bed), maximizes the mass transfer driving force, providing a better utilization of the adsorbent, which may have a rather low selectivity. In addition, with TMB it is possible to reduce the solvent consumption, increase of productivity and purity and therefore less diluted product streams. Contrary to the TMB units, where the solid phase moves counter currently to the fluid phase, in the SMB (Simulated Moving Bed) [1] units the solid motion is simulated by a

* Corresponding author. Tel + 351-225-081671. E-mail:arodrig@fe.up.pt

synchronous shift of all inlet and outlet ports, while the solid phase is held immobile, Figure 2.

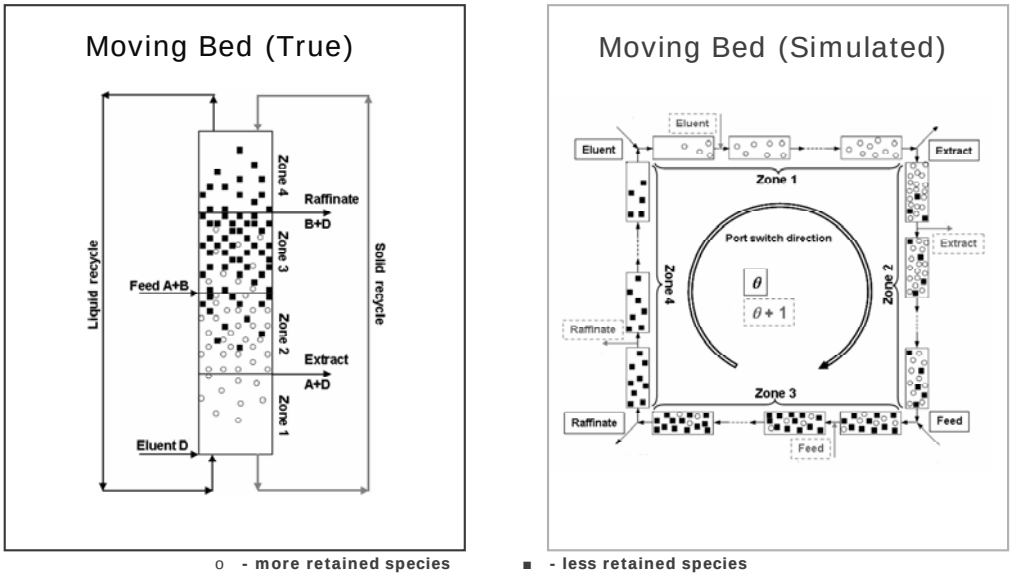

Figure 2 – The True Moving bed (TMB) and Simulated Moving Bed (SMB) analogy.

By this way, several problems usually associated with solid motion, namely, particle and equipment attrition, high pressure drops, particle and flow redistribution are avoid.

The SMB technology has been mainly applied to the so-called “difficult separations”, in fields such as the petrochemical area with the separation of p-xylene from C_8 isomers mixtures. The expansion to new SMB applications in fields such as the biotechnological, fine chemistry and pharmaceutical industries is remarkable in the last decade [2].

From models to practice…

By means of mechanistic models, or more simplistic approaches, it is possible to describe an SMB unit accounting to all its particularities, even the ports discontinuities Table 1 and 2.

Table 1 – SMB nodes balances

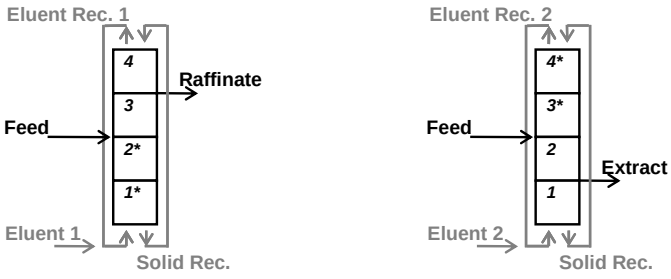
plus the multicomponent adsorption isotherms

$q_{ic} = f_i\left(\langle C_{pic} \rangle, \langle C_{pic} \rangle\right)$ with $k \neq i$ and for all species *i* and in column *c* **(7)**

The deep study of these models provided the development of the "non conventional modes of operation", where, and by means of the introduction of asynchronous ports movements, variation of concentration and/or flow rates, it was possible to extend the versatility of this kind of units and by consequence its performance. The development of the OSS (Outlet Streams Swing) [3] mode of operation is one of these cases.

In the OSS mode of operation the more and less retained species are collected in the extract and raffinate ports non-continuously, i. e., during a part of the time switch the more retained species is collected in the extract while the raffinate flow rate is decreased leading to the violation of the equilibrium theory constraints on zone 4; in the rest of the period the opposite procedure is performed, Figure 3.



Step 1 Raffinate collection **Step 2** Extract collection

Figure 3 - OSS strategy for the test case, (a) the first half of the switch time, (b) the second half of the switch time, equivalent TMB scheme.

This operation mode leads to expansion and contraction of the collection and contaminating fronts increasing the distance between them, Figure 4.

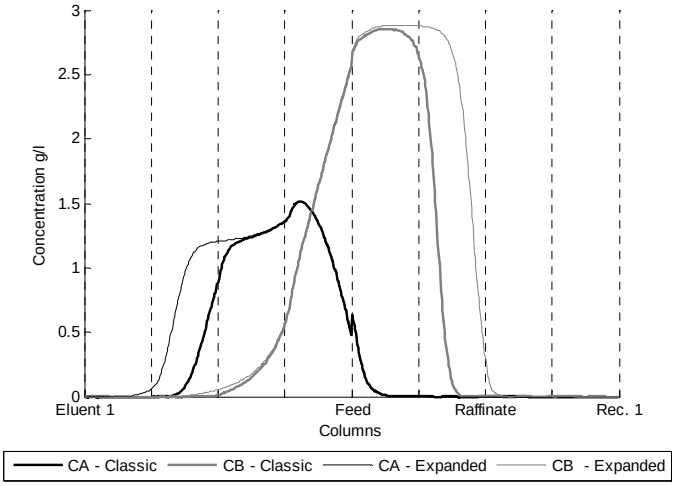


Figure 4 – Classic and expanded fronts from de OSS modus operandi.

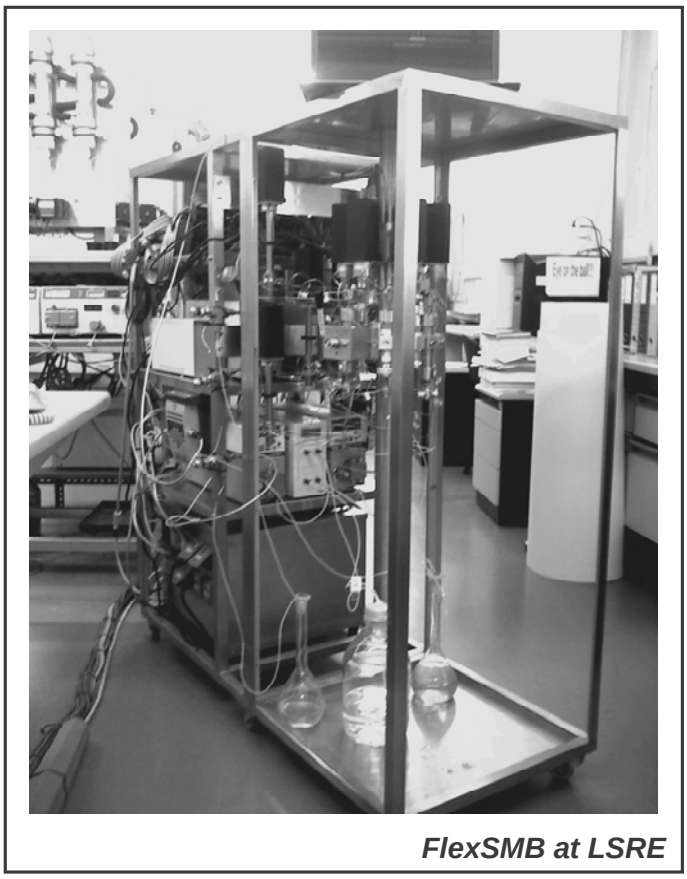
However, the practical application of these “non conventional modes of operation” is per itself a challenge. Generally an SMB unit, industrial, pilot of laboratory-scale, is limited to one or two modes of operation and to implement a new operating mode is necessary to contact the supplier, do adjustments, even to reformulate the entire unit if not to acquire a new one. Therefore, flexibility (at least at laboratory-scale) is seen as one of the more relevant qualities for this kind of equipment.

This aspect was the main reason that led to the design and construction of a 6 columns unit, the FlexSMB-LSRE, Figure 5.



FlexSMB at LSRE

Figure 5 – Flexible SMB unit, the FlexSMB-LSRE.

…from practice to models.

In the published or patented innovative work related with SMB industrial separations, just a few references refer to the adsorbent ageing problems. The “time life” of the adsorbent, a predominant economical factor in the SMB units design as adsorbent cost, has considerable influence on the complete unit design, if not in the main project viability [4].

Nevertheless, the information considering this issue remains restricted to the plant operators and technology owners. Usually an industrial SMB unit operates at the limit (the optimum conditions), a small deviation on its operating parameters will pollute the outlet streams, Figure 6.

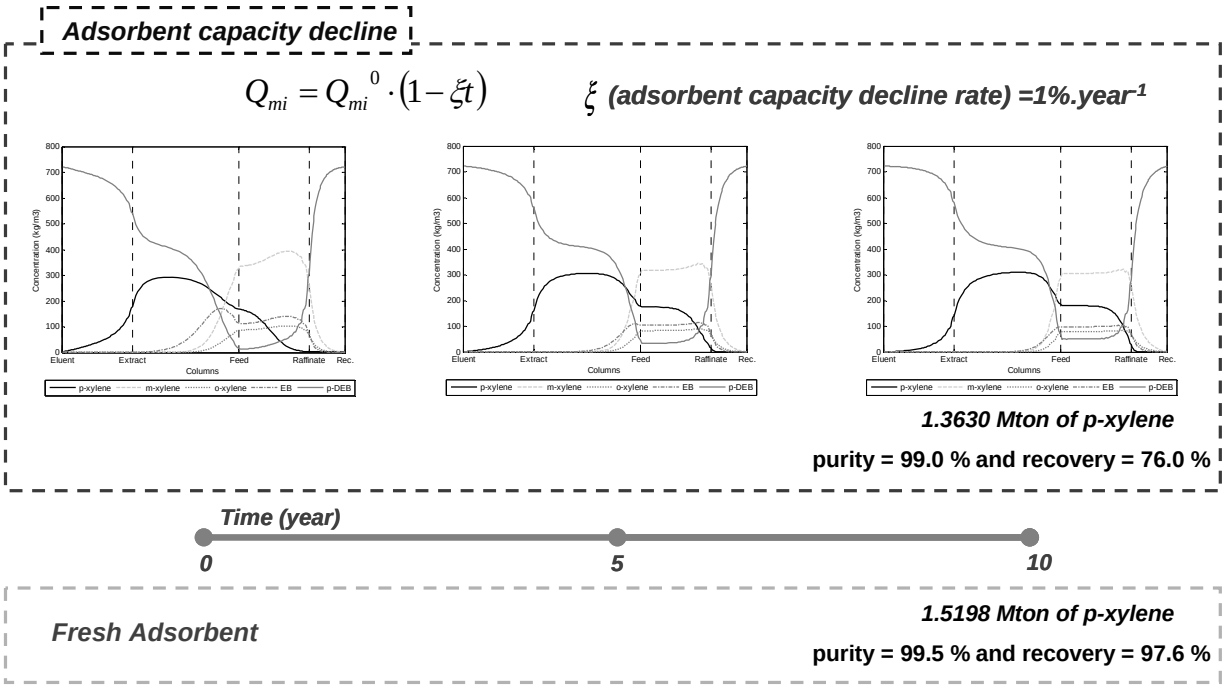


Figure 6 – Concentration profiles of a p-xylene separation unit suffering an adsorbent capacity decline over 10 years. Performance parameters for the ageing and fresh adsorbent cases [5].

In Figure 6, one can observe that p-xylene is being driven to the raffinate port over the time of adsorbent ageing, affecting the p-xylene recovery.

Initially, the unit is designed accounting to the industrial/economical requirements and to equipment/adsorbent restrictions. If the adsorption equilibrium data changes over the time, ageing phenomena, and the unit is kept on the initial operating parameters, the unit will pollute its outlet products, as can be perceived form the separation regions on Figure 7.

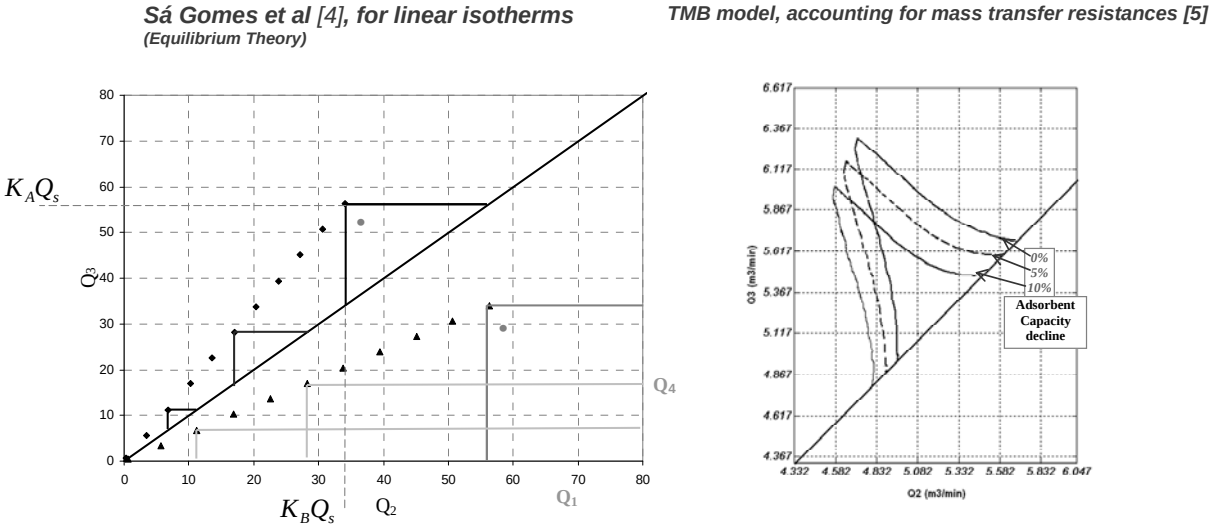

Figure 7 – Adsorbent ageing effect in linear (from [4]) and non linear (from [5]) isotherms case.

The observation of these aspects during an industrial unit operation led to the extension of the common models to account with ageing problems. The analysis of this "extended models" provided some diagnostic methods for the ageing mechanism as well as short cut methods for the compensation (such as the switching time compensation measure or variable zone length, [4,5]) of this kind of problems, Figure 8.

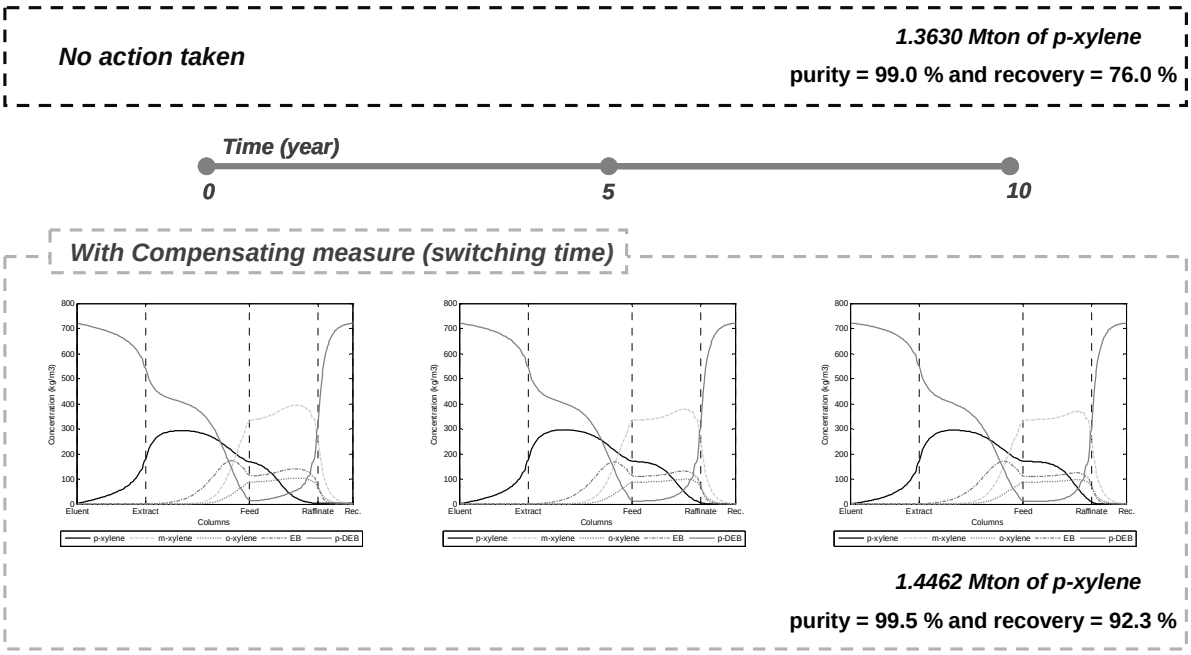

Figure 8 - Concentration profiles of a p-xylene separation unit suffering an adsorbent capacity decline over 10 years, but after implementing a switching time compensation measure. Performance parameters for the adsorbent aged with compensation and with no action cases [5].

By these means it was possible to extend the sieve life maintaining the purity requirments as in the operation of a fresh adsorbent unit.

Conclusion

One can now remind *M. S. Tswett*: “An essential condition for all fruitful research is to have at one’s disposal a satisfactory technique. “*Tout progrès scientifique est un progrès de méthode*” as somebody once remarked. Unfortunately the methodology is frequently the weakest aspect of scientific investigations.”

And in our opinion, a solid method for process development should be the result of the integration of “theory” (the models) and “practice” (experimental applications). Hereby demonstrated with: New operating techniques (the OSS and the FlexSMB-LSRE unit) and More accurate models (dead volumes (SMB units) and Ageing phenomena analysis).

Keywords: Control, Organic Loading Disturbance, Principal Components Analysis, Quantitative Image Analysis, Toxic Shock Load
Topic: Systematic methods and tools for managing the complexity.

Abstract

The wide fluctuations in flow rate and the presence of toxic compounds can damage the high efficiency of high-rate anaerobic granular sludge reactors. As earlier these disturbances are detected, more accurate would be the corrective actions, and less damage will be caused to the microorganisms involved in the process. The use of Principal Component Analysis (PCA) determined a latent variable, combining a weighted sum of operational, physiological, and morphological data, which showed high sensitivity to recognize the operational problems occurred when four organic loading disturbances and three toxic shock loads were applied to Expanded Granular Sludge Bed reactors. The high loadings/weights linked with the morphological parameters, specially the aggregates size distribution (>0.1, >1) and filaments length dynamics (TL/VSS), obtained using quantitative image analysis techniques, illustrate the usefulness of monitor the structural changes of the anaerobic granular sludge. The application of PCA chemometric tool to dataset gathering information from all disturbances allowed the differentiation between organic loading and toxic shock disturbances, as well as the main effects caused by each class of disturbance.

1 Introduction

High-rate anaerobic digestion reactors gained significance during the last decades in the field of wastewater treatment processes. However, these systems are designed with reference to a nominal operating condition, in which the organic loading rate is assumed to be constant in time. Also, some compounds can have inhibitory or toxic effects to the microbial populations, such as detergent and solvents. These facts, coupled with the long start-up periods imply the need to monitor the anaerobic granular sludge stability in order to achieve an appropriate control and sustainability of the process.

The recognition of parameters that could be used for monitoring the process is important to efficient control of those processes. It is equally feasible to obtain values of parameters measured in solid, liquid or gaseous phases. However, parameters involved in reactors control had been limited to indicators of the liquid and the gaseous phases (van Lier et al., 2001), due to difficulties in obtain and inaccuracy associated with morphological parameters.

With the rapid development of instrumental methods the amount of diverse data generated in an environmental process monitoring and/or control is increasingly drastically (Bourgeois et al., 2001; Schügerl, 2001; Spanjers and van Lier, 2006). This advance guide analysts and researchers to gathering further more multivariate data. Concurrently, with computer science and technology developments apply computers

* Corresponding author. Tel + 351-253-604407. E-mail:ecferreira@deb.uminho.pt

and advanced statistical and mathematical methods to analyse this data became easier.

In this framework, image analysis techniques appear as a promising tool to provide quantitative parameters of the solid phase evolution. And, chemometrics based techniques, such as Principal Components Analysis (PCA), can be useful to detect groups, trends, correlations, and outliers in datasets gathering vast amounts of information. This method allows identifying patterns in data, and expressing them in order to highlight their similarities and differences. PCA is a projection method for analyze data and reduce it from an n-dimensional space to few latent/hidden variables, while keeping information on its variability.

A multivariate statistical analysis has been used together with image analysis techniques to pattern recognition, such as discriminant analysis, neural networks, and decision trees (Ginoris et al., 2007). The relationships between morphological parameters and biomass properties in aerobic wastewater treatment processes were also assessed by partial least squares regression (Amaral et al., 2005) and principal components analysis (Jenné et al., 2006).

The objective of this work was to apply the chemometric technique Principal Components Analysis in order to recognize fluctuations, and respective effects, in high-rate anaerobic granular sludge reactors performance caused by organic loading and toxic disturbances.

2 Material and Methods

2.1 Datasets

Four organic loading disturbances (OLD) (Table 1) were applied to an Expanded Granular Sludge Bed (EGSB) reactor fed with $1.5g_{COD\text{-}ethanol}/L$ and hydraulic retention time (HRT) of 8 hours, in steady-state conditions. Also, three toxic shock loads (TSL) were applied in EGSB reactors operating in similar conditions (Table 1).

Table 1. Organic Loading Disturbances and Toxic Shock Loads conditions.

Disturbance	OLD1	OLD2	OLD3	OLD4	TSL1	TSL2	TSL3
Ethanol (g_{COD}/L)	5	1.5	15	15	1.5	1.5	1.5
HRT (h)	8	2.5	8	8	8	8	8
[Toxic] (mg/L)	-	-	-	-	1.6	3.1	40
Exposure phase (h)	72	72	72	384	56	222	222
Recovery phase (d)	7	7	7	7	14	12	7

Three programmes previously developed (Amaral, 2003) were used as the final step of a procedure (Costa et al., 2007) to obtain quantitative morphological information from anaerobic granular sludge.

Three datasets were created gathering morphological, physiological, and reactors performance information. Datasets 1 and 2 included observations of OLD and TSL, respectively. The objective consisted in examine the sensitivity of the latent variables to recognize the disturbances. Dataset 3 encompassed all observations and was created to study the differentiation of the OLD from the TSL, and respective effects. The variables used are described in Table 2.

2.2 Principal Component analysis

Principal components analysis aims at finding and interpreting hidden complex, and possibly causally determined, relationships between features in a dataset. Correlating features are converted to the so-called factors which are themselves noncorrelated (Einax et al., 1997).

SIMCA-P (Umetrics AB) software package was used to perform the Principal Components Analysis. The first step of the analysis consists in the pre-treatment of data by standardization of the variables, i.e., guarantee that each individual variable has about the same range, avoiding that some variables would be more important than others because of scale effects. During this work each variable was autoscaled so that each variable has mean zero and unit standard deviation.

Subsequently, the software iteratively computes one principal component at a time, comprising a score vector t_a and a loading vector p_a. The score vectors contain information on how the samples relate to each other. Otherwise, the loading vectors define the reduced dimension space and contain information on how the variables relate to each other. Usually, few principal components (2 or 3) can express most of the variability in the dataset when there is a high degree of correlation among data.

The criterion used to determine the model dimensionality (number of significant components) was cross validation (CV). Part of data is kept out of the model development, and then are predicted by the model and compared with the actual values. The prediction error sum of squares (PRESS) is the squared differences between observed and predicted values for the data kept out of the model fitting. This procedure is repeated several times until data element has been kept out once and only once. Therefore, the final PRESS has contributions from all data. For every dimension, SIMCA computes the overall PRESS/SS, where SS is the residual sum of squares of the previous dimension. A component is considered significant if PRESS/SS is statistically smaller than 1.0.

3. Results and Discussion

3.1 Recognition of organic load and toxic disturbances

The PCA expressed the importance of the proposed morphological parameters to recognize, possible problematic, disturbances to high-rate anaerobic granular sludge reactors. The latent variables t[1] and t[2] showed high percentages of variation in the first hours of exposure in every disturbances applied (Figs. 1 and 2).

As showed in table 1, LD3 and 4 were the most severe organic loading disturbances. Watching at t[1] (Fig. 1) is visible its high variation in this two OLD, essentially caused by the granules fragmentation, biomass washout, and decrease in specific acetoclastic activity (SAA) and COD removal efficiency. These variables had the higher loadings in Principal Component (PC) 1 (Table 2). In LD1, although the COD removal efficiency was unaffected, granule fragmentation was observed. In LD2 (hydraulic shock load) there was no changes in granules distribution sizes, but a severe release of filaments. For that reason the TL/VSS and LfA parameters had high loadings in PC2 (Table 2), and t[2] show the higher variation in the LD2 (data not shown).

Relatively to toxic shock loads was observed that the detergent SL1 had no significant effects on reactor performance and biomass characteristics. These was detected by the PCA, since the variable t[1] do not show large variation during this TSL (Fig. 2). The detergent SL2 caused the biggest decrease in reactor performance, and, solvent SL3 caused granules fragmentation and continuous deterioration of biomass and reactor performance. Observing the evolution of t[1] in figure 2, is clearly visible an immediate deviation between the inoculum observation in SL2 and the first observation during shock load (after 8h), recognizing the operational problems caused by the detergent. In the same figure, is visible a constant decrease of t[1] during SL3. During toxic shock loads, constant filaments release was visible. This morphological change was responsible by the variability detected in PC2 (data not shown) as showed by the high loadings of TL/VSS associated with the latent variable t[2] (Table 2).

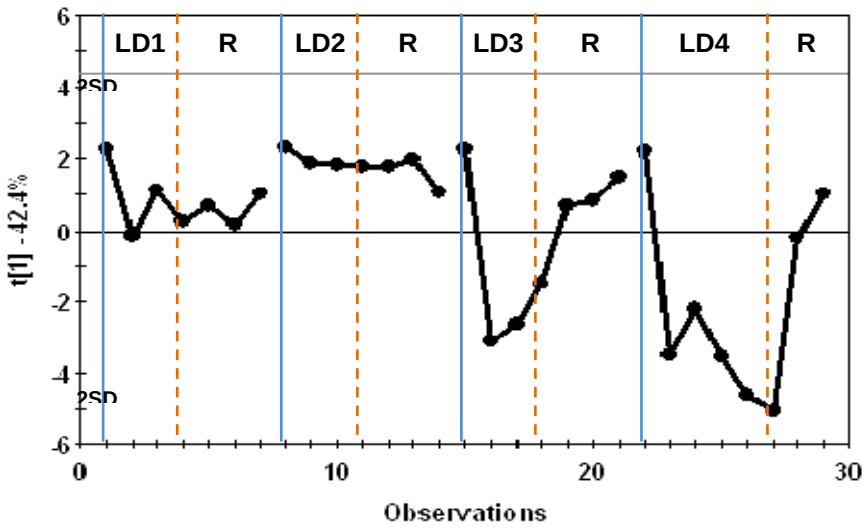

Figure 1. First latent variable (t[1]) evolution during organic loading disturbances. LD – Load Disturbance Phase; R – Recovery Phase.

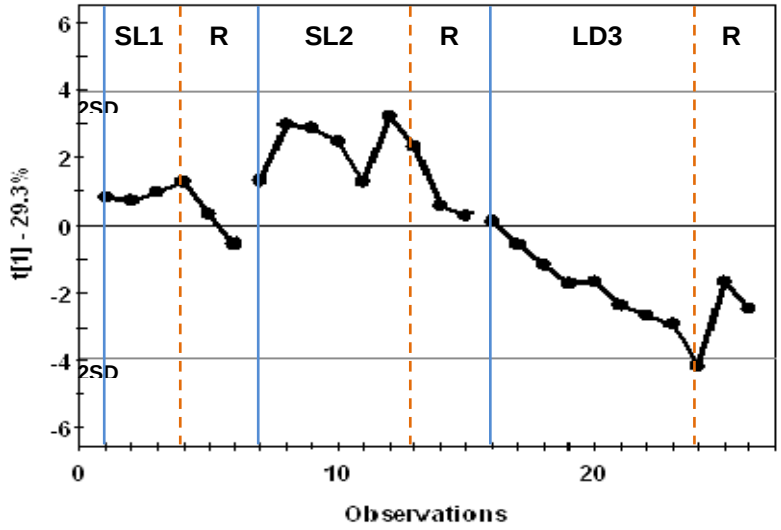

Figure 2. First latent variable (t[1]) evolution during toxic shock loads. SL – Toxic Shock Load Phase; R – Recovery Phase.

Table 2. Loadings/weights associated with the first (t[1]) and second (t[2]) latent variable in organic loading disturbances (LD) and toxic shock loads (SL).

Variable	LD		SL		Name
	t[1]	t[2]	t[1]	t[2]	
OLR	**-0.40**	0.06	0.12	-0.20	Organic Loading Rate
Csd	-	-	**-0.34**	-0.07	Toxic (detergent or solvent) concentration
Eff	**0.40**	0.02	-0.20	**0.30**	Chemical Oxygen Demand (COD) Removal Efficiency
pH	**0.32**	-0.12	0.00	**0.38**	pH
VSS	**-0.40**	-0.12	-0.05	-0.28	Effluent Volatile Suspended Solids
<0.1	-0.12	-0.29	-0.20	**0.30**	% of Aggregates Projected Area with Deq < 0.1 mm
>0.1	**-0.35**	0.19	**-0.43**	-0.09	% of Aggregates Projected Area with 0.1 ≤ Deq (mm) < 1
>1	**0.36**	-0.16	**0.44**	0.07	% of Aggregates Projected Area with Deq ≥ 1 mm
SAA	**0.33**	0.13	-0.26	**0.30**	Specific Acetoclastic Activity
SHMA	0.04	**-0.41**	0.18	-0.04	Specific Hydrogenotrophic Methanogenic Activity
LfA	0.13	**0.55**	0.24	**0.38**	Total Filaments Length / Total Aggregates Projected Area
VSS/TA	0.16	-0.18	0.17	**-0.33**	VSS / Total Aggregates Projected Area
TL/VSS	0.05	**0.55**	0.13	**0.44**	Total Filaments Length / Volatile Suspended Solids
vsed	-	-	**0.46**	0.01	Settling Velocity

Summarising, besides the imposed variables, organic loading rate (OLR) and toxic concentration (Csd), the morphological variables, >1 and >0.1 in t[1], and LfA and TL/VSS in [t2], had the higher loadings/weights, enhancing the need to monitor the biomass morphology to control the reactors. It may be suggested that, from the liquid and gaseous phase, the pH can be an important parameter to monitor/control the process, as reported by others (Liu et al., 2004). The results show the adequacy of use the chemometric technique Principal Component Analysis to recognize disturbances in high-rate anaerobic reactors and detect the respective effects.

3.2 Distinguish organic load disturbances from toxic shock loads

The two firsts Principal Components gathered 51.2% of the total variability in dataset 3 (encompassing observations from organic loading and toxic disturbances). However, analysing the score and loading plots of PC1-PC2 plane (Fig. 3) is possible to visualize the variables with higher influence to distinguish load disturbances from shock load observations and respective effects, i.e. the variables more affected by the disturbances. The organic loading disturbances displaced the observations in direction of negative scores in PC1 and PC2 (line 1 in Fig. 3a). Concerning to the toxic shock load, it was observed that observations were dislocated in the direction of positive scores in PC1 and negative scores in PC2 (line 2 in Fig. 3a).

Watching at the direction lines of the exposure phase observations (Fig. 3a) and the loading plot (Fig. 3b), is visible that the TSL affects mostly the morphological variables LfA and TL/VSS. As stated before a severe release of filaments was observed in these disturbances, being these variables responsible for the detection of operational problems even before the COD removal efficiency decrease. The OLD caused increases in the VSS, and, decreases in the pH and COD removal efficiency. A severe fragmentation phenomenon was also observed, as showed by the increase in the percentage of aggregates projected area with equivalent diameter (D_{eq}) between 0.1–1 mm (>0.1), and consequent decrease in the % of aggregates area with D_{eq} > 1 mm (>1).

The recovery phases observations tend to return to close the inocula observations (Fig. 3a). Effectively, the reactors regain its pre-disturbances performance few hours after their stop, indicating that only temporary inhibitions occurred.

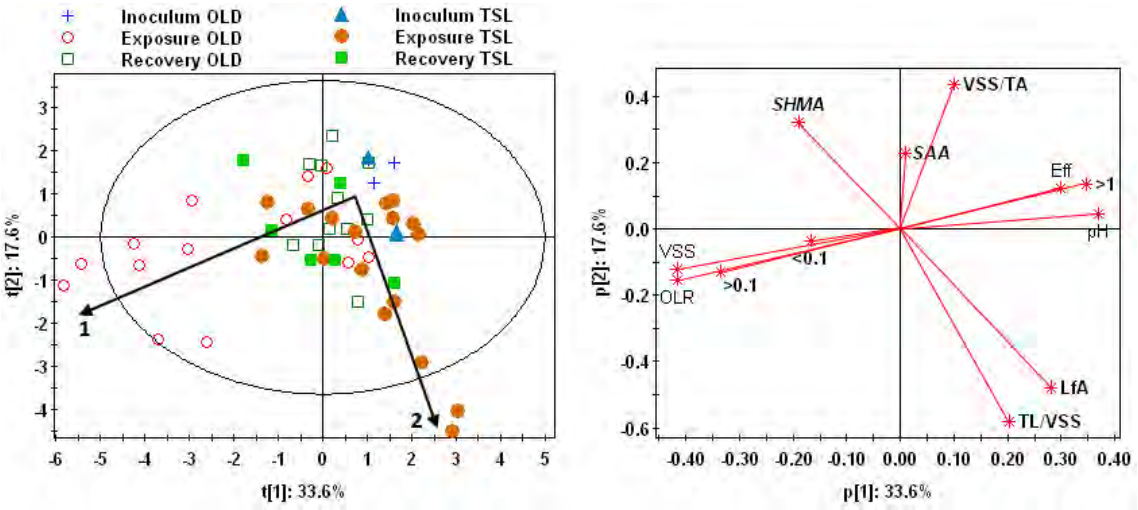

Figure 4. PCA of the first principal component versus the second principal component: (**a**) score plot t[1] *vs.* t[2], and, (**b**) loading plot p[1] *vs.* p[2].

4. Conclusions

The morphological parameters >0.1 and >1, indicator of granules fragmentation, experience high variation in the first hours of disturbances, either when was an organic or a toxic shock load. Their high weights were relevant for the immediate recognition of the deviations to the normal operation of the EGSB reactors detected by the latent variable determined by the PCA. The results enhance the important role that biomass morphology monitoring can have in the recognition of organic loading and toxic disturbances in anaerobic granular sludge reactors. Indeed, the proposed morphological parameters were sensitive enough to detect the disturbances before COD removal efficiency decreased. The PCA allow to distinguish organic loading from the toxic disturbances, and the main effects caused by each other. Increase the OLR caused granules fragmentation and washout (increase in effluent VSS) and decrease in COD removal efficiency. The exposure to detergent and solvent caused the filaments release and consequent increase in LfA parameter, and decrease in the SHMA.

Control of bromelain recovery process through conventional and fuzzy controllers

Manuela S. Leite, Ana M. F. Fileti, Flávio V. Silva*
School of Chemical Engineering, Departament of Chemical Systems Engineering, State University of Campinas (UNICAMP),CP 6066, CEP13083-970, Campinas, São Paulo, Brazil.

Keywords: Fuzzy controller, PID controller, Bromelain, Fieldbus
Topic: Systematic methods and tools for managing the complexity

Abstract

Fuzzy logic has an important role in process control due to its capability to incorporate the empirical knowledge about the process. Systems with unknown behavior can be easily controlled using logical rules. Thus, fuzzy controllers are an important alternative method to the conventional PID control mainly in ill-defined or nonlinear systems. This paper presents an experimental implementation of conventional and fuzzy controllers applied to a bromelain precipitation process.

1 Introduction

Bromelain is a proteolitic enzyme presents in pineapple fruit with high commercial value (Freiman and Sabaa Srur, 1999). As consequence, pharmaceutical and chemical applications have been increasing (Kelly, 1996). Bromelain is recovered from industrial and kitchen waste (pineapple stem and rind).

The enzyme precipitation is a simple operation but the temperature maintenance is crucial. The temperature control avoid the irreversible protein denaturation, improve the process yield and the enzymatic activity (Lucarini et al 2005).

The fuzzy control systems have come into prominence due to their applicable approach, attractive for complex process, their characteristic action based on knowledge of the system and on qualitative dynamic behavior, and when measurements are uncertain, incorporating the non-linearity into the methodology of the project (Eker and Torun, 2006; Traoré et al, 2005; Souza Jr. and Almeida 2001; Babuska et al, 2002; Horiuchi and Kishimoto, 2002; Hiroyuki and Kobayashi, 2000; Martìnez, 1999)

In this work, the design and tuning of conventional PID and fuzzy controllers was experimentally developed for a pilot batch plant to a bromelain recovery process from pineapple juice through the precipitation process with alcohol at low temperature (5℃) in a fed-batch stirred tank, using fieldbus network architecture. The performance between these controllers was evaluated in terms of: ITAE criterion, electrical energy consumption, and mainly in terms of enzymatic activity recovery.

2 Fuzzy Logic

The fuzzy inference simulates a human ability to make decisions using fuzzy logic and approximate reasoning. Mamdani inference is widely applied in fuzzy logic controllers. The output of the inference process is a fuzzy set, specifying a possibility distribution of control

* Corresponding author. Tel + 55-19-3521-3946. E-mail: sl.manuela@gmail.com, flavio@feq.unicamp.br

action. The control action (U or ΔU) is determined by a process called defuzzification. The defuzzifier converts the output of the associate rules (inference) into a single numerical value. The basis of fuzzy control is a set of rules that represent the knowledge of a process operator. Each rule represents a cause and effect relationship and is formatted in an "IF . . . THEN . . ." manner. For a given operating condition (cause), there is a corresponding action (effect) that should be taken to control the process.

For example, the MISO (multiple-input-single-output) rule:

$$\text{IF } x_1 \text{ is } A_1 \text{ and ... and } x_n \text{ is } A_n \text{ THEN } y_i \text{ is } C_i$$

The fuzzy control structure can be classified according to its application. One of the most popular fuzzy structures is based on error (ε) and change-of-error ($\Delta\varepsilon$), constituting the basis of the fuzzy-PD and fuzzy-PI controllers, with U and ΔU output control signals (manipulated variable), respectively.

3 Material and Methods

3.1 Bromelain precipitation plant description

The experimental plant, represented in Figure 1, consisted of a stainless steel stirred tank (1000 mL); a storage tank of the precipitant agent (ethanol 99.5 GL); a variable speed pump for the coolant (1000 L/h maximum capacity) used as manipulated variable; four Pt-100 temperature sensors for monitoring temperatures (ethanol storage, precipitation tank, inlet and outlet cooling fluid); two temperature transmitters (digital output signal) and a level transmitter; a frequency converter to modulate the pump speed of cooling fluid; a micropump that continuously feeds the ethanol into the precipitation tank. This micropump was employed to continuously feed the ethanol into the tank at room temperature (approximately 23 ºC) until the liquid volume reached 750mL, which corresponds to 1:4 v/v ratio between juice and ethanol (best protein precipitation condition, according to Cesar, 1999).

The initial conditions to system variables were determined in order to establish the biases for the control strategy implementation. The analyzed variables, through experimental design, were: the ethanol micropump flow rate; the coolant pump flow rate (manipulated variable); and the coolant inlet temperature. The best values found were, respectively: 2.16 L/h; 374 L/h; and 0 ℃. A 50% (v/v) water propylene glycol s olution was used as cooling fluid and a thermostatic bath kept its temperature constant.

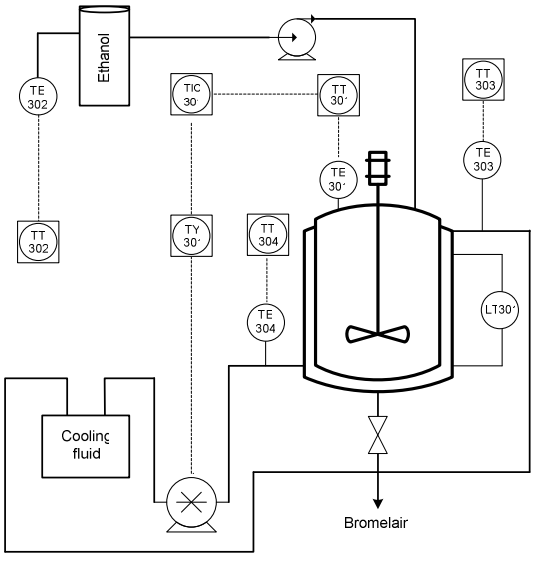

Figure 1. Fed-batch precipitation system flow chart.

3.2 Sample preparation and determination of the enzymatic activity

The stem and rind of pineapple fruit (species “Pérola”) were triturated and mixed to get a uniform solution. Distilled water was used at a dilution rate of 1:1. Solids were filtered out from the mixture by means of paper filters. The filtrate, called pineapple juice, contains the bromelain enzyme. Samples containing 150 mL of pineapple juice were frozen at -18ºC (César et al, 1999) until they were individually used in the experiments (fed into the tank).

The determination of the enzyme activity was used as parameter for evaluation of the performance of both types of controllers. The analysis of the enzymatic activity is based on the biuret colorimetric method. Under alkaline conditions substances containing two or more peptide bonds form a purple complex with copper salts in the reagent. According to this method, a unit (U) of enzymatic activity corresponds to the amount of enzyme able to change in a unit the absorbance reading at 540 nm, during 10 min at 37℃.

3.3 Fieldbus network architecture

The management of the digital control system was performed through a Foundation Fieldbus communication system, according to Figure 2.

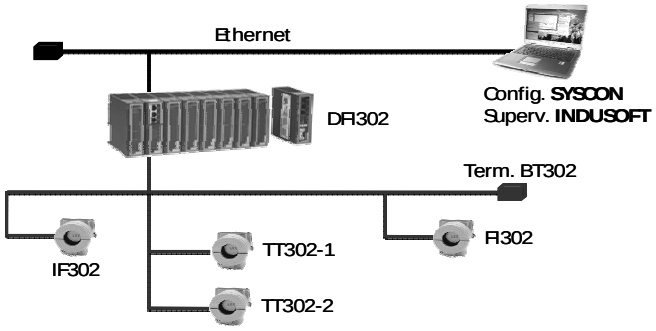

Figure 2. Fieldbus network for bromelain precipitation process.

The field devices used to monitor and control the precipitation tank, are as follows: distributed Fieldbus interface (DFI302), converters device (IF302 and FI302) and temperature transmitters (TT302). Software SYSCON 7.0 was used to implement the conventional control loop and to configure Fieldbus network devices. The software INDUSOFT Web Studio 6.1 was used for the management and data acquisition of the system.

3.4 Controllers design

- Conventional Controller

The first method of Ziegler-Nichols was used for PID tuning purposes in open-loop runs and were obtained values of the parameters K_c, τ_i and τ_d for the PID controller. This controller has the form of Equation 1 (Stephanopoulos, 1984).

$$U(t) = u_{ss} + K_c\left[\varepsilon(t) + \frac{1}{\tau_i}\int_0^T \varepsilon(t)dt + \tau_d \frac{d\varepsilon(t)}{dt}\right] \quad \text{(eq.1)}$$

- Fuzzy Controller

Initially, some experiments were carried out to have expert knowledge about precipitation process. Positive and negative disturbances were applied in the manipulated variable at different moments of the batch run, with different volumes, and the controlled variable behavior was observed. Thus, the process dynamic was identified and precipitation process nonlinearities could be observed. This knowledge was essential to tune fuzzy controller. After that, different universe of discourse, base of rules and support sets of membership functions were experimentally tested.

The implementation of the fuzzy-PI controller was carried out using the Fuzzy Toolbox of software MATLAB 7.0.1. The MISO strategy was used in this controller and three linguistic variables were used: temperature error and change-of-error (input linguistic variable) and change in coolant flow rate (output linguistic variable), represented by Equations 2, 3 and 4, respectively.

$$\varepsilon(t) = Y(t) - Y_{SP}(t) \text{ (Eq.2)} ; \Delta\varepsilon(t) = \varepsilon(t) - \varepsilon(t - \Delta t) \text{ (Eq.3)};$$
$$\Delta U(t) = U(t) - U(t - \Delta t) \text{ (Eq.4)}$$

In this study were used triangular membership functions. The linguistic expressions for the magnitude of the linguistic variables contain the following adjectives: negative large (NL), negative medium (NM), negative small (NS), zero (ZR), positive small (PS), positive medium (PM), positive large (PL). The rule base was implemented using the above adjectives and Mamdani inference system. The center of area was used for the output variable calculation (defuzzification), (Eq. 5).

$$u^* = \frac{\sum_{i=1}^{N} u_i \mu_{OUT}(u_i)}{\sum_{i=1}^{N} \mu_{OUT}(u_i)} \qquad (5);$$

The triangular membership functions, and their corresponding labels of error (ε), incremental error (Δε). and increment output value (ΔU), were determined by observing the system nonlinearities and they are presented in Figure 3 and Figure 4.

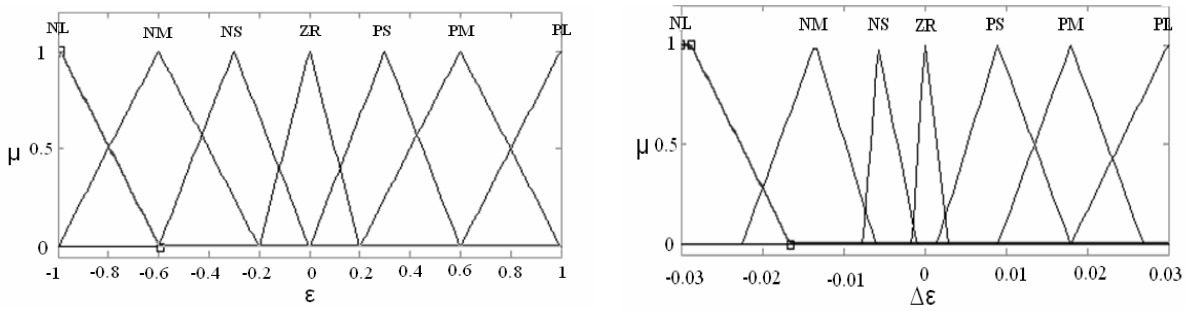

Figure 3. Membership functions of ε and Δε.

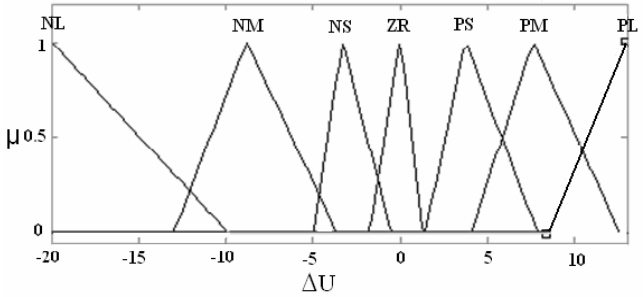

Figure 4. Membership function of ΔU.

Modifications in the configuration of the fuzzy controller (universe of discourse, rule base and support sets of membership function) were made as well, based on the accomplishment of experimental tests. The performance of the controller was evaluated and new strategies in its configuration were implemented when necessary. Table 1 shows 49 rules used for this fuzzy controller

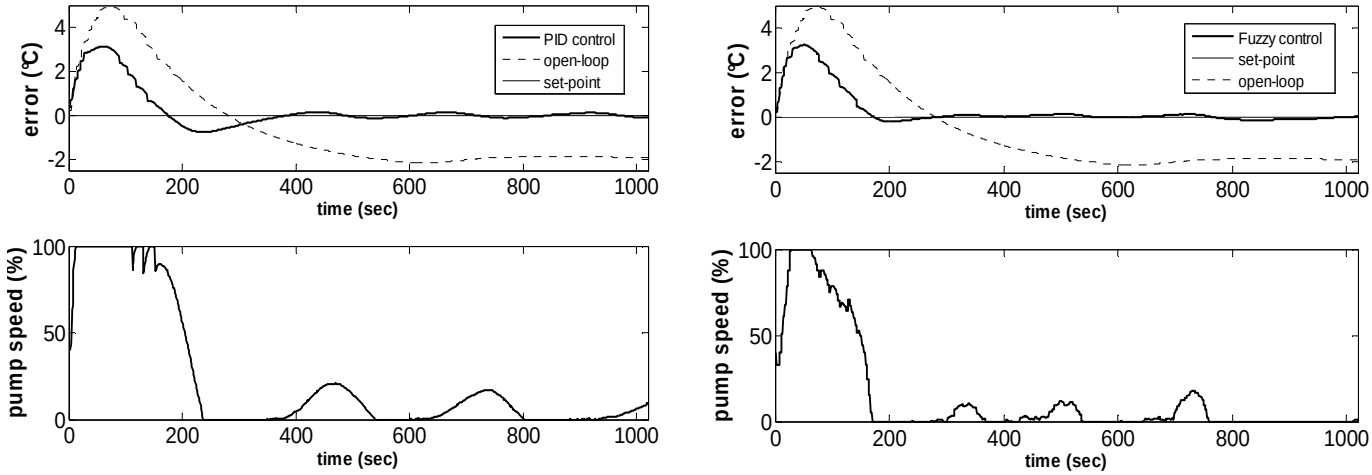
Table 1. Rule base of the fuzzy-PI controller.

ERROR (ε)	CHANGE-OF-ERROR (Δε)						
	NL	**NM**	**NS**	**ZR**	**PS**	**PM**	**PL**
PL	NS	NS	NS	PL	PL	PL	PL
PM	NS	ZR	PS	PM	PL	PL	PL
PS	NM	NS	ZR	PS	PM	PL	PM
ZR	NL	NM	NS	ZR	PS	PM	PL
NS	NL	NL	MN	NS	ZR	PS	PS
NM	NL	NL	NL	MN	NS	ZR	ZR
NL	NL	NL	NL	NL	MN	NS	ZR

4 Results and Discussion

For conventional controller, the best adjusted parameters were: K_c = 35.0 %/℃, τ_i = 28.0 s, and τ_d = 7.0 s. Figures 5a and 5b show the temperature behavior under a well-tuned conventional PID and fuzzy-PI controller, respectively.

From these results, could see that addition of ethanol is critical. In order to keep overshoot at minimum level, intense controller response is required, causing pump saturation, which was noted under both control strategies. In fact the saturation effect was far less noticeable when the fuzzy controller was applied (from 130 to 35 s), favoring conservation of the equipment and smaller electric energy consumption (from 9.11 to 3.65 kWh).



a b

Figure 5. Behavior of the controlled and manipulated variables under: a) PID control and b) fuzzy-PI control.

5 Conclusion

From the results, it could be concluded that both controllers are suitable for the precipitation tank temperature control (same overshoot and rise time value). However, the fuzzy controller showed better global performance criteria: small ITAE, small response time and pump saturation time, and a larger enzymatic activity of the product (79.73 % higher than using PID).

The fuzzy controller presented electric energy consumption that was 59.93% less when compared to the energy required by the conventional controller, providing a significant reduction of operational costs. The greater efficiency of the fuzzy controller can be attributed to its capability of adaptation to the nonlinearities, presenting favorable technical comparison with the conventional feedback controller.

In this application, the fuzzy controller was simple in structure, easy to implement, better in performance, and more versatile than the conventional controller.

Topic: Systematic methods and tools for managing the complexity.

Abstract

In this work, the simulations of fouling in heat exchanger networks are performed based on linear and asymptotic fouling models. The effects of various model parameters on a variation with time of outlet temperature of hot and cold streams, heat transfer coefficient and heat transfer rate are investigated. In addition, the problem of optimal cleaning schedule of heat exchangers is formulated using a new technique based on continuous of time horizon approach. The formulated optimization problem minimizes the summation of operating cost with subject to various operating constraints. Where, the number of cleaning operation is fixed priorly, and the time period for each cleaning operation is then determined. We illustrate the proposed technique and compare our technique with traditional discretization of time approach in case studies: (i) a single heat exchanger for 24 months horizon, (ii) the optimal cleaning schedule of heat exchanger network consisting 10 exchangers for 18 months horizon. Our developed technique can overcome the difficulty in using logical variables encountered in the cleaning schedule optimization problem. Our approach can efficiently solve the cleaning schedule problem while obtain a better solution compared with previous work.

1 Introduction

Energy consumed plays an important role in the operating costs of all chemical industries. Therefore, heat exchanger networks are implemented in almost all chemical plants. However, fouling of heat exchangers is one of major industrial problems. It leads to the reduction of heat transfer efficiency and heat transfer rate. Consequently, it reduces production rate, and increases cleaning and maintenance costs. Thus, the effective methods for fouling mitigation are required. In order to restore thermal performance of the heat exchanger, fouling can be removed by regular cleaning. Normally, cleaning improves the heat exchanger performance resulting in the reduction of energy cost. However, during cleaning period the heat exchanger must be stopped, resulting in the requirement of external utilities. Thus, cleaning too often may not be economically favorable after all.

The approach to address cleaning schedule problem can be classified into two main categories: discrete-time and continuous-time models (Floudas and Lin, 2005). However, all most of the work have been done based on the discrete-time approaches. The major drawbacks of the discrete-time approaches lie on the fact that the discretization time plays an important role in the reliability of the solution obtained. Smaili et al. (1999) studied the optimization of cleaning schedule of heat exchanger network used in sugar industry. This work described the use of a mixed integer nonlinear programming to the problem. They reported that in order to obtain a reliable optimal cleaning schedule, an accuracy mathematical model of the fouling behavior of the network is required.

Georgiadis and Papageorgiou (2001) proposed a mathematical model of the fouling in batch plant operation, where a short-term scheduling problem was considered. The objective was to determine the optimal utilization of available plant resources over a given time horizon. An iterative procedure for solving the resulting non-convex mixed integer nonlinear programming was proposed. This approach involves solving a series of mixed integer linear programming sub-problems. Further, a mixed integer nonlinear programming formulation of the cleaning schedule problem for continuously operating heat exchanger networks was studied by Smaili et al. (2002). It was reported that even a global optimal solution obtained from mixed integer nonlinear programming formulation may not be the best schedule, if the discretization time is too coarse.

Additionally, Lavaja and Bagajewicz (2004) illustrated a mixed integer linear programming for cleaning schedule optimization. This work was applied in a typical preheat train configuration. They did not approximate the nonlinear equations related to heat transfer or the fouling models. They used a special rearrangement in order to obtain linear expressions. The model was capable of rendering global optimality for small case.

In this work, we develop an algorithm for optimal heat exchanger network cleaning schedule based on continuous time approach. The model considered here does not approximate the nonlinear equations related to heat transfer or the fouling models. The optimal cleaning schedule of heat exchanger network is obtained by solving the optimization problem formulated.

2 Heat exchanger model description

The formulation presented here is based on constant flow inputs and physical parameters. Only changes due to cleaning actions are considered. Film heat transfer coefficients are also assumed to remain constant despite changes in Prandtl and Reynold numbers caused by fouling. In addition, the heat exchanger is bypassed for isolation during cleaning action. And, the fouling in bypass heat exchanger is neglected. Further, each heat exchanger is modeled using a lumped parameter where the change in overall heat transfer coefficient is related to the fouling formation presented in Eq. 1.

$$r_f(t) = \frac{1}{U(t)} - \frac{1}{U_c}. \tag{1}$$

Where, $U(t)$ is overall heat transfer coefficient (BTU/ft^{2}h$^\circ$F), U_c is overall heat transfer coefficient when the unit is clean, and $r_f(t)$ is fouling resistance (BTU/ft^{2}h$^\circ$F).

In this work, linear and asymptotic fouling formulation models were considered for estimating the changes in $r_f(t)$ as shown in Eqs. 2 and 3, respectively.

$$\dot{r}_f(t) = {r_f}^{\infty}(1 - e^{-t/\tau}) \tag{2}$$

$$\dot{r}_f(t) = {r_f}^{\infty} \tag{3}$$

Heat transfer rate of cold stream (Q_c) and hot stream (Q_h) are shown in Eqs. 4 and 5, respectively.

$$Q_c = F_c C_{p,c}(T_{c,out} - T_{c,in}) \tag{4}$$

$$Q_h = F_h C_{p,h}(T_{h,in} - T_{h,out}) \tag{5}$$

The heat transfer rate in a heat exchanger is expressed as in Eq. 6.

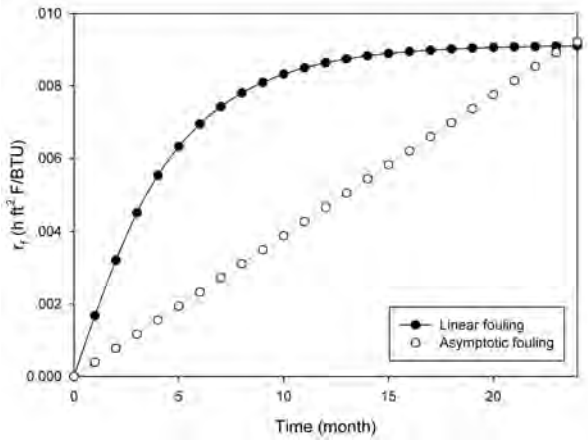

Figure 1: Fouling formation of asymptotic and linear fouling models.

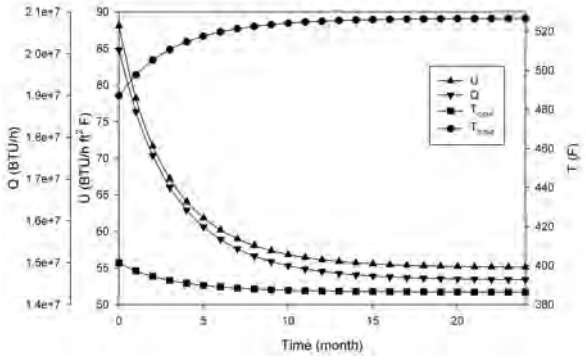

Figure 2: The variation of U, Q, $T_{c,out}$ and $T_{h,out}$ in single heat exchanger with asymptotic fouling.

$$Q = UA\frac{(T_{h,in} - T_{c,out}) - (T_{h,out} - T_{c,in})}{ln(T_{h,in} - T_{c,out})/(T_{h,out} - T_{c,in})} \tag{6}$$

The performance of heat exchanger is calculated using the NTU-effectiveness method. Heat exchangers are modeled as a simple counter current. Where, we can computed $T_{h,out}$ and $T_{c,out}$ by using Eqs. 7 and 8, respectively.

$$T_{h,out} = \frac{1 - \frac{F_hC_{p,h}}{F_cC_{p,c}}}{e^{\frac{UA}{F_cC_{p,c}}(1-\frac{F_hC_{p,h}}{F_cC_{p,c}})} - \frac{F_hC_{p,h}}{F_cC_{p,c}}}T_{h,in} + \frac{1 - e^{\frac{UA}{F_cC_{p,c}}(1-\frac{F_hC_{p,h}}{F_cC_{p,c}})}}{e^{\frac{UA}{F_cC_{p,c}}(1-\frac{F_hC_{p,h}}{F_cC_{p,c}})} - \frac{F_hC_{p,h}}{F_cC_{p,c}}}T_{c,in} \tag{7}$$

$$T_{c,out} = \frac{F_hC_{p,h}}{F_cC_{p,c}}(T_{h,in} - T_{h,out}) + T_{c,in} \tag{8}$$

Figure 1 presents the fouling formation of linear and asymptotic models in 24 months period without cleaning. The variation in asymptotic fouling model of overall heat transfer coefficient, heat transfer rate, outlet temperature of hot stream and outlet temperature of cold stream in 24 months without cleaning are presented in Figure 2. The variation of asymptotic fouling changes rapidly at the early stage of operation and then stabilizes to the final value at asymptote. The increasing of fouling results in the reduction of overall heat transfer coefficient. The outlet temperature of hot stream increases with time, while the outlet temperature of cold stream decreases with time. This is due to the fact that fouling reduces the heat transfer efficiency. Figure 3 shows the variation with time of heat transfer rate with various different parameters in asymptotic fouling model. In comparison, the increasing of time decay fouling formation

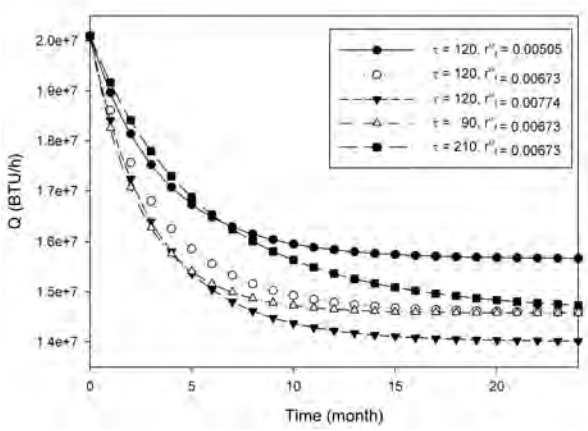

Figure 3: The variation of a single heat exchanger with different parameters in asymptotic fouling model.

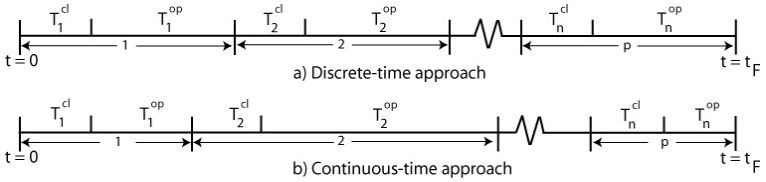

Figure 4: Discrete and continuous time approach.

(τ) results in slow formation of fouling. The effectiveness of heat exchanger increases by increasing the time decay of fouling formation (τ).

3 Optimization of cleaning schedule

We considered the cleaning schedule for a heat exchanger network comprising N heat exchangers during time period t_F of continuous plant operation. The goal is to minimize the total operating cost including cleaning cost and cost on energy losses in each process stream as shown in Eq. 9.

$$F = \sum_{n=1}^{N} C_E \left(\int_0^{t_F} (Q_{n,clean} - Q_n(t)) dt \right) + \sum_{n=1}^{N} C_{cl} k_n \tag{9}$$

where, N is the number of heat exchangers in the network. C_E is the cost of furnace extra fuel. $Q_{n,clean}$ is the heat transfer rate between hot and cold streams of heat exchanger n^{th} in clean condition. Q_n is the heat transfer rate between hot and cold fluids of heat exchanger n^{th}. C_{cl} is the cleaning cost. k_n is the number of cleaning actions of heat exchanger n^{th}.

$Q_n(t)$ is not continuous at a point where cleaning action occurs. There are two approaches, discrete and continuous time approaches, in order to evaluate the objective function based on Eq. 9. The basic idea in the discrete time formulation is to divide the length of time horizon (t_F) considered into a number of specified small periods (P) as shown in part (a) of Fig. 4. The decisions to be made are associated with these time periods. The length of each period can be adjusted as necessary. However, the size of the search space increases with the decreasing of the length of each period. In this work, we applied the continuous-time approach as shown in part (b) of Fig. 4, where the number of cleaning operation is fixed priorly, and the time period for each cleaning operation is then determined. Each time period consists of two subperiods. The first period is a cleaning subperiod (t^{cl}), where heat exchangers are being cleaned. And the second one is an operating subperiod (t^{op}). In the operating subperiod, the heat exchangers are operated, and the formation of fouling occurs.

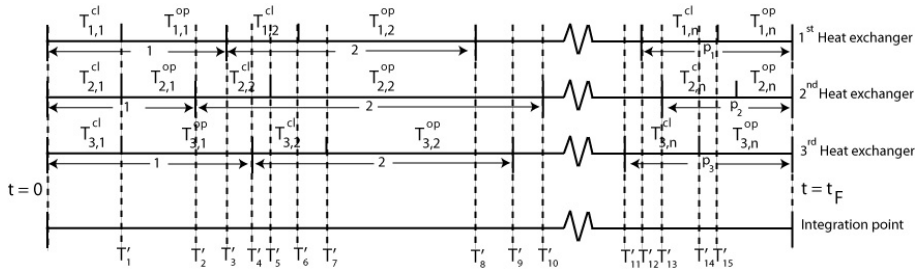

Figure 5: Integration points used in our algorithm.

Various constraints were applied in order to determine the optimal cleaning schedule. The outlet cold temperature of each heat exchanger must be greater than the inlet cold temperature associated, and the outlet hot temperature of each heat exchanger must be lower than the inlet hot temperature associated. Moreover,there is also restriction in minimum value that the temperature of each cold stream is allowed to be reached.

In our algorithm, the integral term appeared in the objective function as shown in Eq. 9 is calculated from the summation of all point to point integration, where the discontinuity occurs at each point. Figure 5 shows integration points in the network with three exchangers.

We proposed using modified differential evolutionary algorithm (DE) to solve the formulated optimization problem. DE is a very simple population based optimizer which is at the same time very powerful and robust (Storn and Price, 1997).

4 Case studies

The optimization of cleaning schedule using our formulation described in previous section are presented and illustrated in two case studies. The first case focuses on the optimal cleaning schedule of a single heat exchanger. The second case is an optimal cleaning schedule of heat exchanger network previously addressed in the work by Smaili et al. (2002). In the discrete time approach, the time horizon is divided into 30 days period. In each period, the cleaning subperiod is 6 days, and the operating subperiod is 24 days. The cleaning cost is 4,000 £/unit. The cost of furnace utility is 0.01 £/kWh. The parameters used in both cases were also taken from Smaili et al. (2002).

4.1 Case study 1

In the first case, the time horizon considered is 24 months. The heat exchanger is counter current shell and tube. The maximum decrease on outlet temperature of cold stream is 2%. We focused on the influence of initial fouling rate and time decay of fouling formation on the number of cleaning actions and objective function obtained using our algorithm and traditional discrete-time approach. Table 1 shows the number of cleaning actions and and objective functions obtained in the case study 1.

Table 1: The comparison of the solutions obtained in the case study 1.

		Discrete time		Continuous time	
Parameters		Cleaning	Objective func.	Cleaning	Objective func.
$r_f{}^{\infty}$	0.003365	10	172,434 £	9	166,085 £
	0.006730	11	176,912 £	10	169,393 £
	0.013461	12	194,756 £	11	177,931 £
τ	90	12	226,524 £	11	221,751 £
	120	11	176,912 £	10	169,393 £
	210	10	170,541 £	9	141,404 £

The rapid change in heat transfer rate occurs in the case of large value of initial fouling rate. Consequently, the rapid reduction of outlet temperature of cold stream requires more cleaning actions. Thus, the operating cost increases when the initial fouling rate increases. The increasing in the decay of fouling formation results in the slow deposition of fouling. In the case of small value of time decay of fouling formation, the outlet temperature of cold stream rapidly decreases. Thus, the operating cost decreases when the time decay of fouling formation increases. The number of cleaning actions decreases with the increasing of the time decay of fouling formation. Because, the large value of time decays of fouling formation provides small value of fouling formation.

4.2 Case Study 2

We considered the optimal cleaning schedule of heat exchanger network under fouling condition. The operating time horizon considered is 18 months. The maximum decrease on outlet temperature of cold stream is also 2%. We focused on the influence of cleaning cost on the number of cleaning actions and objective function obtained using our algorithm and traditional discrete-time approach. Table 2 shows the number of cleaning actions and and objective functions obtained in the case study 2.

Table 2: The comparison of the solutions obtained in the case study 2.

Cleaning cost	Smaili et al. (2002)	Discrete time	Continuous time
$4,000£$	$392,294£$	$351,555£$	$292,050£$
$8,000£$	No reported	$486,035£$	$405,010£$

The performance obtained using continuous time formulation are better than that obtained using discrete time formulation. This is due to the fact that in continuous time approach, the time period between each cleaning operation which is continuous in nature is not required to be defined priorly.

5 Conclusions

In this work, the effects of various model parameters on a variation of outlet temperature of hot and cold streams, heat transfer coefficient and heat transfer rate were investigated. In addition, the problem of optimal cleaning schedule of heat exchangers was formulated using a new technique based on continuous of time horizon approach. The problems formulated were solved by using differential evolutionary algorithm. Our proposed formulation technique was illustrated in case studies. The linear fouling model and asymptotic fouling model were considered. The performance of our technique compares favorably with traditional discretization of time approach approach. The performance obtained using continuous time formulation were better than that obtained using discrete time formulation.

Keywords: Water minimization, water reuse, mathematical programming, optimization
Topic: Systematic methods and tools for managing the complexity.

This paper introduces a novel strategy for designing optimal water using networks (WUN) involving fixed contaminant load and fixed flowrate operations and featuring multiple contaminants and water sources. A mixed integer linear programming (MILP) based procedure is used to generate a few structurally different starting points for the non-convex nonlinear program (NLP). The problem is decomposed into calculation stages by assuming that the water streams go through the units in series. The binary variables then select which unit belongs to a certain stage. The algorithm is compared to a closely related LP-based method taken from the literature and to the one employed by the global optimization solver BARON. The results from a large set of example problems confirm its effectiveness in avoiding local solutions. In contrast to the previous method they are easily scalable and, for some of the larger problems, could find better solutions than BARON with significantly fewer computational resources.

1 Introduction

Water is seen as probably the most broadly used resource in industry. These usages lead to contaminated wastewater, which may pose an environmental pollution problem. Increasing water costs, restrictions on water use and increased environmental awareness have driven designers towards conceiving more efficient water systems looking for both freshwater minimization and wastewater generation. Several contributions have appeared in the literature that look into this problem. In all of them, the identification of water reuse and/or recycling opportunities has been regarded as an innovative step within the two most commonly used scientific solution approaches: the insight-based pinch technology, largely supported by graphical methods, and the more systematic mathematical programming approaches. Targeting/design methods for water systems can also be classified based on the problem being handled. Ideally, a fully integrated water-using and treatment network should be sought but due to the inherent complexity of the problem, many researchers have focused on either the water-using or the distributed wastewater treatment (WTN) design.
When compared to pinch based approaches, mathematical programming methods have the advantage of effectively dealing with multicontaminant systems. All water reuse possibilities can be embedded into a superstructure and the problem formulated as a NLP. However, unless computationally expensive global optimization solvers are employed (e.g. BARON), suboptimal solutions may result. One alternative is to use heuristic procedures to generate multiple, structurally different, starting points to the NLP, thus increasing the probability of finding the global optimal solution. Recent examples of such methods can be found in Teles et al. (2008) for WUNs and in Castro et al. (2007) for WTNs. The former is very effective but may lead to a prohibitively high number of mathematical problems to solve as the number of operations increases. With the aim of reducing the overall computational burden of the search procedure, while keeping the same success rate, this paper proposes a novel MILP-based algorithm. The novelty is to employ binary variables to select the best operation for a particular calculation stage of the initialization procedure.

2 Problem Statement

The design of a water-using system involves a set *W* of fresh water sources containing a number of pollutants (set C), with known concentrations ($c_{w,c}^{wat}$), that are available to satisfy the demands of every water-using operation (set O), which fall in two broad categories (Prakash and Shenoy, 2005): fixed contaminant load operations (set O^{fl}) which are quality controlled and may be modeled as mass transfer units, and fixed flowrate operations (set O^{ff}) that are quantity controlled and do not involve any mass transfer. Data for the former is often expressed by a limiting flowrate (f_o^{lim}), together with maximum inlet ($c_{o,c}^{in\,max}$) and outlet ($c_{o,c}^{out\,max}$) concentrations, which can be related to the mass exchange ($\Delta m_{o,c}$) through $\Delta m_{o,c} = f_o^{lim} \cdot \left(c_{o,c}^{out\,max} - c_{o,c}^{in\,max}\right), \ \forall o \in O^{fl}, c \in C$. For the latter, the inlet (f_o^{in}) and outlet (f_o^{out}) flowrates are given. The outlet concentrations are independent on the inlet concentrations (must be lower than $c_{o,c}^{in\,max}$) and so are fixed to $c_{o,c}^{out\,max}$. The objective is to minimize the total freshwater flowrate into the system, Eq 1.

3 Mathematical NLP Formulation

The model variables of the general NLP that includes all reuse and recycling possibilities are the following: $F_{w,o}^{wat}$, represents the flowrate of fresh water source *w* needed to satisfy the demand for operation unit *o*; $C_{o,c}^{in}$ and $C_{o,c}^{out}$ are, respectively, the inlet and outlet concentrations for the fixed contaminant load operations; F_o^{tot} is the total flowrate into fixed load operation *o*; $F_{j,o}^{oper}$ gives the total flow rate from operation *j* to operation *o*; and F_o^{tsys} represents the outlet flowrate from operation *o* heading for the treatment system.

The model constraints are now described. Eq 2 is the total flow balance over the unit's inlet mixers, where the inlet flow to operation *o* (known for fixed flowrate units) may come from freshwater streams and/or from the units' outlet streams. Eq 3 is the total flow balance over the unit's outlet splitters, where the exiting flow may be heading to the same, to other water-using units, or to the treatment system. For fixed contaminant load operations, Eqs 4-7 apply, while for fixed flowrate operations, Eq 8 suffices, which ensures that the inlet concentrations do not exceed their specified maximum values. Eqs 4-5 are the mass balances over the mixers of and over the fixed load units. Eq 6 and 7 are the upper bounds on the concentration variables.

$$\text{Min} \sum_{w \in W} \sum_{o \in O} F_{w,o}^{wat} \tag{1}$$

$$F_o^{tot}\Big|_{o \in O^{fl}} + f_o^{in}\Big|_{o \in O^{ff}} = \sum_{w \in W} F_{w,o}^{wat} + \sum_{j \in O} F_{j,o}^{oper} \quad \forall o \in O \tag{2}$$

$$F_o^{tot}\Big|_{o \in O^{fl}} + f_o^{out}\Big|_{o \in O^{ff}} = F_o^{tsys} + \sum_{j \in O} F_{o,j}^{oper} \quad \forall o \in O \tag{3}$$

$$F_o^{tot} \cdot C_{o,c}^{in} = \sum_{w \in W} F_{w,o}^{wat} \cdot c_{w,c}^{wat} + \sum_{j \in O} F_{j,o}^{oper} \cdot (C_{j,c}^{out}\Big|_{j \in O^{fl}} + c_{j,c}^{out\,max}\Big|_{j \in O^{ff}}) \quad \forall o \in O^{fl}, c \in C \tag{4}$$

$$\Delta m_{o,c} = F_o^{tot} \cdot \left(C_{o,c}^{out} - C_{o,c}^{in}\right) \forall o \in O^{fl}, c \in C \tag{5}$$

$$C_{o,c}^{in} \le c_{o,c}^{in\,max} \quad \forall o \in O^{fl}, c \in C \tag{6}$$

$$f_o^{in} \cdot c_{o,c}^{in\,max} \ge \sum_{w \in W} F_{w,o}^{wat} \cdot c_{w,c}^{wat} + \sum_{j \in O} F_{j,o}^{oper} \cdot (C_{j,c}^{out}\Big|_{j \in O^{fl}} + c_{j,c}^{out\,max}\Big|_{j \in O^{ff}}) \ \forall o \in O^{ff}, c \in C \tag{8}$$

4 Mathematical Programming Approaches

The presence of non-convex bilinear terms in the constraints imposes significant difficulties for commercial local NLP solvers, which may fail to find feasible solutions or end up with suboptimal networks. One alternative is to use global optimization solvers like BARON, but these tend to be extremely demanding computationally, as will be seen later on. Hence, valid approaches that are able to significantly reduce the computational effort and still obtain the global optimal solution are particularly relevant. This section presents a new efficient method to generate feasible networks for the initialization of the general NLP, after giving an overview of that by Teles et al. (2008).

4.1 Review of LP-based method of Teles et al. 2008 (TCN)

Doyle and Smith (1997) proposed a systematic initialization procedure, where an approximated version of the NLP, which is linear, is generated by replacing the outlet concentrations in all operations by their predefined maximum values and by relaxing the mass balance over the units. The idea behind TCN is similar in the sense that the concentration variables are also replaced by appropriate parameters. However, instead of relying on problem data to preset the fixed load operations' outlet concentrations and solving the full problem, TCN tackles each operation one at a time, so that the concentrations of all water streams that can be used to meet the demand of the unit under consideration are known beforehand. This procedure removes all bilinearities and leads to a succession of partial freshwater minimization, LP problems.

In TCN, the general superstructure is approximated by the complete set of substructures that assume that the water streams go through the operations in sequence, from the point they enter the water-using system up to the point they are sent to the downstream treatment system. For each sequence, every fixed load operation is pre-allocated to a single position, ranging from 1 to $|O^{fl}|$. Fixed flowrate operations are easier to handle since they consist of a linear subsystem that can be considered simultaneously with any fixed load operation. Overall, the proposed strategy involves the solution of a potentially large number of mathematical problems $(|O^{fl}|!\cdot(1|_{|O^{ff}|=0} + |O^{fl}|\Big|_{|O^{ff}|>0}) \cdot (|O^{fl}| \text{LPs} + 1 \text{NLP})$, which is little dependent on the number of fixed flowrate operations. Thus, and although the generation of multiple starting points can improve the chances of escaping local optima, as the number of operations increases, the total computational effort can reach prohibitive values.

4.2 New MILP-based algorithm (M1)

The new algorithm M1 employs a similar decomposition approach, but avoids the generation of redundant sequences, most of them unable to converge to global optimality by local solvers. Like in TCN, all fixed flowrate operations are considered within a single calculation stage. The total number of starting points generated equals the number of fixed load units $|O^{fl}|$. The total number of MILPs solved is equal to $|O^{fl}|^2$.

Figure 1 illustrates the superstructure used in the initialization procedure for the case where the fixed flowrate units are allocated to the second calculation stage. With this strategy, it is possible to reuse the outlet stream from a particular fixed flowrate unit into itself (internal recycling), into the other fixed flowrate units, or still into the fixed load unit that is allocated to the stage in question. Furthermore, the outlet from the chosen fixed load unit can also feed the fixed flowrate units (to avoid bilinear terms, one assumes that the outlet concentrations are at their maximum values, Doyle & Smith, 1997).

The algorithm is now illustrated with the example given in Table 1, for the case where the fixed flowrate system is allocated to stage two, like in Figure 2. Starting with the first stage, the MILP selects unit O_4, leading to $Y_{O_4} = 1$. Afterwards, the dynamic sets that facilitate the writing of the constraints are updated. For the second calculation stage, the unit just selected goes into the set of previous operations, PvO={O_4}, see Figure 2. The active operations, which include the fixed flowrate units, are AcO={O_1, O_2, O_3, O_5, O_6}. The optimizer selects fixed load unit O_2 and so the next assignments are: $Y_{O_2} = 1$,

AcO={O_1, O_3} and PvO={O_2, O_4, O_5, O_6}. In the third stage, unit O_3 is selected leaving O_1 to be the last element in the sequence. After the algorithm has gone through all calculation stages, we get a feasible water-using network and an upper bound on total freshwater consumption. Such network is then used as a starting point for the solution of the general NLP. Table 1 lists the results for this (S2) and the other starting points.

The MILP mathematical formulation is very similar to the general NLP given in section 3. In Eq 10 and 12, unit j can feed unit o if it has been assigned to previous stages or if $j \in O^{ff} \wedge j=o$. More than a single unit will normally be involved, so units j, either fixed load or fixed flowrate, can feed fixed flowrate units o. The maximum inlet concentration constraint over the mixers is given by Eq 12, where all the outlet concentrations from previous selected units are known. Eq 13 replaces the mass balance over the fixed load units (Eq 5). Since the outlet concentrations need not to be determined, it is enough to ensure that the maximum outlet concentration is not exceeded. Note that the mass exchange term is only added for the chosen unit, while for the others, Eq 12 ensures that Eq 13 is always met since $c_{o,c}^{in\,max} \le c_{o,c}^{out\,max}$. Eq 14 assures that the outlet flowrate from previously selected unit j to the chosen unit o, does not exceed the amount still available. Eq 15 ensures a zero inlet flowrate for non-selected fixed mass load units, where the limiting flowrate f_o^{lim} acts as the upper bound. Finally, note that only fixed load units can be selected so the binary variables are restricted to the O^{fl} subset, as it can be seen in Eq. 16, which guarantees that a single unit is selected.

$$\text{Min} \sum_{w \in W} \sum_{o \in AcO} F_{w,o}^{wat} \tag{9}$$

$$F_o^{tot}\Big|_{o \in O^{fl}} + f_o^{in}\Big|_{o \in O^{ff}} = \sum_{w \in W} F_{w,o}^{wat} + \sum_{j \in PvO \vee (j \in AcO \wedge (j \in O^{ff} \vee (j \in O^{fl} \wedge o \in O^{ff})))} F_{j,o}^{oper} \quad , \ \forall o \in AcO \tag{10}$$

$$F_o^{tot}\Big|_{o \in O^{fl}} + f_o^{out}\Big|_{o \in O^{ff}} = F_o^{tsys} + \sum_{j \in O^{ff} \vee (j \in O^{fl} \wedge o \in O^{ff})} F_{o,j}^{oper} \ , \ \forall o \in AcO \tag{11}$$

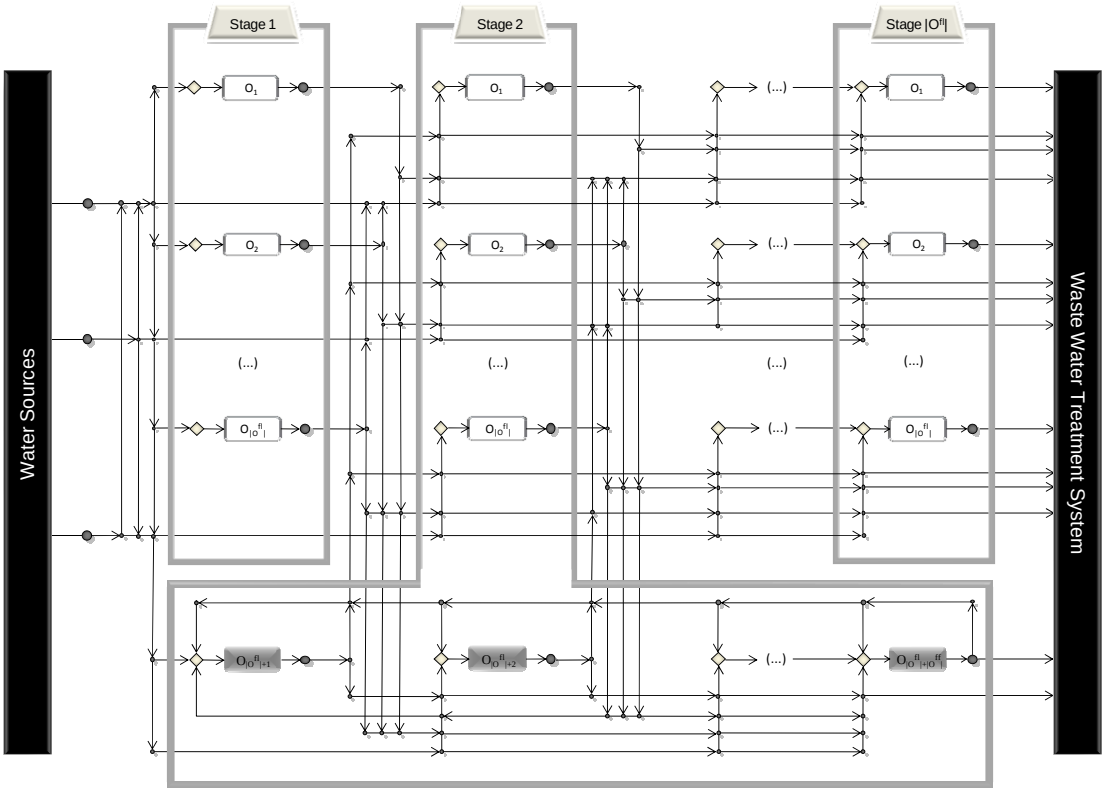

Figure 1 - General superstructure for the initialization process of model M1.

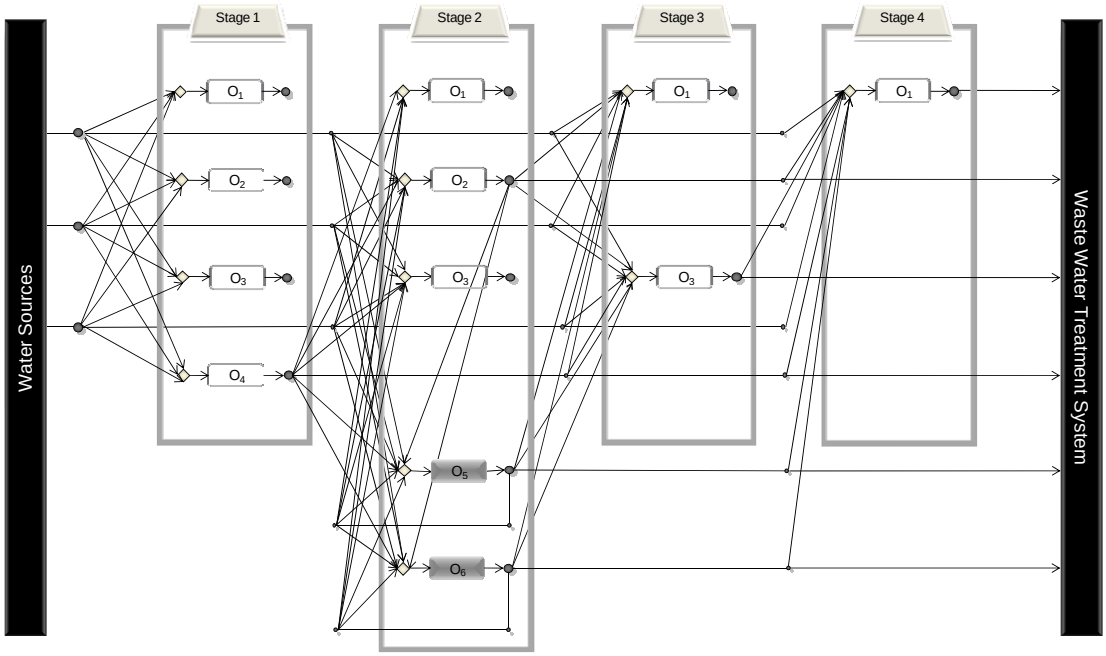

Figure 2 – Illustration of the initialization phase of model M1.

$$\sum_{w\in W} F_{w,o}^{wat}\cdot c_{w,c}^{wat} + \sum_{j\in PvO}\left[\left\langle F_{j,o}^{oper}\cdot c_{j,o}^{out}\right\rangle\Big|_{j\in O^{fl}} + \left\langle F_{j,o}^{oper}\cdot c_{j,c}^{out\,max}\right\rangle\Big|_{j\in O^{ff}}\right] + \sum_{j\in A\,c\,O\wedge(j\in O^{ff}\vee(j\in O^{fl}\wedge o\in O^{ff}))}(F_{j,o}^{oper}\cdot c_{j,c}^{out\,max}) \le \left(F_o^{tot}\Big|_{o\in O^{fl}} + f_o^{in}\Big|_{o\in O^{ff}}\right)\cdot c_{o,c}^{in\,max}, \forall\, o\in A\,c\,O, c\in C \tag{12}$$

$$\sum_{w\in W} F_{w,o}^{wat}\cdot c_{w,c}^{wat} + \sum_{j\in PvO}\left[\left\langle F_{j,o}^{oper}\cdot c_{j,o}^{out}\right\rangle\Big|_{j\in O^{fl}} + \left\langle F_{j,o}^{oper}\cdot c_{j,c}^{out\,max}\right\rangle\Big|_{j\in O^{ff}}\right] + \sum_{j\in Ac\,O\wedge j\in O^{ff}}(F_{j,o}^{oper}\cdot c_{j,c}^{out\,max}) + \Delta m_{o,c}\cdot Y_o \le F_o^{tot}\cdot c_{o,c}^{out\,max}, \forall\, o\in O^{fl}\cap A\,c\,O, c\in C \tag{13}$$

$$\sum_{j\in A\,c\,O} F_{o,j}^{oper} \le f_o^{tsys},\quad \forall\, o\in PvO \tag{14}$$

$$F_o^{tot}\Big|_{o\in O^{fl}} \le f_o^{lim}\cdot Y_o,\quad \forall\, o\in A\,c\,O, o\in O^{fl} \tag{15}$$

$$\sum_{\substack{o\in A\,c\,O\\ o\in O^{fl}}} Y_o = 1 \tag{16}$$

5 Computational Results

Table 2 shows the characteristics of the 36 test problems considered, while Table 3 lists the computational results for TCN, M1 and BARON. The study was performed in an Intel Core 2 Duo 2.4 GHz processor, with 2 GB of RAM memory, running Windows XP Professional. All mathematical formulations and algorithms were executed in GAMS 22.5. The resulting MILPs were solved with CPLEX, while the NLPs were solved by the local solver CONOPT. The results have shown that the new method is slightly less effective than its predecessor in escaping local optima, since it could find the optimal solutions in 21 out of the 25 problems that TCN could tackle. The advantage is that it requires significantly fewer computational resources and so it can go well beyond the previously observed practical limit of seven fixed load units, as illustrated with those examples featuring twenty units, which took less than four minutes to solve. The new method is even more successful than the global optimization solver BARON in Exs 31-

33, with the added advantage of being orders of magnitude faster.

6 Conclusions

This paper has presented a new MILP-based strategy for the optimal design of water-using networks featuring multi-contaminants and both fixed contaminant load and fixed flowrate operations. A new approach has been proposed to generate a small set of very good starting points for the solution of the non-convex NLP. It has been compared to a closely related LP-based method taken from the literature and to the one employed by the global optimization solver BARON. The results from a large set of example problems confirm its effectiveness in avoiding local solutions despite the small number of starting points. In contrast to the previous method they are easily scalable and, for some of the larger problems, could find better solutions than BARON with significantly fewer computational resources.

Keywords: Hybrid separation, Power separation, Exergy
Topic: Systematic methods and tools for managing the complexity

Abstract
In recent years, hybrid processes composed of a distillation column coupled with another separation process (membrane, pressure-swing adsorption unit, etc.) have received increased attention by both the industry and the scientific community. Combining such processes often leads to a large number of possible design arrangements. Therefore, efficient design methods are required, even at the conceptual design level. In this paper, general thermodynamic insights relative to the integration of a distillation column with an auxiliary separation process are developed – the aim being to minimize the number of distillation trays within the hybrid system. Two developments are discussed: the first concerns an extension of the definition of the concept of power of separation, previously introduced by Sorin and co-workers, to non-isothermal processes; the second establishes the basis of a shortcut method for finding the redistribution of a given separation duty between the sub-processes of a hybrid system (involving distillation) which minimizes the number of distillation trays.

Introduction

As many authors have reported in the literature (Moganti et al., (1994) and Stephan et al., (1995)), combining a distillation column with a membrane allows for a reduction of the number of distillation trays. Given the significant number of possible hybrid configurations between a distillation column and a membrane network, Kookos (2003) as well as Szitkai et al., (2002) proposed a mathematical programming methodology based on a superstructure representing all possible parallel hybrid arrangements. They considered the problem of finding a distillation column design and a membrane network design forming a hybrid for which the annualized cost was minimal. However, as was mentioned by Bausa and Marquardt (2000), although important and useful, the results of such an optimization will provide “no understanding of whether the solution obtained can be further improved or whether there are inherent constraints which cannot be overcome”.

In this paper, the definition of power of separation, a thermodynamic function introduced by Sorin and Rheault (2007) for isothermal processes will be extended for non-isothermal processes such as distillation. The property of additivity of this function will then be used to decompose a distillation/membrane hybrid process. Through a numerical study, it will be shown that the minimum number of column trays corresponds to the maximum power of separation of the membrane. This observation will offer the advantage of reducing the problem’s complexity by considering, as a first step of the conceptual design, the design of the membrane alone. The separation of the water-ethanol mixture in a process composed of a distillation column and a pervaporation membrane will be used as an example illustrating this shortcut design approach.

Power of Separation of a Non-Isothermal Process

By using the exergy balance around an isothermal separation process, Sorin and Rheault (2007) focused on the part of the exergy rise within the process which is associated with the variation of activities of the species in the products and the feedstock. They called this term the power of separation (P_{sep}) of the process. More precisely, P_{sep} can be expressed through the Gibbs free energy variation rate (ΔG), the process temperature (T) and the environment temperature (T_0) as:

$$P_{sep} = \frac{T_0}{T} \Delta G \,. \qquad (1)$$

The aim of the present section is to extend this definition to a non-isothermal separation process. The following development may be generalized to any non-isothermal separation process with any number of components and streams. However given that the interest of the present paper is mainly focused on distillation processes and given that the conclusions obtained here for binary mixtures may be easily extended to any number of components in the mixture, the following development is restricted to binary distillation.

The increase of the exergy rate of products over the feedstock (ΔE) for a binary distillation process can be expressed using the multi-step separation process presented on a temperature (T) – molar fraction (X_a) of volatile component diagram (figure 1). The shape of saturated liquid and vapor lines presented in figure 1 is chosen only to illustrate the procedure, it can be done for other shapes of T-X diagrams, for example for azeotropic mixtures.

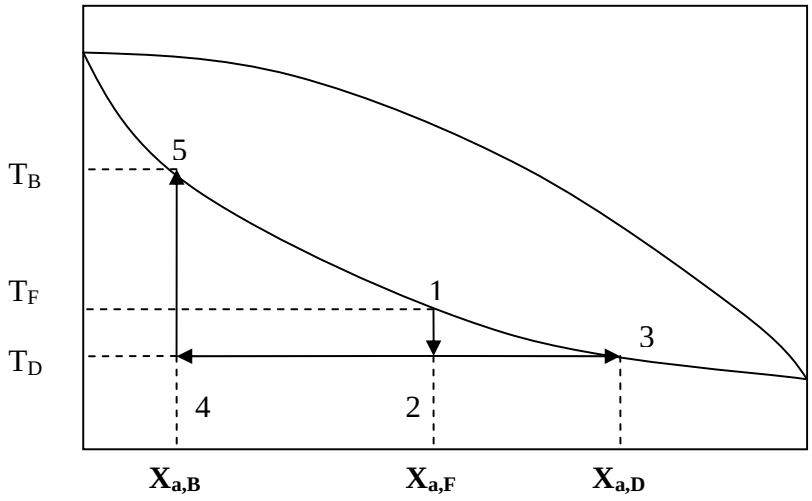

Figure 1. T-X diagram for a binary distillation.

The points 1, 3 and 5 correspond to feedstock, distillate and bottom products. The process of separation can be presented as an assembly of elementary processes, for example, the

feedstock cooling (1-2), the isothermal separation of the feedstock (2-3,4) and the heating of the bottom liquid (4-5). Given that ΔE is a thermodynamic function of state it can be presented as:

$$\Delta E_{1-3,5} = \Delta E_{2-1} + \Delta E_{2-3,4} + \Delta E_{5-4} \qquad (2)$$

Each term on the left and right sides of equation (2) may be expressed through the corresponding difference in enthalpy ΔH and entropy ΔS rates:

$$\Delta E_{out-in} = \Delta H_{out-in} - T_0 \Delta S_{out-in} \qquad (3)$$

where the indexes in and out correspond to the inlet and outlet of each elementary process respectively. For the heat transfer processes 1-2 and 5-4 equation (3) may be written as:

$$\Delta E_{out-in} = \Delta H_{out-in} (1 - \frac{T_0}{\overline{T_{out-in}}}) \qquad (4)$$

where $\overline{T_{out-in}}$ is the average thermodynamic temperature of the corresponding processes of cooling and heating. According to Sorin and Rheault (2007), for the isothermal separation process 2-3,4, equation (3) takes the form:

$$\Delta E_{out-in} = \Delta H_{out-in} (1 - \frac{T_0}{T}) + P_{sep} \qquad (5)$$

and the last term of the right side of equation (5) can be expressed through the variation of the activities $a_{i,j}$ of a component i at a point j (2, 3 and 4).

In turn, according to Prausnitz et al., (1986) the activity variation of the components along the elementary processes 2-1 and 5-4.follows the relation:

$$(\frac{\partial \ln a_i}{\partial T})_{P,X} = (h_i^0 - \overline{h_i}) / RT^2 \qquad (6)$$

where h_i^0 and $\overline{h_i}$ are the molar and the partial molar enthalpy of the component i. Assuming that the term $(h_i^0 - \overline{h_i})$ is constant with temperature, integrating (6) and multiplying by T_0 leads to:

$$RT_0 \frac{\ln a_{i,out}}{\ln a_{i,in}} = (h_i^0 - \overline{h_i})(\frac{T_0}{T_{in}} - \frac{T_0}{T_{out}}) \qquad (7)$$

Multiplying equation (7) by the corresponding molar rates $n_{i,j}$ adding it to equation (2) and substituting the corresponding terms from equations (4) and (5), yields:

$$RT_0 \sum_i n_i \frac{\ln a_{i,out}}{\ln a_{i,in}} = \Delta E_{1-3,5} - \Delta H_{2-3,4}(1-\frac{T_0}{T_2}) - \Delta H_{2-1}(1-\frac{T_0}{\overline{\overline{T_{2-1}}}}) -$$
$$\Delta H_{5-4}(1-\frac{T_0}{\overline{\overline{T_{5-4}}}}) + \sum_i n_i (h_i^0 - \overline{h_i})(\frac{T_0}{T_1} - \frac{T_0}{T_2}) + \sum_i n_i (h_i^0 - \overline{h_i})(\frac{T_0}{T_4} - \frac{T_0}{T_5}) \quad (8)$$

The left hand side of equation (8) is the power of separation for a non-isothermal process. It is the part of exergy rise due exclusively to the activities variation of the product components over the ones of feedstock free from heating, cooling and heat of mixing effects. Equation (8) shows that the power of separation is an additive thermodynamic function. In particular, the power of separation of a hybrid process is the sum of the power of separation of the distillation column and that of the auxiliary separator.

Distillation Column/Membrane Hybrid: Power of Separation Short-Cut Method

Consider a hybrid process with a fixed separation task and composed of a distillation column with a given reflux ratio and an additional separation unit. The present section aims at validating the following hypothesis: the number of trays within the distillation column may be reduced by increasing the power of separation of the additional separator. This hypothesis is verified by using the example of the separation of water-ethanol mixture in a hybrid process composed of a distillation column and a pervaporation membrane (fig. 2).

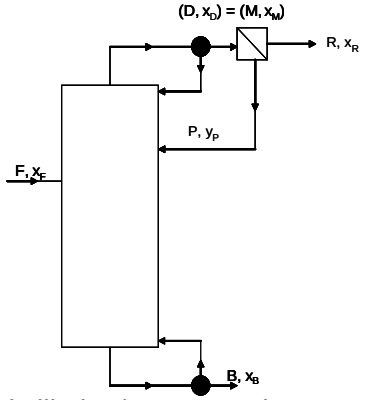

Fig. 2. Distillation/pervaporation membrane hybrid.

Assume that the distillation column verifies the constant molar overflow (CMO) hypothesis and that the hybrid is such that the (saturated vapor) permeate is returned to the column with no mixing, i.e. the position at which the permeate enters the column is determined as the position where the vapor exiting the corresponding tray has the same composition as the permeate. The following hybrid design problem is considered. For given flow rates and compositions of the hybrid's input and output streams (B, x_B, F, x_F, R, x_R), a given reflux ratio for the distillation column, a fixed (and constant) internal pressure for the column and fixed pressures at both sides of the membrane, determine the conditions for the minimum number of trays in the column as well as for the minimum membrane surface area. The membrane area has been evaluated according the shortcut method proposed by Bausa and Marquardt (2000) the number of distillation trays was calculated iteratively using the McCabe-Thiele diagram. The membrane area and the number of distillation trays for the hybrid structure in fig. 2 were evaluated for different molar fractions of ethanol in the distillate. As can be observed in fig. 3 (the membrane surface area and number of distillation trays correspond to square and triangular points respectively), when the membrane's power of separation is increased, its surface area

increases; in that case, the column's power of separation decreases (because the hybrid has constant power of separation and because power of separation is additive), which results in a decrease of the number of distillation trays. As can be seen by these results, the power of separation of the membrane or distillation column is intrinsically linked to the process' size.

This observation, based on thermodynamics, offers the advantage of simplifying the conceptual design task by optimizing only one of the hybrid sub-processes. To be more precise, in the present case study (see Fig. 3), the size of both processes can be studied by considering only one parameter: the power of separation of the membrane. Maximizing the power of separation of the membrane alone would result in a hybrid with minimal number of distillation trays (and minimal power of separation of the column, since the hybrid's power of separation is fixed); on the other hand, minimizing the membrane's power of separation would result in a hybrid design with minimal membrane surface area. These results show that the power of separation of a process seems to be intimately linked to its size.

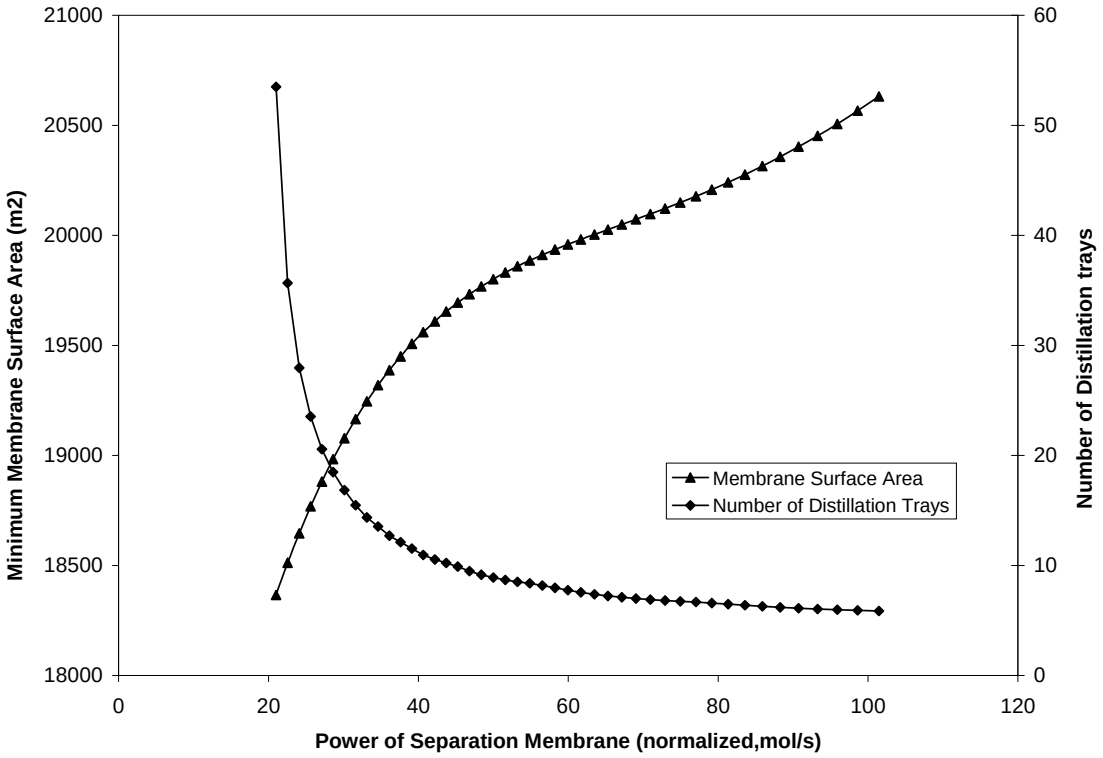

Fig. 3. Numerical results for the water-ethanol separation.

Conclusion

A short-cut method to minimize the number of distillation trays for hybrid processes is proposed. It is based on the property of additivity of power of separation of the units forming the hybrid process, i.e. the power of separation of the process is the sum of the power of separation of each sub-process. The result of this is that by maximizing the power of separation of one of the sub-processes, the optimal design of the column or/and the membrane module can be worked out independently from each other. This allows to reduce the complexity of the conceptual design of hybrid processes.

Topic: Integration of life sciences & engineering.

Abstract

Parameter identification is a critical aspect for mathematical modelling of biological systems. When the number of parameters increases, this task can become very challenging and understanding how sensitive is the model output to variations in parameter values can be very helpful. If a small change in a parameter results in relatively large changes in the state variables, the model answer is said to be sensitive to this parameter. This means that this type of parameters have to be determined very precisely to achieve an accurate model. On the contrary, parameters to which the process dynamics exhibit a small sensitivity do not need to be measured rigourously.

Local sensitivity analysis determines the model sensitivity to changes in the parameters values within a small local region about a given set of nominal values. Global sensitivity methods account for interactions between parameters and explore the entire range of each parameter. Thus, parametric global sensitivity analysis is presented here as a robust alternative for this type of analysis, detecting non influential parameters and their interactions. The performance of this methodology is illustrated with a benchmark dynamic model describing a biochemical pathway.

1 Introduction

Developing suitable dynamic models of biochemical pathways is a key step towards the development of predictive models for cells or whole organisms. Such models can ultimately provide explanations of the biological phenomena becoming a fundamental aspect in Systems Biology. Since the amount and quality of experimental data increases and the underlying mechanisms of biological systems are better understood, the complexity of the models necessarily increases. That usually involves an increase in the number of parameter often leading to over-parametrised models where the parameter identification problem turns very challenging. In that case, the sensitivity analysis (the study of the impact that changes in the value of the parameters have on the output of the model) can be used to decide which parameters should be the focus of the model calibration efforts, or even as an analysis tool to test model identifiability. Moreover, sensitivity methods should serve as diagnostic tools that help to improve mathematical models guiding model reformulations efforts when unidentifiable parameters are found.

Saltelli et al (2005) have reviewed and categorized the available sensitivity analysis methods. Roughly, they can be classified into local and global approaches. Local methods measure the variation of the output due to the change of model parameters around a given nominal value. They have the advantage of being straightforward to implement and computationally cheap. However, although these methods are valid for linear cases or when the value of the parameters is known, they can be misleading for the general nonlinear case. In contrast, global sensitivity analysis methods consider the effects of changing parameters simultaneously while spanning the entire admissible region of the parameter space.

In this work, global sensitivities are presented as a robust alternative for this type of analysis, detecting non influential parameters and their interactions in non linear dynamical models. The derivative based global sensitivity measures, presented in Kucherenko et al (2008) for explicit functions, are here extended for models described by deterministic ordinary differential equations (ODEs). These values and the computational time required for their computation are contrasted with the well known Sobol' indices Sobol' (2001). A parameter ranking based on these measures is established and compared with the one based on local sensitivities. These rankings allow the prioritisation of parameters that can be subsequently estimated using robust global optimization methods Egea et al (2007). The performance of this methodology is illustrated with a benchmark problem regarding a model of a biochemical pathway with three enzymatic steps Rodriguez-Fernandez et al (2006).

2 Methods

2.1 Mathematical model

A challenging benchmark problem, involving a biochemical pathway with three enzymatic steps, was considered. The mathematical formulation of the nonlinear dynamic model can be found in Rodriguez-Fernandez et al (2006). The identification problem consists of the estimation of 36 kinetic parameters of the nonlinear biochemical dynamic model (8 nonlinear ODEs) which describes the variation of the metabolite concentration with time.

For this study, model outputs corresponding to 8 metabolite concentrations at 21 time-points taken from 0 to 120 s were considered. In order to get a better understanding of the model structure, the local and global sensitivity measures of each metabolite concentration towards the entire set of 36 parameters were investigated. Hence, each of these methods produced a $8 \times 21 \times 36$ matrix.

2.2 Sensitivity analysis methods

Local sensitivities provide the slope of the calculated model output in the parameter space at a given set of nominal values considered for the parameters so the behavior of the response function is described only locally in the input space. Moreover, preliminary experiments and model calibration tests should be carried out in order to obtain a first guess for the parameter values and an iterative scheme involving both steps is required in order to study the model sensitivity. In addition, these methods are linear thus they are not sufficient for dealing with complex models, especially those in which there are nonlinear interactions between parameters.

In contrast, global sensitivity analysis (GSA) methods evaluate the effect of a parameter while all other parameters are varied simultaneously, thus accounting for interactions between parameters without depending on the stipulation of a nominal point (they explore the entire range of each parameter).

The most widely used methods in GSA are, FAST and extended FAST, the Morris method and its adaptations and the Sobol' method considered as one of the more powerful despite its high computational cost.

2.2.1 Numerical methods for the calculation of local sensitivity indices

They are several numerical methods for calculating the local sensitivity indices although the computed values should be the same among the precision of the considered method.

The decoupled direct method (DDM) has proven to be the best general method for the numerical calculation of local sensitivities (Saltelli et al. (2000)). One of the best known implementations of this method is ODESSA, a package of FORTRAN routines for simultaneous solution of ordinary differential

equations and the associated fist-order parametric sensitivity equations, developed by Leis and Kramer (1988). ODESSA is a modification of the initial-value solver LSODE, and is the one used in this work.

2.2.2 Sobol' global sensitivity indices

The method of global sensitivity indices developed by Sobol' is the most established among the variance-based methods. The method is based on the ANOVA decomposition of the variance of the model output. A detailed description of the method can be found in Sobol' (2001) were Sobol' defines two type of indices: S_{p_a} that accounts only for the effect of the parameters of the subset a and $S^T_{p_a}$ that also accounts for the interactions of the parameters of the subset a with the rest of the parameters.

Calculation of Sobol' indices is based on the evaluation of a series of integrals over the parameter space. For that, the Quasi Monte Carlo algorithm (QMC) using the Sobol' low-discrepancy sequences (LDS) was selected in this work among the existing possibilities. In such a way, the sensitivity indices can be calculated in a straightforward manner according to the formulas:

$$S_{p_a} = \frac{\frac{1}{N}\sum f(p_a, p_b) f(p_a, p'_b) - (\frac{1}{N}\sum f(p))^2}{\frac{1}{N}\sum f^2(p) - (\frac{1}{N}\sum f(p))^2} \tag{1}$$

$$S^T_{p_a} = \frac{1}{2}\frac{\sum \left[f(p_a, p_b) f(p'_a, p_b)\right]^2}{\frac{1}{N}\sum f^2(p) - (\frac{1}{N}\sum f(p))^2} \tag{2}$$

Thus, each Quasi Monte Carlo sample point requires three computations of the model $f(p_a, p_b)$, $f(p'_a, p_b)$ and $f(p_a, p'_b)$. For the computation of the Sobol' indices of an entire set of n parameters, using N sample points, the number of function evaluations is $N_F = N(n+2)$.

2.2.3 Derivative based Global Sensitivity Measures

Kucherenko and co-workers Kucherenko et al (2008) presented the derivative based global sensitivity measures (DGSM) based on averaging local derivatives using Quasi Monte Carlo sampling methods. They applied this technique to a set of explicit functions showing that it is much more accurate than the Morris method. Moreover, they demonstrated that there is a link between these measures and the Sobol' sensitivity indices.

In this work, these measures are extended in order to be able to handle ordinary differential equations (ODEs). The details of this methodology are described below.

Consider a differentiable function $f(p)$, where $p = \{p_i\}$ is a vector of parameters defined in the unit hypercube H^n $(0 \leq p_i \leq 1, i = 1, ..., n)$. Local sensitivity measures are based on partial derivatives

$$E_i\left(p^*\right) = \frac{\partial f}{\partial p_i} \tag{3}$$

Sensitivity measure $E_i\left(p^*\right)$ depends on a nominal point and it changes with a change of p^*. This deficiency can be overcome by averaging $E_i\left(p^*\right)$ over the parameter space H^n. Such a measure can be defined as:

$$\bar{M}_i = \int_{H^n} E_i dp \tag{4}$$

Another measure, which is the variance of $\bar{M}_i$, is also considered

$$\bar{\Sigma}_i = \left[\int_{H^n} \left(E_i - \bar{M}_i\right)^2 dp\right]^{1/2} \tag{5}$$

$\bar{\Sigma}_i$ can also be presented as

$$\bar{\Sigma}_i^2 = \int_{H^n} E_i^2 dp - \bar{M}_i^2 \tag{6}$$

Combining $\bar{M}_i$ and $\bar{\Sigma}_i$ a new measure $\bar{G}_i$ can be introduced

$$\bar{G}_i = \bar{\Sigma}_i^2 + \bar{M}_i^2 = \int_{H^n} E_i^2 dp \tag{7}$$

Being s a number of parameters in a subset we can define the so called "alternative global sensitivity estimator", $\bar{G}_s$, as

$$\bar{G}_s = \frac{\sum_{i=1}^{s} G_i}{\sum_{i=1}^{n} G_i} \tag{8}$$

Non-monotonic functions have regions of positive and negative values of partial derivatives $E_i\,(p^*)$, hence due to the effect of averaging values $\bar{M}_i$ can be very small or even zero: i.e. for a symmetrical at a middle point ($p = 0.5$) function $\bar{M}_i = 0$. To avoid such situations measures based on the absolute value of $|E_i(p^*)|$ can be used:

$$\bar{M}_i^* = \int_{H^n} |E_i|\, dp \tag{9}$$

$$\bar{\Sigma}_i^* = \left[\int_{H^n} \left(|E_i| - \bar{M}_i^* \right)^2 dp \right]^{1/2} \tag{10}$$

Similar measures were introduced in Campolongo et al (2006) within the framework of the Morris method. Using an analogy with variance based global sensitivity measures, the set of measures $\bar{M}_i$, $\bar{\Sigma}_i$ and $\bar{G}_i$ are called derivative based global sensitivity measures (DGSM).

Analogously with the calculation of Sobol' indices, the integrals (Eq. 9-10) were evaluated here by means of the Quasi Monte Carlo algorithm (QMC) using the Sobol' LDS. Local sensitivities (Eq. 3) were computed with ODESSA simultaneously with the original system so the number of function evaluations is reduced to $N_F = N$.

2.3 Extension to ODEs systems

Since dealing with a systems of ODEs, the sensitivity indices of every observed state variable at each measurement time point with respect to each of the parameters, are available. In order to summarize all this information, global sensitivity indices as the average of all the S_i for each parameter are defined:

$$S_i = \frac{1}{N_y} \frac{1}{N_t} \sum_{j=1}^{N_y} \sum_{k=1}^{N_t} S_{ij}(t_k) \tag{11}$$

The same expression is applicable to S_i^T, $\bar{M}_i$, $\bar{\Sigma}_i$ and $\bar{G}_i$.

3 Results and discussion

3.1 Local sensitivity analysis

The local sensitivity indices were computed at a nominal point p^* and at $5p^*$ and their values are shown in Figures 1-2.

With these results a ranking of importance for the parameters was established. For the nominal point, p^*, the ten less influential parameters are p_2, p_3, p_8, p_9, p_{14}, p_{15}, p_{30}, p_{32} p_{33} and p_{36}. They account for the 5 % of information while the ten more influential ones represent the 50 % of the model sensitivity. That

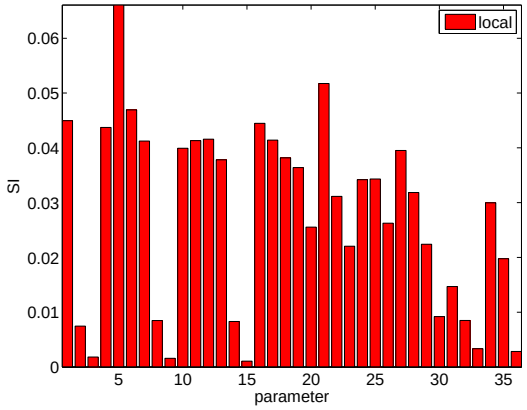

Figure 1: Local sensitivities at p^*

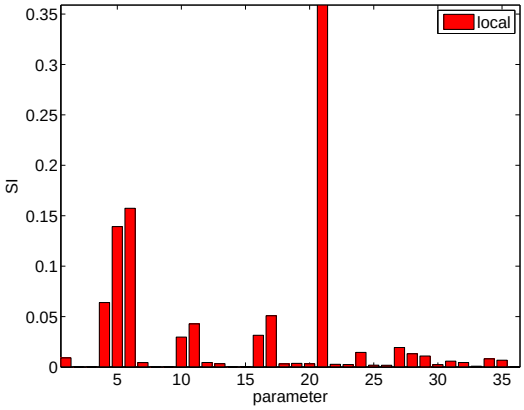

Figure 2: Local sensitivities at $5p^*$

indicates that our efforts must be focused on the proper estimation of the most influential parameters whereas the less important can be fixed to their nominal values.

However, when computing the same ranking for a different point, as $5p^*$, the results are completely different. Since the sensitivity analysis is usually performed before the parameter estimation, more robust methods are needed in order to ensure that small changes in the parameters values will not significantly change the results of the study.

3.2 Global sensitivity analysis

The values of the total Sobol' indices and the $\bar{G}_i$ measure were computed using the same number of sample points ($N = 2^{10}$). The integrations were computed over a logarithmic parameter space assumed to be uniformly distributed within one order of magnitude larger and one order smaller than the nominal values. The results are shown in Figures 3-4.

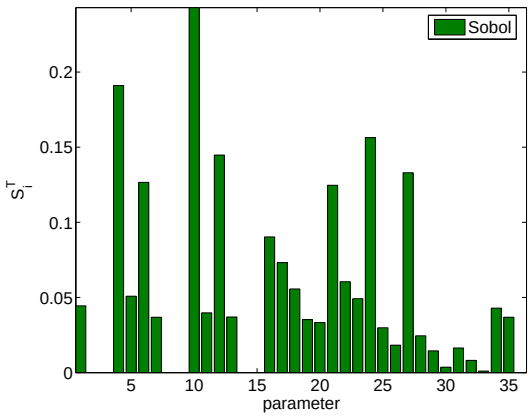

Figure 3: Sobol', Set of bounds I

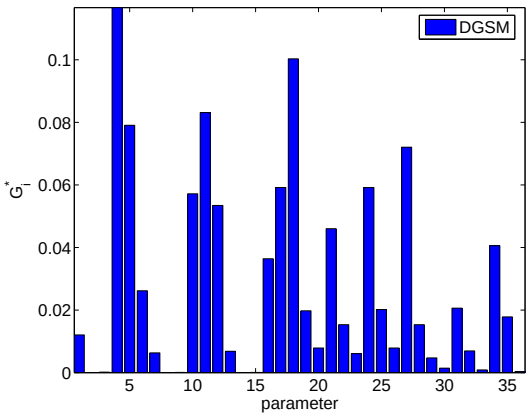

Figure 4: DGSM, Set of bounds I

From the ten less influential parameters, nine are coincident (p_2, p_3, p_8, p_9, p_{14}, p_{15}, p_{25}, p_{33} and p_{36}) showing that $\bar{G}_i$ is a good proxy to S_i^T. Moreover, it can be seen that one third of the parameters accounts for the 50 % of the model sensitivity.

Besides, eight are in agreement with the results of the local sensitivities at the nominal point but no connection can be established with the results for the vector $5p^*$ although this point is included in the considered set of bounds.

4 Conclusion

Accurate parameter estimation of complex dynamical systems can become very challenging as models can contain hundreds or even thousands of parameters. The results of a sensitivity analysis can be used to establish a ranking of importance for the parameters, allowing to fix unessential parameters and to prioritize the most influential ones and facilitating the identification task.

In this contribution, a novel methodology for global sensitivity analysis reducing $(n + 2)$ times the number of function evaluations with respect to the well known Sobol' indices was presented. The results obtained by both methods are equivalent and more robust than those provided by the local sensitivities that are strongly dependent on the selection of the nominal point.

Especial attention should be payed to the number of sample points considered for the integration since low convergence may also be the source of inaccurate results.

Topic: Systematic methods and tools for managing the complexity

Abstract

Triple-layered Rotavirus-like particles (RLPs), a vaccine candidate against rotavirus disease, are produced using the baculovirus/insect cells system. This extremely complex process has assembly efficiencies of the three constitutive viral proteins of RLPs (VP2, VP6 and VP7) normally around 11-15%. In order to optimize batch performance, it is essential to evaluate *a priori* the effect of critical process parameters as the multiplicity of infection (MOI – #virus.cell^{-1}) on process kinetics. A stochastic mathematical model was developed (Roldão *et al.*, 2008a) and used to find optimal asynchronous infection regimes. Results indicate that maximum productivity for VP2 (used as a model for the remaining viral proteins) is achieved at MOI=0.01 virus.cell^{-1} while the minimum is obtained at MOI=10 virus.cell^{-1}. Moreover, model simulations show that high MOIs have no advantage over low ones in protein expression due to maximum translation capacity. One can conclude that optimal protein production is a compromise between high intracellular protein templates, obtained at high MOIs, and high infected cell densities, obtained at low MOIs. The acquired knowledge demonstrates the potential of mathematical models in process design and will show its usefulness in process optimization. In a second study, several baculovirus titration methods were evaluated to find the one estimating viral titers with best accuracy as it strongly affects MOI variability and consequently batch consistency. The techniques that better combined titer accuracy, cost *per* titration, titration time and labor intensity were the $TCID_{50}$, MTT and flow cytometric assays. Nevertheless, it is compulsory to confirm titers accuracy by at least two different titrations methods.

1. Introduction

Genetically engineered baculovirus are powerful vectors for expression of heterologous proteins in insect cells. This system is being applied to the production of RLPs as a vaccine against rotavirus disease which currently has a higher mortality than AIDS/HIV in under-five children. RLPs based vaccines are non-infectious, highly immunogenic and safer to produce than existing live attenuated ones. Nevertheless, the optimisation of RLPs production is extremely complex as it involves the assembly of VP_2, VP_6 and VP_7. Thus, strategies to maximize individual protein production and to suppress product-derived contaminants negatively impacting the overall process are essential to increase assembly efficiencies for higher values than the normal 11-15%.

The design of such strategies starts from an initial screening of which critical process parameters most affects process kinetics. In this respect, MOI is considered one of the most relevant ones and therefore was investigated. The stochastic mathematical model developed by Roldão *et al.* (2008a) shows here its usefulness in finding optimal asynchronous infection

regimes. This model combines the stochastic nature of infection (randomness of virus binding to the host cells) with intracellular dynamics, namely vDNA replication, mRNA synthesis and protein expression (see Eqs. 1 to 15). These three main intracellular events occurring after infection were simulated for different MOIs (0.01, 0.1, 1, 10 and 40 virus.cell^{-1}) to extract process specificities and verify model robustness. Additionally, final protein yields were compared for a wide range of MOIs (10^{-3} to 10^{2} virus.cell^{-1}) to assess the MOIs maximizing viral protein expression.

The successfulness of an optimized process depends on the robustness and efficiency of the production workflow. One must guarantee that critical parameters are tightly controlled. As an example, irreproducible MOIs caused by inaccurate viral titer estimation have a profound impact on process performance and batch consistency. The selection of an appropriate titration method to the recombinant baculovirus in use, capable of distinguishing between infectious and non-infectious virus is essential to reduce titer errors and MOI variability. Therefore, several methods for baculovirus titration were evaluated in this study and suggestions regarding the ones showing better compromise between time/cost/accuracy were extracted.

2. Model Development

2.1. Assumptions

A set of simplifying hypothesis were assumed based either on the literature or on experimental observations:

i. Stochastic infection: low MOIs are important for process optimisation.
ii. Structured protein expression: intracellular dynamics of vDNA, mRNA and viral protein are considered.
iii. Gene size: intrinsic protein expression kinetics is ruled by the size of the underlying gene.
iv. Maximum translation capacity: maximum translation capacity of mRNA blocks coming from the polyhedrin promoter.

2.2. Mathematical equations

The dynamics of cell density is given by:

$$\frac{dn}{dt} = \mu n - k_d n \qquad \text{Eq. 1}$$

with μ (h^{-1}) the specific growth rate and k_d (h^{-1}) the cells death rate defined as:

$$k_d = \begin{cases} k_{d,\text{int}} + \Delta k_d \log_{10}\left(\sum_k dna_k\right), & \text{t} > \text{TOI} + \delta^* \\ k_{d,\text{int}}, & \text{otherwise} \end{cases} \qquad \text{Eq. 2}$$

where $k_{d,int}$ (h^{-1}) is the intrinsic cell death rate of *Sf*-9 cells, *TOI* (h) the time of infection, δ^* (hpi) the time required for the infection to accelerate host cell death, Δk_d (h^{-1}) the increase in cell death rate due to infection correspondent to 10 intracellular vDNA copies and dna_k (dna$_k$.cell^{-1}) the intracellular vDNA concentration delivered by virus *k* (*k* denotes the foreign gene in the virus). The rate of virus *k* entry, $r_{inf,k}$ (dna$_k$.cell^{-1}h^{-1}) is defined as:

$$r_{\text{inf},k}\,dt = \begin{cases} X_k, & t \le TOI + \delta_{reinf} \\ 0, & t > TOI + \delta_{reinf} \end{cases} \qquad \text{Eq. 3}$$

with X_k a random variable denoting the number of viruses *k* per unit cell (dna$_k$.cell^{-1}) which penetrate the cells in the time interval *[t, t+dt]* and δ_{reinf} (hpi) the time period over which cells continue to be re-infected. It is here assumed that the random variable X_k follows the Poisson probabilistic model:

$$P_{X_k=nk} = \frac{\exp(-\lambda(t))\lambda(t)^{nk}}{nk!} \quad \text{Eq. 4}$$

The shape parameter $\lambda(t)$ of the Poisson distribution is defined here as follows:

$$\lambda(t) = k_a v_k(t) dt \quad \text{Eq. 5}$$

with k_a (ml.cell^{-1}.h^{-1}) the first order attachment constant and v_k (dna$_k$.ml^{-1}) the concentration of extracellular virus k at time t. It can be interpreted as the average number of virus binding to a single cell in the time interval *[t, t+dt]*. The dynamics of extracellular virus v_k is given by:

$$\frac{dv_k}{dt} = \left(-r_{\inf,k} + r_{bud,k}\right) n \quad \text{Eq. 6}$$

Extracellular virus concentration has two contributions: the depletion of virus due to infection and also virus budding, which are the newly synthesized virus in the host cells secreted to the extracellular medium. The intracellular dynamics of vDNA delivered by virus k, dna_k (dna$_k$.cell^{-1}), is defined by:

$$\frac{d\ dna_k}{dt} = \eta_t r_{inf,k} + r_{dnarep,k} - r_{bud,k}, \quad dna_k(0) = 0 \quad \text{Eq. 7}$$

The first term is the rate of infection multiplied by the trafficking efficiency, η_t. The second term is the vDNA replication rate, $r_{dnarep,k}$ (dna$_k$.cell^{-1}.h^{-1}), in the host cells nucleus, defined as:

$$r_{dnarep,k} = \begin{cases} k_{RDNA} dna_k \left(1 - \dfrac{\delta^* - (t - TOI)}{\delta^* - \delta_{DNA,low}}\right), & \delta_{DNA,low} \le t \le \delta^* \\ 0, & otherwise \end{cases} \quad \text{Eq. 8}$$

where k_{RDNA} (h^{-1}) is the first-order vDNA replication constant, $\delta_{DNA,low}$ (hpi) the time for onset of vDNA replication and δ^* is defined as :

$$\delta^* = \frac{\delta_{10}}{\log_{10}\left(\sum_k dna_k\right)} \quad \text{Eq. 9}$$

with δ_{10} (hpi) the critical time instant correspondent to 10 intracellular vDNA copies. The third term in Eq. 7 is the virus budding rate, $r_{bud,k}$ (dna$_k$.cell^{-1}.h^{-1}):

$$r_{bud,k} = \begin{cases} k_{bud} dna_k, & \delta_{bud,low} \le t - TOI \le \delta_{bud,high} \\ 0, & otherwise \end{cases} \quad \text{Eq. 10}$$

with $\delta_{bud,low}$ (hpi) and $\delta_{bud,high}$ (hpi) the time of onset and halt of virus budding, respectively, and k_{bud} (h^{-1}) the first-order virus budding constant. The transcription of foreign gene k into the corresponding mRNA under the control of polyhedrin promoter, is defined as:

$$\frac{d\ rna_k}{dt} = r_{transc,k} - k_{DRNA,k} rna_k, \quad rna_k(0) = 0 \quad \text{Eq. 11}$$

with rna_k the intracellular concentration of mRNA coding for protein k (rna$_k$.cell^{-1}), $r_{transc,k}$ (rna$_k$.cell^{-1}.h^{-1}) the transcription rate of gene k and $k_{DRNA,k}$ (h^{-1}) the first order degradation rate. The transcription rate is as follows:

$$r_{transc,k} = \begin{cases} k_{rna,elong} \dfrac{dna_k}{S_k} \left(1 - \dfrac{\delta^* - (t - TOI)}{\delta^* - \delta_{polh,low}}\right), & \delta_{polh,low} \le t - TOI \le \delta^* \\ 0, & otherwise \end{cases} \quad \text{Eq. 12}$$

with $k_{rna,elong}$ (bp.h^{-1}) the RNA polymerase elongation rate, S_k (bp) the size of gene k and $\delta_{polh,low}$ (hpi) the characteristic time post infection for the onset of polyhedrin promoter transcription. The translation of mRNA into viral proteins is defined by:

$$\frac{dvp_k}{dt} = r_{transl,k}, \quad vp_k(0) = 0 \qquad \text{Eq. 13}$$

with vp_k (μg.cell^{-1}) the concentration of intracellular viral protein k and the $r_{transl,k}$ (μg.cell^{-1}.h^{-1}) the corresponding synthesis rate:

$$r_{transl,k} = \begin{cases} \dfrac{k_{rib,elong} rna_k}{S_k mp_k}\left(1 - \dfrac{\delta^* - (t - TOI)}{\delta^* - \delta_{polh,low}}\right) i_{transl}, & \delta_{polh,low} \le t - TOI \le \delta^* \\ 0, & otherwise \end{cases} \qquad \text{Eq. 14}$$

with $k_{rib,elong}$ (bp.rna$_k^{-1}$.h^{-1}) the ribosomal elongation rate, mp_k (μg) the molecular weight of vp_k and i_{transl} an adimensional parameter to account for the hypothesis of a maximum translation capacity. The term i_{transl} is defined here as:

$$i_{transl} = \begin{cases} 1, & \sum_k S_k rna_k \le L_{transl,\max} \\ \dfrac{L_{transl,\max}}{\sum_k S_k rna_k}, & \sum_k S_k rna_k > L_{transl,\max} \end{cases} \qquad \text{Eq. 15}$$

where $L_{transl,max}$ (rna$_k$.bp.cell^{-1}) is the maximum translation capacity.

2.3. Model calibration

The stochastic/structured model was implemented in MATLAB™. Two integration methods were evaluated: the direct Euler method and the 4th/5th order Runge-Kutta solver (MATLABs' *ode45* function). The Euler method for an integration step of t = 0.1 h was taken as a reasonable compromise between accuracy and computation time. Model calibration was performed using intra and extracellular data of vDNA, mRNA and VP collected over time in experiments with MOI= 5 virus.cell^{-1} and a starting cell density $n(0)$=10^6 cells.ml^{-1}. Process parameters can be viewed in Roldão *et al.* (2008a).

3. Results

All intracellular events were simulated for MOIs of 0.01, 0.1, 1, 10 and 40 virus.cell^{-1}. The population dynamics of healthy and infected cells (Figure 1) show that for high MOIs, 100% infection occurs within the first 3 hpi whereas at low MOIs a high percentage of cells remain healthy and growing in the first 36 hpi, being only infected in a second round of infection due to virus budding (16-36 hpi).

In terms of vDNA replication, maximum intracellular vDNA content is a trade-off between two different factors: high MOI represents more 'seeds' for vDNA replication but reduces the time window for vDNA replication; for low MOIs, virus budding is extended over a long period of time, which will continuously infect and re-infect the existing host cells. Intracellular mRNA and VP follow closely the vDNA replication pattern. Interestingly, model simulations show similar maximum protein yields for the tested MOIs. This apparent insensitiveness to variations in MOI can be explained by the maximum translation capacity of mRNA blocks coming from the polyhedrin promoter. Final volumetric protein productivities, on the other hand, vary significantly for the tested MOIs. Such differences can be explained at the light of the effect of MOI on cellular growth (Figure 2). Since cellular growth is significantly more inhibited at high MOIs than

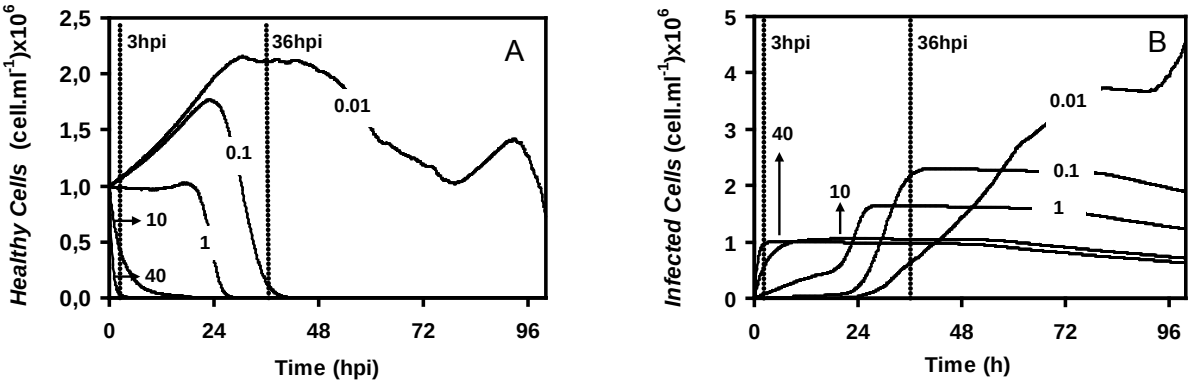

Figure 1. Kinetic profile of healthy (A) and infected (B) cells population. The numbers next to the lines indicate the MOI.

at low MOIs, for similar specific protein yields, the volumetric productivities will be much lower at high MOIs. This phenomenon is visible when comparing the yields of VP2 for MOIs of 0.01 and 10 virus.cell^{-1}. While similar specific productivities are achieved at both MOIs (11 and 12 mg.cell$^{-1}\times10^{-9}$ for 0.01 and 10 virus.cell^{-1} respectively), volumetric productivity at MOI of 0.01 is almost 4-fold higher than at MOI of 10 virus.cell^{-1} (Figure 3).

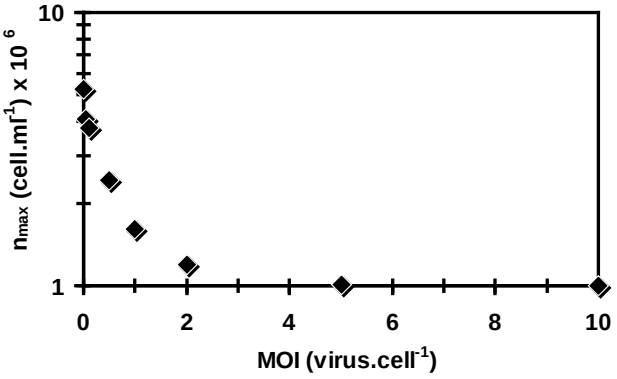

Figure 2. Effect of MOI on maximum cell concentration (n_{max})

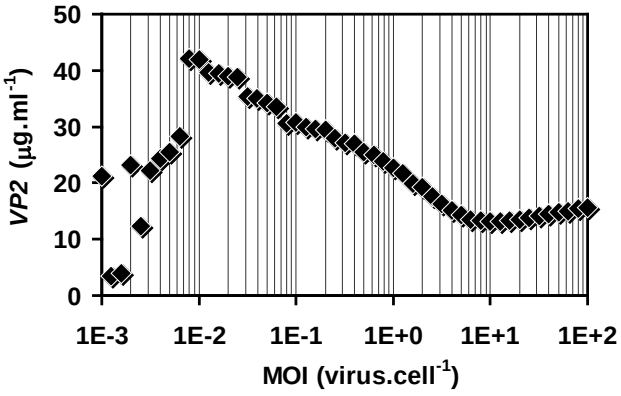

Figure 3. Effect of MOI on VP2 volumetric productivity

Results in Figure 3 indicate the existence of a maximum at MOI=0.01 and a local minimum at MOI=10 which can be attributed to the no-saturation of the translation machinery although 100% infection was obtained in the first infection cycle. For very high MOIs, there is saturation in protein expression due to maximum translation capacity. Therefore, one can conclude that optimal protein production is a compromise between high intracellular protein templates, obtained at high MOIs, and high infected cell densities, obtained at low MOIs. The application of this modelling and optimisation methodology to the remaining VPs, will allow the establishment of optimal operational conditions for optimization of RLPs titre.

Since this model explores the hypothesis of gene size being the main factor affecting the rate of protein expression, the effect of both gene size and MOI on final protein productivities was addressed (Figure 4). Optimal MOIs seem to be independent of the gene size. This result is rational because the recombinant gene size does not affect either the infection kinetics or the vDNA replication rate or the budding of progeny virus. It only affects the transcription and translation mechanisms, meaning that it only impacts on the intracellular accumulation of protein. Moreover, the increase in gene size results in the decrease of protein productivities as

mentioned in Palomares *et al.* (2002).

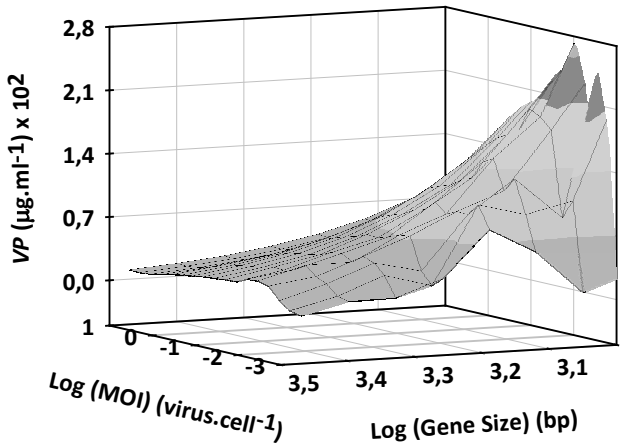

Figure 4. Gene size and MOI effect on final volumetric protein productivity

In the second study, several methods for baculovirus titration were evaluated: $TCID_{50}$ for baculovirus with and without a reporter protein (Green Fluorescent Protein – GFP), microculture tetrazolium assay (MTT), AlamarBlue assay, cell size based assay, growth cessation assay, real time Q-PCR, plaque assay and flow cytometry assay (Roldão *et al.*, 2008b). The techniques that better combined all important variables (accuracy, cost *per* titration, titration time and labor intensity) and therefore proved reliable for titer estimation were the $TCID_{50}$, MTT and flow cytometric assays with titer errors and approximated costs *per* titration of 19% and 14€, respectively. Nevertheless, it is compulsory to confirm titers accuracy by at least two different titrations methods.

4. Conclusion

Mathematical/analytical tools are here demonstrated to play a determinant role in recombinant protein expression. The predictive capacity of the stochastic model will be particularly useful in designing co-infection experiments for optimization of RLPs production as infection statistics becomes a crucial factor and one must guarantee that the infected cells carry all genes required for RLP assembly.

Abstract

In this paper, experimental investigations of a robust RST control scheme for the regulation of the ethanol in fed-batch cultures of *S. cerevisiae* is presented. Our main objective is to prove its efficiency and robustness in experimental applications ranging from laboratory to industrial scales. The controller only requires one on-line measurement signal, making it easily implementable in an industrial environment. Disturbance rejection is ensured thanks to an on-line parameter adaptation procedure, which delivers as a side product an estimate of the growth rate that can be used for process monitoring purposes. The robustification of the controller is achieved in a simple way, using the observer polynomial.

1 Introduction

S. cerevisae is one of the most popular host microorganism for vaccine production. The possibility to easily express a variety of different recombinant proteins explains its important role in the pharmaceutical industry. In order to maximize productivity, a common strategy is to regulate the ethanol concentration at a low value, thus ensuring an operating point close to the edge between the respirative and respiro-fermentative regimes where the yeast respirative capacity is exactly filled (bottleneck assumption of Sonnleitner and Käppeli's model (1986)). Several applications of this principle can be found, for instance in Chen et al. (1995) and Valentinotti et al. (2003). However, these control schemes all require the on-line measurement of the ethanol concentration, implying the availability of an (unfortunately quite expensive) ethanol probe. This explains that alternative strategies based on more basic measurement signals, such as the dissolved oxygen concentration, have been proposed, e.g. in Akesson (1999), or that software sensors reconstructing ethanol from the measurements of basic signals have been designed (Hulhoven et al., 2006).

In a recent study of Renard et al. (2006), a RST controller with Youla parametrization is developed for the regulation of the ethanol concentration and tested successfully in real-life experiments. One of the main advantage of this approach is that it is based on a simple linear model linking the feed flow rate to the ethanol concentration, and a simple linear model of the disturbance, which represents the substrate demand for cell growth. The prior knowledge of only one stoichiometric coefficient is required, whereas the apparent growth rate can be easily estimated on-line (in order to ensure a good disturbance rejection).

The objective of the present study is to present an alternative and simpler formulation of the RST control scheme based on the observer polynomial (Dewasme et al. (2007)), and to demonstrate its large applicability range and robustness in the scaling-up of the ethanol regulation from laboratory bioreactors to industrial ones.

This paper is organized as follows. The next section introduces the nonlinear model of Sonnleitner and Käppeli (1986). The linearization of the system, the controller design and the on-line parameter adaptation are presented in Section 3. Section 4 illustrates the performance of the ethanol regulation in a series of different real-life experiments from laboratory-scale to industrial-scale bioreactors. The last section is devoted to general conclusions and comments.

2 Modeling yeast fed-batch cultures

The yeast strain *S. cerevisiae* presents a catabolism that can be macroscopically described by the following three main reactions:

Substrate oxidation: $$S + k_5 O \xrightarrow{r_1} k_1 X + k_7 P \quad (1a)$$

Substrate fermentation: $$S \xrightarrow{r_{21}} k_2 X + k_4 E + k_8 P \quad (1b)$$

Ethanol oxidation: $$E + k_6 O \xrightarrow{r_3} k_3 X + k_9 P \quad (1c)$$

where X, S, E, O and P are, respectively, the concentration in the culture medium of biomass, substrate (typically glucose), ethanol, dissolved oxygen and carbon dioxide. k_i are the yield coefficients and r_1, r_2 and r_3 are the reaction rates which are strong non linear functions of the main components, taking the classical form of Monod laws.

This kinetic model, which is often encountered in the literature, is based on Sonnleitner's bottleneck assumption (Sonnleitner and Käppeli, 1986, see Figure 1).

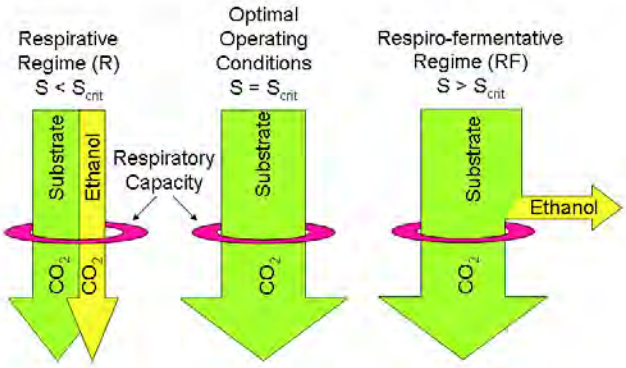

Figure 1: Representation of Sonnleitner's bottleneck assumption (1986).

During a culture, the yeast cells are likely to change their metabolism because of their limited respiratory capacity. When the substrate is in excess (concentration $S > S_{crit}$), the yeast cells produce ethanol through fermentation, and the culture is said in respiro-fermentative (RF) regime. Ethanol has a detrimental effect on the cells growth because it directly inhibits the cells respiratory capacity (Pham, 1999). On the other hand, when the substrate becomes limiting (concentration $S < S_{crit}$), the available substrate (typically glucose), and possibly ethanol (as a substitute carbon source), if present in the culture medium, are oxidized. The culture is then said in respirative (R) regime.

Component-wise mass balances give the following differential equations :

$$\frac{dX}{dt} = (k_1 r_1 + k_2 r_2 + k_3 r_3) X - DX \quad (2a)$$

$$\frac{dS}{dt} = -(r_1 + r_2)X - D(S - S_{in}) \quad (2b)$$

$$\frac{dE}{dt} = (k_4 r_2 - r_3)X - DE \quad (2c)$$

$$\frac{dO}{dt} = -(k_5 r_1 + k_6 r_3)X - DO + OTR \quad (2d)$$

$$\frac{dP}{dt} = (k_7 r_1 + k_8 r_2 + k_9 r_3)X - DP - CTR \quad (2e)$$

$$\frac{dV}{dt} = F_{in} \quad (2f)$$

where S_{in} is the substrate concentration in the feed, F_{in} is the inlet feed rate, V is the culture medium volume and D is the dilution rate ($D = \frac{F_{in}}{V}$). *OTR* and *CTR* represent respectively the oxygen transfer rate from the gas phase to the liquid phase and the carbon transfer rate from the liquid phase to the gas phase. Classical models of *OTR* and *CTR* are given by:

$$OTR = k_L a(O_{sat} - O) \quad (3a)$$

$$CTR = k_L a(P - P_{sat}) \quad (3b)$$

where $k_L a$ is the volumetric transfer coefficient and, O_{sat} and P_{sat} are respectively the dissolved oxygen and carbon dioxide concentrations at saturation.

3 Simple design of an adaptive robust controller

The basic principle of the controller is to regulate the ethanol at a constant low setpoint, leading to a self-optimizing control in the sense of Skogestad (2004) and ensuring that the yeast culture operates in the respiro-fermentative regime, close to the biological optimum, i.e., the edge with the respirative regime.

The control structure is provided following the next decisions:

- The most evident choice of a manipulated variable in a fed-batch system is the feed flow rate F_{in}. Considering that we are looking for the simplest way of modeling the bioreactor, we assume then that F_{in} appears as the main and only input of the system.
- As explained in Valentinotti et al. (2003), the maximum of productivity is obtained at the edge between the respirative and respiro-fermentative regimes, where the quantity of ethanol is constant and equal to zero (*VE=0*). Unfortunately, evaluating accurately the volume is a difficult task as it depends on the inlet and outlet flows including F_{in} but also the added base quantity for pH control and several gas flow rates. So, for those practical limitations, a sub-optimal strategy is elaborated through the control of the ethanol concentration around a low value depending on the sensitivity of commercially available ethanol probes.
- A linear control framework is chosen as it makes the design of robust controllers easier than in a nonlinear framework.
- A RST (2-degree-of-freedom) controller is selected as it offers a great decoupling of the servo/regulation tasks (desired performance specifications and rejection of disturbances).

Substrate consumption represents one of the fastest dynamics of the system. As the theoretical value of S_{crit} is very small (below *0.1g/l*) and assuming a quasi-stationnarity of *S* (i.e. considering that there is no accumulation of glucose in the bioreactor while working not

far from the optimal operating conditions), the very small quantity of substrate is almost instantaneously consumed by the cells ($\frac{d(VS)}{dt} \approx 0$).

Inserting this assumption in the differential system (2), a discrete transfer function linking the ethanol concentration to the feed rate can be obtained for both the respirative and respiro-fermentative regimes:

$$E(k) = \frac{bq^{-1}}{1-q^{-1}}\left[F_{in}(k) - d_i(k)\right] \quad (4a)$$

$$d_i(k) = \frac{c}{1-\gamma q^{-1}}\delta(k) \quad (4b)$$

where the parameters *b* and *c* are functions of the operating regime and d_i is seen as the perturbation representing the cells growth (γ is an image of the cells growth rate). For the sake of clarity, we call bq^{-1} the polynomial *B*, $1-q^{-1}$ the polynomial *A*, *c* the polynomial *C* and $1-\gamma q^{-1}$ the polynomial *D*.

The two-degree-of-freedom RST controller, applied to the linearized model of the bioreactor (see Figure 2), is designed to control the ethanol concentration at E_{ref}. The control law can be written as:

$$R(q^{-1})F_{in}(k) = -S(q^{-1})E(k) + T(q^{-1})E_{ref} \quad (5)$$

and, omitting the backward-shift operator for the sake of clarity, the closed-loop equation takes the form

$$E(k) = \frac{BT}{AR+BS}E_{ref} + \frac{BR}{AR+BS}d_i(k) \quad (6)$$

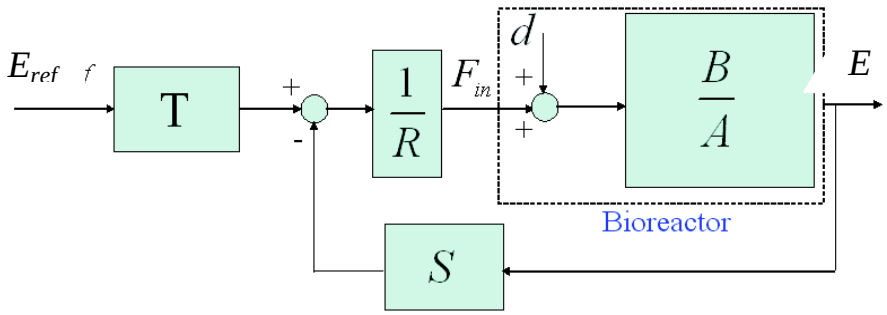

Figure 2: closed-loop control of the bioreactor model where B, A, R, S and T are polynomials in backward-shift operator q^{-1}.

The *RST* controller polynomials are then computed using a pole-placement procedure (Astrom et al, 1997). They are found by solving a diophantine equation of the form:

$$AR + BS = A_0 A_m \quad (7)$$

where A_m is chosen to tune the tracking performances and A_0 is the observer polynomial, which can be selected independently of A_m so as to confer some robustness to the controller.

Following the internal model principle (Francis et al, 1976), the unstable pole γ of the disturbance d_i should be included into the *R* polynomial (i.e, *D* is a factor of *R*). This disturbance will be canceled out if a correct estimation of the parameter γ is available, for

instance through a *Recursive Least Squares* algorithm (Astrom et al, 1997). Indeed, after the initial time, (4b) can be written as:

$$d_i(k) - \gamma\ d_i(k-1) = 0 \qquad (8)$$

4 Experimental results

Experimental applications of the control scheme to fed-batch cultures of *S. cerevisiae* have been performed with laboratory-scale and industrial-scale bioreactors. Experimental results are presented in Figures 3 and 4.

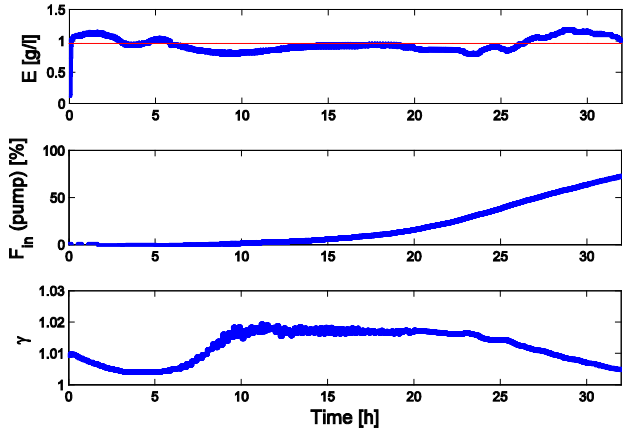

Figure 3: Experimental results of the ethanol regulation applied to laboratory-scale fed-batch cultures of S. Cerevisiae. Evolution of the ethanol concentration E around E_{ref}=1g/l, the feed flow rate F_{in} expressed in % of the maximal pump speed and the parameter γ, image of the cells growth rate.

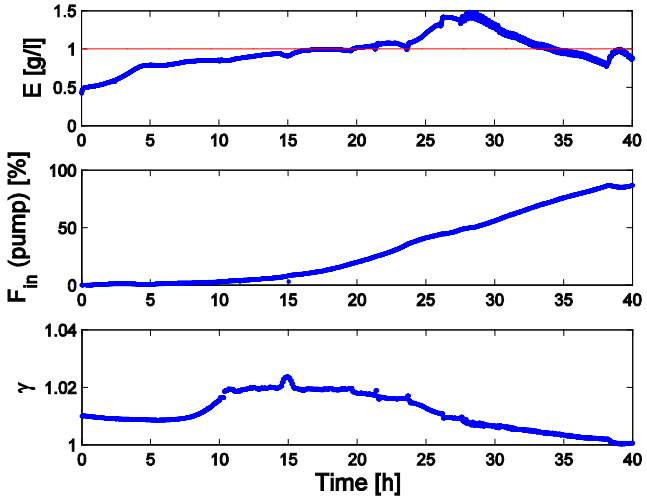

Figure 4: Experimental results of the ethanol regulation applied to industrial-scale fed-batch cultures of S. cerevisiae. Evolution of the ethanol concentration E around E_{ref}=1g/l, the feed flow rate F_{in} expressed in % of the maximal pump speed and the parameter γ, image of the cells growth rate.

The results are comparable independently of the bioreactor scale. Indeed, in the two situations, the ethanol concentration stays around the setpoint E_{ref}=1g/l during the first *10h* and then follows it almost exactly for the next *10h*. Actually, the first hours correspond to the adaptation of the *γ* parameter. When the estimate converges, the regulation of the ethanol concentration becomes more accurate (as the disturbance, which represents the substrate demand for cell growth, can be compensated almost exactly).

After *20h*, the ethanol concentration deviates slightly from the setpoint. This can be explained by an apparent decrease of the cell growth as reflected by the estimated value of *γ*. This limitation phenomenon can be due to a lack of some nutriments in the culture medium. Indeed, cell growth is so efficient that the culture medium is exhausted after a certain batch time. After this time, the feed flow rate evolution becomes linear as *γ* decreases. Despite this deviation, the controller maintains *E* around *1g/l* and prevents it from moving too far from the setpoint. This demonstrates the efficiency of the tracking control even in the presence of unexpected and unmodelled phenomena like the observed limitation.

5 Conclusion

An adaptive RST controller is designed to regulate the ethanol concentration at an imposed setpoint. This design is based on pole placement (for setpoint tracking) and the selection of an observer polynomial (for loop robustification), which can be achieved independently.

In all the experimental validations, the controller performed well independently of the bioreactor scale, demonstrating its reliability under various conditions. As compared to conventional open-loop operation, the application of the control scheme can lead to very significant productivity gain.

Abstract

In this study, we consider the problem of optimizing the productivity of fed-batch cultures of *S. Cerevisiae*. This bioprocess is described by nonlinear kinetic models based on the bottleneck assumption of Sonnleitner and Käppeli (1986) and ethanol inhibition resulting from the fermentation of a possible excess of substrate feeding. In contrast with most published studies where the critical substrate level is assumed constant, we investigate the situation where this critical substrate level depends on the yeast respiratory capacity, and in turn on the oxygen and ethanol concentration in the culture medium. The challenge is thus to maintain the process at a high level of productivity by avoiding the accumulation of ethanol. To this end, two adaptive extremum-seeking schemes coupled to a feedback control loop regulating either the substrate or ethanol concentration are developed.

1 Introduction

Yeasts are one of the most important host microorganisms in manufacturing of biopharmaceuticals. Industrial vaccine production is usually achieved using fed-batch cultures of genetically modified yeast strains, which can express different kinds of recombinant proteins.

From an operational point of view, it is necessary to determine an optimal feeding strategy (i.e. the time evolution of the input flow rate to the fed-batch culture) in order to maximize productivity. The main problem that can be encountered at this stage is the presence of an overflow metabolism. The fermentation of an excess of substrate (glucose) can lead to the accumulation of ethanol in the culture medium, and in turn to the inhibition of the cell respiratory capacity.

To avoid this undesirable effect, a closed-loop optimizing strategy is required, which could take various forms (Chen et al. (1995), Renard et al. (2007)). In particular, the use of extremum seeking strategies for bioprocess optimization has received an increasing attention in recent years (Ariyur et al. (2003), Titica et al. (2003)).

In this study, we develop two adaptive extremum-seeking strategies based on Lyapunov stability arguments: (i) in order to determine on-line the critical substrate concentration and to avoid the production of ethanol. (ii) in order to keep the ethanol concentration constant.

2 Modeling yeast fed-batch cultures

The yeast strain *S. cerevisiae* presents a catabolism that can be macroscopically described by the following three main reactions:

Substrate oxidation: $$S + k_5 O \xrightarrow{r_1} k_1 X + k_7 P \quad (1a)$$

Substrate fermentation: $$S \xrightarrow{r_{21}} k_2 X + k_4 E + k_8 P \quad (1b)$$

Ethanol oxidation: $E + k_6 O \xrightarrow{r_3} k_3 X + k_9 P$ (1c)

where X, S, E, O and P are, respectively, the concentration in the culture medium of biomass, substrate (typically glucose), ethanol, dissolved oxygen and carbon dioxide. k_i are the yield coefficients and r_1, r_2 and r_3 are the nonlinear reaction rates given by:

$$r_1 = \min(r_S, \frac{r_o}{k_5}) \quad (2a)$$

$$r_2 = \max(0, r_S - \frac{r_o}{k_5}) \quad (2b)$$

$$r_3 = \max(0, \min(r_E, \frac{r_o - k_5 r_S}{k_6})) \quad (2c)$$

where the kinetic terms associated with the substrate consumption r_S, the oxidative or respiratory capacity r_o and the ethanol oxidative rate r_E are given by $r_S = \mu_S \frac{S}{S + K_S}$, $r_o = \mu_o \frac{O}{O + K_O}$ and $r_E = \mu_E \frac{E}{E + K_E}$, respectively. These expressions take the classical form of Monod laws where μ_S, μ_o and μ_E are the maximal values of specific growth rates and K_S, K_O and K_E are the saturation constants of the corresponding element.

This kinetic model, which is often encountered in the literature, is based on Sonnleitner's bottleneck assumption (Sonnleitner et al, 1986, see Figure 1). During a culture, the yeast cells are likely to change their metabolism because of their limited respiratory capacity. When the substrate is in excess (concentration $S > S_{crit}$), the yeast cells produce ethanol through fermentation, and the culture is said in respiro-fermentative (RF) regime. On the other hand, when the substrate becomes limiting (concentration $S < S_{crit}$), the available substrate (typically glucose), and possibly ethanol (as a substitute carbon source), if present in the culture medium, are oxidized. The culture is then said in respirative (R) regime.

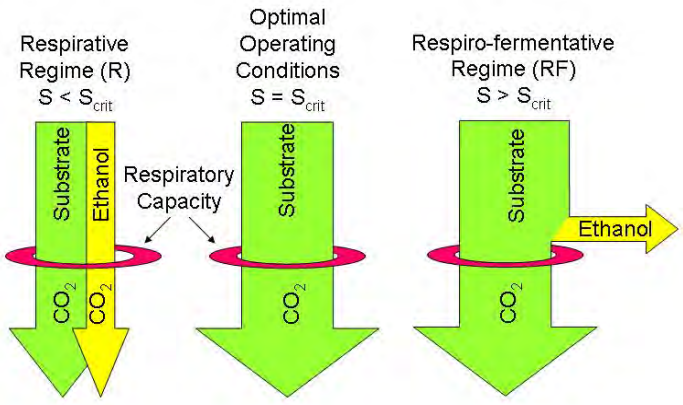

Figure 1: Illustration of Sonnleitner's bottleneck assumption for yeast limited respiratory capacity (1986).

Component-wise mass balances give the following differential equations :

$$\frac{dX}{dt} = (k_1 r_1 + k_2 r_2 + k_3 r_3) X - DX \quad (3a)$$

$$\frac{dS}{dt} = -(r_1 + r_2)X - D(S - S_{in}) \quad (3b)$$

$$\frac{dE}{dt} = (k_4 r_2 - r_3)X - DE \quad (3c)$$

$$\frac{dO}{dt} = -(k_5 r_1 + k_6 r_3)X - DO + OTR \quad (3d)$$

$$\frac{dP}{dt} = (k_7 r_1 + k_8 r_2 + k_9 r_3)X - DP - CTR \quad (3e)$$

$$\frac{dV}{dt} = F_{in} \quad (3f)$$

where S_{in} is the substrate concentration in the feed, D is the dilution rate ($D=F_{in}/V$), F_{in} is the inlet feed rate and V is the culture medium volume. *OTR* and *CTR* represent respectively the oxygen transfer rate from the gas phase to the liquid phase and the carbon transfer rate from the liquid phase to the gas phase. Classical models of *OTR* and *CTR* are given by:

$$OTR = k_L a(O_{sat} - O) \quad (4a)$$

$$CTR = k_L a(P - P_{sat}) \quad (4b)$$

where $k_L a$ is the volumetric transfer coefficient and, O_{sat} and P_{sat} are respectively the dissolved oxygen and carbon dioxide concentrations at saturation.

Ethanol has a detrimental effect on the cells growth because it directly inhibits the cells respiratory capacity (Pham, 1999). The production of ethanol depends on a critical substrate level (S_{crit}) which is not constant. After a trivial mathematical manipulation, a relation between the critical substrate concentration level and the cell respiratory capacity can be obtained as:

$$S_{crit} = \frac{K_S r_o}{k_5 \mu_S - r_o} \quad (5)$$

In order to maintain the system at the edge between the respirative and respiro-fermentative regimes, it is necessary to determine on-line the critical substrate concentration (S_{in}) and to control the substrate concentration in the culture medium around this value.

3 Adaptive extremum-seeking strategies

The adaptive extremum-seeking strategy that is chosen in this study is related to the techniques developed in Titica et al. (2004), Guay and Zhang (2003) and Marcos et al. (2004), which take their roots in the classical work of Ariyur and Krstic (2003). It consists in a permanent estimation of the system dynamics through the analysis of a “control error signal” (which in the present case is a function of the difference between S and the set point S_{crit}) following the injection of a periodical excitation signal d into the adaptive system. This allows the convergence of the parameter estimates to their true values and the stabilization of the error signal around zero (but not exactly zero as the excitation is permanent).

Two original adaptive strategies based on substrate or ethanol control are presented. We first define the main parameters to estimate. Then, we derive adaptation laws and a control law from the consideration of a candidate Lyapunov function ensuring system stability.

The parameters to estimate on line are the kinetic terms in equations (3b) or (3c), depending on the controlled variable, and these terms are denoted $\theta_S = r_1 + r_2$ and $\theta_E = k_4 r_2 - r_3$, respectively . In the case of substrate control, a second parameter is introduced, which represents the angular coefficient of a linear approximation of equation (5), i.e., $S_{crit} \approx \alpha r_0$.

Defining $Z_S = k_p(S - S_{crit}) + k_i \int (S - S_{crit})dt - d$ and $Z_E = k_p(E - E_{sp}) + k_i \int (E - E_{sp})d - td$, the error control variables where *d* is the excitation or *"dither signal"* and E_{sp} the ethanol set point chosen by the user, we consider the following Lyapunov candidate functions:

$$V_S = \frac{1}{2} Z_S^2 + \frac{1}{2\gamma_S} \tilde{\theta}_S^2 + \frac{1}{2\gamma_\alpha} \tilde{\alpha}^2 \quad (6a)$$

$$V_E = \frac{1}{2} Z_E^2 + \frac{1}{2\gamma_E} \tilde{\theta}_E^2 \quad (6b)$$

where γ_i (*i*=*S*,*E*) and γ_α are strictly positive tuning parameters.

A stabilizing controller is obtained if one can prove the strict negativity of the Lyapunov function derivative.

Differentiating V_i (*i*=*S*,*E*) and forcing $\dot{V}_i$ to be negative as in $\dot{V}_i = -k_z Z_i^2$, we obtain:

$$\dot{\hat{\theta}}_i = -\gamma \; k_p Z_i X \quad (7)$$

and, only in the case of substrate regulation:

$$\dot{\hat{\alpha}} = -\gamma \; Z_S (k_p \dot{r}_o + k_i r_o) \quad (8a)$$

$$\hat{S}_{crit} = \hat{\alpha} \; r_o \quad (8b)$$

Finally, the control law is given by:

$$D = \frac{\left[\frac{k_Z Z_S - a + k_d d}{k_p} - \hat{\theta} X \right]}{S - S_{in}} \quad (9)$$

with the dither signal d chosen as:

$$\dot{d} = a + k_i (S - \hat{\alpha} \; r_o) - k_p \hat{\alpha} \; \dot{r}_o - k_d d \quad (10)$$

where *a* is a closed-loop excitation signal and k_d is a new striclty positive design parameter. In a similar way, the ethanol control law can be derived as:

$$D = \frac{\left[\frac{k_Z Z_e - a + k_d d}{k_p} - \hat{\theta} X \right]}{k_4 S_{in} - E} \quad (11)$$

where *d* is chosen as:

$$\dot{d} = a + k_i (E - E_{sp}) - k_d d \quad (12)$$

4 Simulation results

We apply the controller designed in the previous section to a simulated case-study corresponding to classical small-scale (*20 liter* bioreactor) culture conditions.

Figures 2 and 3 present the simulation results. The productivity is quite satisfactory as more than *150 g/l* of biomass are obtained within *less than 40 hours*. Note that in this simulation, a fast convergence to the optimal operating conditions is achieved thanks to a judicious choice of the tuning parameters (typically γ and γ_S).

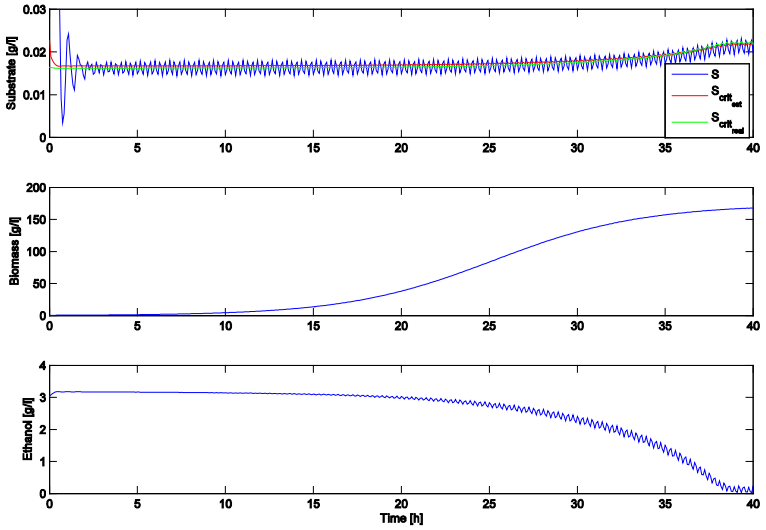

Figure 2: Substrate control. Substrate ($S, \hat{S}_{crit}$ and S_{crit}), biomass (X) and ethanol (E) concentration values.

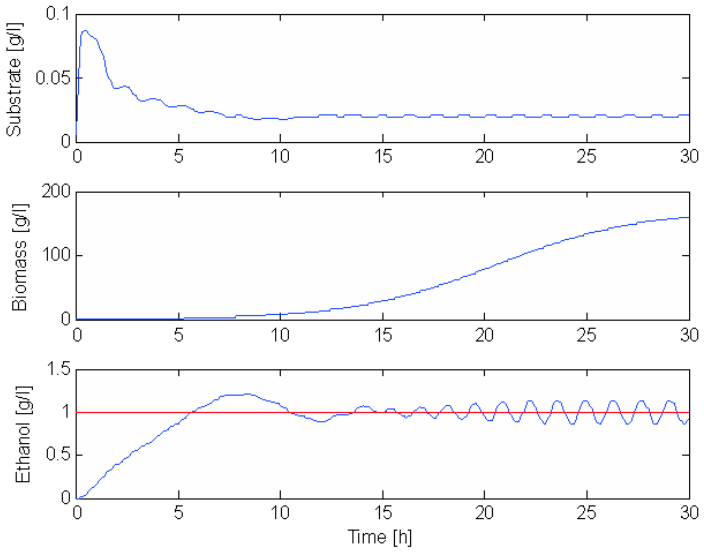

Figure 3: Ethanol control. Substrate ($S, \hat{S}_{crit}$ and S_{crit}), biomass (X) and ethanol (E) concentration values.

In the second case (Figure 3), ethanol control depends only on one parameter adaptation (θ_E) resulting in an easier choice of the tuning parameter values. Results are comparable even if the choice of a measurable reference concentration ($E_{ref} > 0.5$, according to the probe sensitivity) does not correspond to the theoretical extremum ($E=0$).
Finally, note that ethanol measurement is a more practical solution than glucose measurement, as it is difficult to measure the critical glucose concentration with currently available commercial probes. Indeed, the probe sensitivity is generally not sufficient to correctly measure concentrations below *0.1 g/l*. As the ethanol concentration set point can be imposed by the user, it is easier in this case to avoid sensitivity problems. However, the larger the setpoint, the less optimal the solution (fortunately productivity remains quite good for small changes in this value).

5 Conclusion

Two original adaptive extremum seeking strategies based either on substrate or ethanol regulation are derived and applied to yeast fed-batch cultures. The productivity is quite satisfactory as more than *150 g/l* of biomass are obtained within less than *40 hours* for both control strategies. Substrate control leads to the optimal operating conditions in the sense of Sonnleitner and Käppeli's model (1986) while the ethanol control is a very good but sub-optimal solution. However, substrate control has some practical drawbacks related to glucose probe sensitivity.

Topic: Systematic methods and tools for managing the complexity.

Abstract

Currently, there is still a gap between studies addressing the physiology of insect cells and reports focusing on increasing the productivity in the insect cell/baculovirus system. A detailed description and modelling of the cellular metabolic state with and without infection would allow to understand how the culture and infection conditions influence growth and productivity. In this work, Metabolic Flux Analysis was applied to assess the metabolic shifts in the *Spodoptera frugiperda* Sf-9 insect cell line as a consequence of growth and baculovirus infection. For that purpose, a simple model of the central metabolism has been constructed and used for the analysis of metabolic adaptations due to cell density and baculovirus infection. The knowledge of how the infection process impacts on the intracellular metabolic fluxes was then used for the rational design of strategies to achieve higher recombinant baculovirus yields in high cell density cultures. Either medium exchange or different suplementation schemes of selected nutrients were emloyed, leading to higher volumetric titers and specific yields.

1 Introduction

Baculovirus (BV)-infected insect cells have been used extensively as an expression system for the production of recombinant proteins (Summers, 2006). More recently, an increasing number of investigators have tackled the use of BVs to direct gene expression in mammalian cells (Kost and Condreay, 2002), for which efficient vector production at high cell density bioreaction is needed. The robustness of suspension cultures of *Spodoptera frugiperda* (Sf-9) cells and the high cell densities and productivities generally attained are advantageous for bioprocess development (Ikonomou et al., 2003). However, early on researchers have come to the conclusion that recombinant protein yields decrease in batch cultures infected during the later stages of growth (Caron et al., 1990). The literature related to the production of BV vectors is very scarce, with some early works demonstrating similar effects of cell density on the yields of wild type viruses. Another significant factor influencing system productivity is the MOI, i.e. the number of infectious particles (IP) per cell added to a culture. More specifically, the interplay between MOI and cell concentration at infection (CCI) is of utmost importance for efficient experimental planning and to better comprehend the BV-insect cell system.

Wth this complex scenario, very few works have attempted to analyze the metabolism of insect cells, trying to understand the effects exerted by BV infection at different MOIs. A detailed description and modelling of the cellular metabolic state with and without infection would help to understand how the culture conditions influence growth and productivity in this system. More specifically, the knowledge of how the infection process impacts on the intracellular metabolic fluxes would enable us to design strategies to achieve higher

productivities in high cell density cultures (Reuveny et al. 1993).
During the last decade, Metabolic Flux Analysis (MFA) has been emerged to quantitatively characterize the metabolism of cells, initially to study the capabilities of engineered microorganism for biotechnological applications. This approach uses mass balancing techniques and the assumption of steady-state to translate the information of a metabolic network supposed to govern the system in a set of linear constraints (Stephanopoulos et al., 1998). These constraints are then combined with measurements of extracellular excretion and uptake rates to calculate the rates of intracellular reactions. The application of mass balance techniques to animal cell cultures has become increasingly popular, although very few studies have been made with insect cell cultures.
In the present work, MFA is used to estimate the intracellular flux distributions of Sf-9 cell cultures subjected to different infection and culture conditions in terms of CCI, MOI and medium composition. For this purpose, the profiles of compounds related to cellular metabolism were analyzed in the culture medium, and several indicators of system productivity were evaluated for the different experiments.

2 Methods

2.1) Experimental cultures

Sf-9 cells were infected with a recombinant BV for evaluation of virus production and culture behavior. Cultures were performed either in 125 mL spinner flasks (Wheaton, USA) or 1-5L biorreactors (B. Braun, Sartorius, Germany) at 27^{o}C. The experiments were performed varying the CCI (1x10^{6} cells.mL^{-1} (CCI 1), 2x10^{6} cells.mL^{-1} (CCI 2) and 3-4x10^{6} cells.mL^{-1} (CCI 3)), using both low (< 5 IP/cell) and high MOIs (> 5 IP/mLI). Additional infections were performed, in which different medium composition coditions were tested, namely by exchanging the medium at the time of infection or adding selected nutrients along with virus inoculation. Every 24 h, culture samples were taken and centrifuged at 1 700 g, during 10 minutes, at room temperature to separate cells from supernatant. Aliquots of the supernatant were then stored at 4^{o}C for virus titration, or at - 20^{o}C to measure the concentrations of glucose and other sugars, lactate, key trycarboxylc acid cycle (TCA) intermediates, ammonia and free amino acids. Additionally, the pools of intracellular co-factors were followed (NAD(H), NADP(H) and ATP). Recombinant BV titration was performed by end point dilution based on the green fluorescent protein (GFP) signal.

2.2) MFA

A model for the central metabolism of Sf-9 cells was built containing the information available from previous models developed for other animal cell lines and the published information available for Sf-9 cells metabolism (Ferrance et al., 1993; Drews et al., 1995 and 2000). The model assumes that the Sf9 cell line uses glucose as the main carbon source. Moreover, it considers the main reactions of central metabolism of cultured animal cells, namely glycolysis, pentose-phosphate pathway, anaerobic fermentation pathway, tricarboxylic acids cycle, respiratory pathways, glutaminolysis, amino acids metabolism and biomass formation (Fig. 1).
On the basis of this metabolic network, a system of mathematical equations was formulated, according to the general MFA theory (Stephanopoulos et al., 1998):

$$\mathbf{r}(t) = \mathbf{A}\mathbf{v}(t) \quad \text{(Eq. 1)}$$

With **r**(t) the vector for the accumulation rates of each compound considered in the network, **A** the stoichiometric matrix of the metabolic network and **v**(t) the vector of the fluxes through the various biochemical reactions. It is generally accepted as reasonable to assume the pseudo-steady-state hypothesis for intracellular metabolites, considering that the accumulation term is negligible. In order to solve this system of equations, some fluxes were experimentally determined. The most common case is to determine trans-membrane rates of

metabolites consumed and/or secreted by the cells. These modelling constraints are crucial when applying the MFA approach because in a typical biochemical network the number of reaction rates is usually higher than the number of metabolites, resulting in an underdetermined system where not all the rates can be uniquely determined. After measuring these rates, the redundant system at hand was solved by the weighted least squares method using the Penrose pseudo-inverse matrix. The balanceable rates, which arise from system redundancy, have been used to calculate the consistency index, *h*, according to the description in Wang and Stephanopoulos (1983). The comparison of *h* with the χ^2-test function was done in order to evaluate the consistency of the experimental values along with the assumed biochemistry and the pseudo-steady-state assumption. To check for the presence of gross measurement errors, the consistency index was calculated for each rate when that rate is not involved, allowing the identification of those rates for which the values of *h* decline the most (i.e., fluxes having higher errors associated). The above-mentioned calculations were performed using the CellNetAnalyzer software (Klamt et al., 2007).

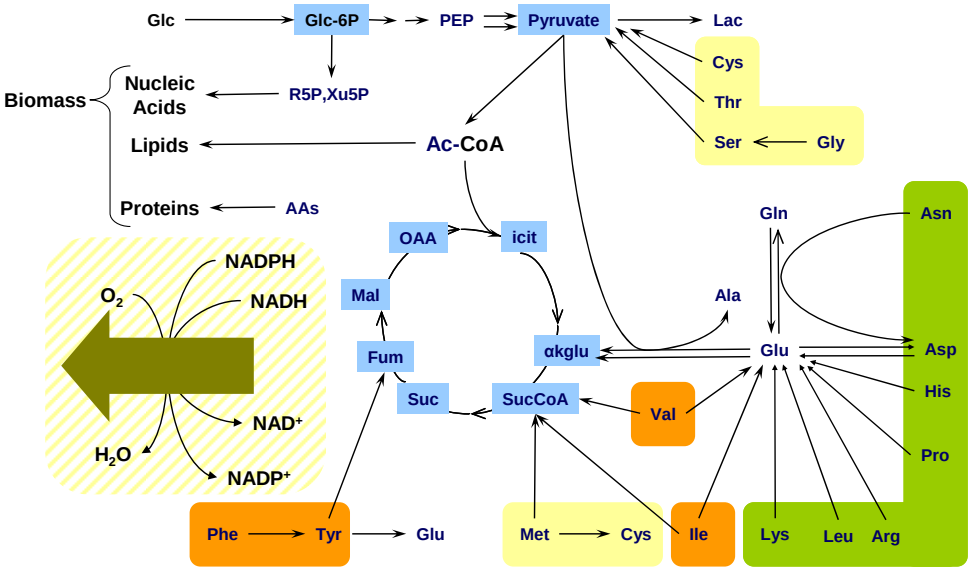

Figure 1 - Model of central metabolism of the *Spodoptera frugiperda* Sf-9 cell line.

3 Results and Discussion

In terms of process productivity, our results confirm that a cell density effect on recombinant baculovirus production occurs which is dependent on the MOI used, with a high MOI "delaying" the drop in production to higher cell densities (Fig. 2). There is a scarcity of data in the literature regarding the factors that affect BV production by insect cells. From a metabolic perspective, the decrease in protein yields when infecting the cells at later stages of growth has been attributed to nutrient depletion rather than the accumulation of inhibitory by-products (Bédard et al., 1994). This is consistent with the fact that the common compounds excreted by mammalian cell lines, ammonia and lactate, do not usually accumulate to toxic levels in Sf-9 cells (Drews et al., 1995). However, most of these studies lacked a detailed description of cellular metabolism, failing to identify the specific components responsible for decreased system productivity. Our results demonstrate that the major alterations of cellular metabolism occurring following infection are related to decreased fluxes through the TCA cycle and growth inhibition, these effects being dependent on the MOI used (Fig. 3). At the same time, the specific consumption rates of glucose are

considerably inhibited after virus infection, which is consistent with the halt in cell replication (data not shown).

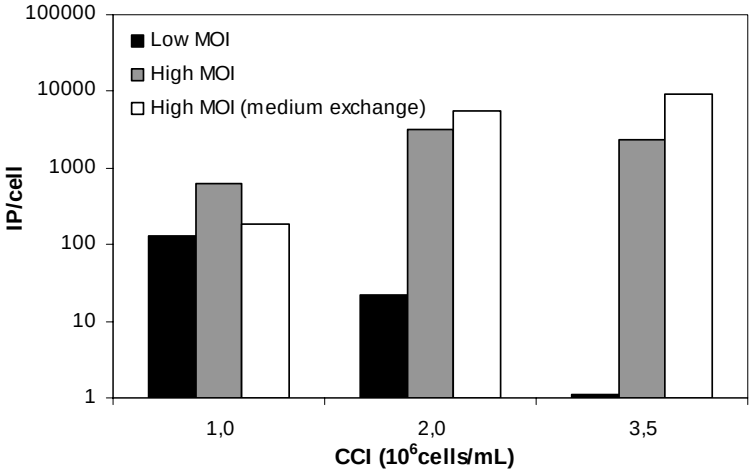

Figure 2 – Effect of different combinations of MOI, CCI and medium exchange at infection on specific productivity.

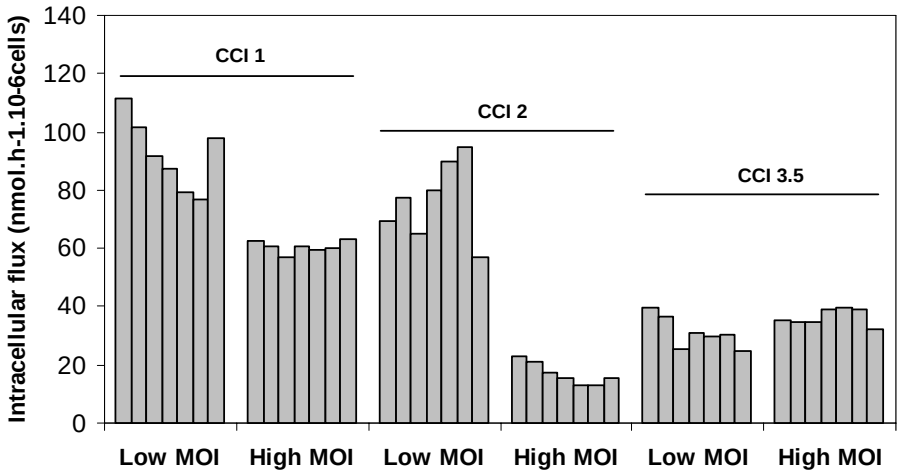

Figure 3 – Effect of different combinations of MOI and CCI on the TCA cycle fluxes.

On the other hand, these findings were corroborated by the marked alterations observed in the intracellular levels of energy and redox co-factors. In fact, it was observed an increase in the levels of intracellular ATP, along with a decrease in the NAD^+/NADH and $NADP^+$/NADPH ratios (data not shown), clearly indicating that the events following BV incorporation have a profound impact on the energetic state of the cells.

We then rationalized that by deliberately altering the cells envirome at the time of infection we could impact the central energy production pathways in order to maintain consistent high energetic levels throughout infection. For this purpose, we performed additional cultures with complete medium exchange, attaining not only higher volumetric titers, but also higher specific yields when compared to the previous cultures (Fig. 2). However, total medium replacement, though feasible for small scale cultures, is not suitable for higher production scales, increasing the cost of the bioprocess due to the need for separation devices and extra medium costs. On the other hand, the addition of complex nutrient mixtures such as different kinds of serum substitutes and hydrolysates could be beneficial for increasing

recombinant BV yields, but hinder the identification of the individual components that may be limiting production. Considering this, selected nutrient supplementation schemes at the time of infection were tested, namely different combinations of key TCA cycle intermediates and glutamine, in order to assess the role of these components on the metabolic state of Sf-9 cells and system productivity. The final results showed an increase in specific yields when compared to non-supplemented cultures. Moreover, after investigating the intracellular flux distributions of infected supplemented cultures, it was observed a relative increase in the TCA cycle rates.

Altogether, the results obtained provide the basis for interconnecting cellular metabolism with infection process allowing culture optimization for BV vectors production. The growing application of recombinant BVs for gene therapy represents an opportunity to deepen the knowledge on this system.

Keywords: Lactose fermentation, cheese whey, bio-ethanol, recombinant *S. cerevisiae*
Topic: Integration of life sciences and engineering.

Abstract

The development of *Saccharomyces cerevisiae* strains with the ability to ferment lactose has a high biotechnological interest, particularly for cheese whey bioremediation processes with simultaneous bio-ethanol production. We have developed a flocculent *S. cerevisiae* strain that efficiently ferments lactose to ethanol, using a combination of genetic engineering and evolutionary engineering approaches. This strain fermented efficiently and nearly completely (residual lactose < 3 $g \cdot L^{-1}$) lactose concentrations up to 150 $g \cdot L^{-1}$, including 3-fold concentrated cheese whey, producing ethanol titres up to 8% (v/v). The ethanol productivity obtained with this strain (> 1.5 $g \cdot L^{-1} \cdot h^{-1}$) was higher than that reported for batch or fed-batch fermentations with other lactose-consuming recombinant *S. cerevisiae* strains. The strain is highly flocculent, a property that makes it interesting for the development of high cell density fermentation processes, which may attain much higher productivity.

Introduction

Cheese whey is a by-product of dairy industries, particularly the watery portion that is formed during the coagulation of milk casein in cheese making or in casein manufacture. Whey is produced in large amounts (about 9 litres of whey are generated per each Kg of cheese produced) and has a high polluting load, therefore creating a significant environmental problem (Siso, 1996). The world whey production is estimated to be around 82 million tons per year (Pesta et al., 2007). In Portugal, the production of liquid whey is estimated to be 500 – 560 thousand tons per year (Frazão, 2001), and the largest part of it is processed by concentration and drying. Whey has a BOD (biochemical oxygen demand) of 30 – 50 $g \cdot L^{-1}$ and a COD (chemical oxygen demand) of 60 – 80 $g \cdot L^{-1}$. Lactose is largely responsible for these high BOD and COD; protein recovery reduces the COD only by about 10 $g \cdot L^{-1}$ (Siso, 1996; Domingues et al., 1999a) On the opposite hand, however, whey represents about 85 – 95% of the milk volume and retains 55% of milk nutrients. Among the most abundant of these nutrients are lactose (4.5 – 5% w/v), soluble proteins (0.6 – 0.8% w/v), lipids (0.4 – 0.5% w/v) and mineral salts (8 – 10% of dried extract) (Siso, 1996). Therefore, whey has a vast potential as a source of added value compounds, challenging the dairy industry to face whey surplus as a resource and not solely as a waste problem.

The first step in most procedures for cheese whey valorisation consists in the recovery of the protein fraction. Whey proteins have high nutritional value as well as reported health benefits. Separation of whey proteins is typically done by ultrafiltration, producing whey protein concentrates (WPC), as well as high volumes of a lactose-rich stream, the permeate, that remains a major pollutant since it retains the lactose. The lactose in the permeate (ca. 5% w/v) may be used as a substrate for the production of valuable compounds by fermentation. The classical examples are ethanol and single cell protein (SCP) production in yeast-based

bioprocesses, although biotechnologists have proposed a multitude of alternative bio-products (see e.g. Siso, 1996; Pesta et al., 2007).

Thus, a bioprocess for the production of ethanol from the lactose in cheese whey can perform two roles: on the one hand it can reduce the whey polluting load, contributing to cheese whey bioremediation, and, on the other hand, an useful product (ethanol) is obtained that can be used as fuel or in food-related applications (e.g. in vinegar manufacturing or in the beverage industry). Being a waste product, whey has advantage over food-related fermentation feedstocks, such as corn, for bio-ethanol production.

Direct fermentation of whey or whey permeate to ethanol is hardly economically competitive with the currently established processes (using cane sugar and cornstarch as substrates) or with emerging second generation technologies (using lignocellulosic biomass as raw material), mainly because the low lactose content (ca. 5% w/v) results in low ethanol titre (2 – 3% v/v), making the distillation process too expensive. Concentration of whey lactose, e.g. by ultrafiltration, is an option to obtain higher ethanol titres. The use of cheese whey powder as an alternative source of concentrated lactose to the production of ethanol has also been recently proposed (Kargi and Ozmihci, 2006; Ozmihci and Kargi, 2007). High ethanol concentrations (10 – 12% v/v) may be obtained by fermentation of concentrated lactose media (up to 200 g L^{-1} lactose) thus significantly reducing the distillation costs. Microbial strains are needed that can efficiently convert such high concentrations of lactose into ethanol, allowing the development of fermentation processes that reach high ethanol titres as well as high ethanol productivities. Such processes must be designed to minimise residual lactose at the end of fermentation, since one of the major motivations for whey utilization is to reduce/eliminate its polluting load.

There are a few established industrial systems to produce ethanol from whey, which has been done in some countries, such as Ireland, Denmark, United States and New Zealand (Siso, 1996; Pesta et al., 2007). Recently, a German dairy company (Müllermilch) announced the construction of a plant near Dresden to produce 10 million liters of bio-ethanol per year from dairy by-products.

Kluyveromyces fragilis has been the microorganism of choice for most industrial plants producing ethanol from whey (Siso, 1996; Pesta et al., 2007), because *Saccharomyces cerevisiae*, the yeast usually chosen for industrial processes involving alcoholic fermentation, is unable to metabolise lactose. Nevertheless, the ability to metabolise lactose can be transferred to *S. cerevisiae* strains by genetic engineering, a problem that has been addressed over the past 20 years by several strategies (for a review see e.g. Rubio-Texeira, 2006). One of those strategies involves cloning of the *LAC4* (β-galactosidase) and *LAC12* (lactose permease) genes of the lactose-consuming yeast *Kluyveromyces lactis* in *S. cerevisiae* strains (Sreekrishna and Dickson, 1985; Rubio-Texeira et al., 1998). However, most strains obtained displayed undesirable characteristics (such as slow growth, genetic instability or problems derived from the use of glucose-galactose mixtures) or were ineffective for ethanol production.

This paper provides an outline of our recent work on engineering a flocculent *S. cerevisiae* strain for efficient lactose to ethanol fermentation. Detailed accounts of the work described here have already been published elsewhere (Guimarães et al., 2008a; Guimarães et al., 2008b).

Construction of a flocculent lactose-consuming *S. cerevisiae* strain

A recombinant *S. cerevisiae* strain with the ability to express both the *LAC4* and *LAC12* genes of *K. lactis* was initially constructed (for details see Domingues et al., 1999b). The plasmid KR1B-LAC4-1 (Sreekrishna and Dickson, 1985), which harbors the *LAC4* and *LAC12* genes, was co-transformed with a linear fragment from the plasmid YAC4 containing the *URA3* gene. The host strain (NCYC869-A3) was a uracil-deficient mutant of the flocculent haploid *S. cerevisiae* strain NCYC869 (*MATα FLO1*).

Using this strategy, a recombinant strain able to metabolize lactose was obtained. However, that original recombinant (strain T1) showed a rather poor lactose fermentation phenotype, growing slowly in lactose and presenting a low ethanol conversion yield (Table 1). The flocculation ability of the strain T1 was also poor when compared with the host strain (Guimarães et al., 2008a).

Evolutionary engineering of the recombinant strain for efficient lactose to ethanol fermentation

In order to improve the lactose fermentation phenotype of the recombinant strain (T1) we used an evolutionary engineering approach. Evolutionary engineering refers to the exploitation of the evolutionary principles to enhance microbial properties in a biotechnological context, provided the desired phenotype is amenable to direct or indirect selection (Sauer, 2001). Evolutionary engineering approaches have been used successfully in the improvement of genetically engineered *S. cerevisiae* strains for xylose and arabinose fermentation (see e.g. Sonderegger and Sauer, 2003; Wisselink et al., 2007).

The strategy that we used to improve the lactose fermentation performance of the recombinant strain T1 consisted in serial transfer/dilution in gently shaken (40 rpm) flasks (for details see Guimarães et al., 2008a). This strategy was designed to keep the recombinant growing in lactose for many generations (>120), as well as to select for the most flocculent cells. The cells recovered at the end of the experiment presented significantly improved lactose fermentation performance compared to T1. These evolved cells were considered to be an independent strain, which was named T1-E (evolved T1). The evolved recombinant strain, T1-E, consumed lactose 2-fold faster and produced 30% more ethanol than T1 (Table 1). Moreover, T1-E flocculated in an earlier phase of the fermentations and formed much bigger flocs than T1, as could be easily observed by visual inspection of the cultivation flasks.

Table 1 – Comparison of fermentation parameters of strains T1 and T1-E in shake-flask cultivations with 25 $g \cdot L^{-1}$ of lactose. Data from a similar fermentation with a *K. lactis* strain (CBS2359) are also show for comparison.[1]

Yeast strain	T1	T1-E	*K. lactis*
Specific growth rate (h^{-1})	0.14 ± 0.01	0.21 ± 0.01	0.28
Final biomass concentration ($g \cdot L^{-1}$)	3.48 ± 0.09	2.81 ± 0.09	2.56
Maximum ethanol concentration ($g \cdot L^{-1}$)	7.08 ± 0.79	10.52 ± 0.04	8.86
Ethanol conversion yield (% of theoretical)	53 ± 5	69 ± 1	65

[1]Shake-flask fermentations were done at 30 ºC with 150 rpm agitation in yeast defined mineral medium (for details see Guimarães et al., 2008a). Data are means ± ranges of duplicate independent cultivations for T1, and means ± standard deviations of triplicate cultivations with single colony isolates for T1-E. Data for *K. lactis* are from a single cultivation.

A series of physiological and genetic studies were done to compare the original recombinant and the evolved strain. Two molecular events that targeted the *LAC* construct in the evolved strain were identified: (1) a 1593 bp deletion in the intergenic region (promoter) between *LAC4* and *LAC12*, and (2) a decrease of the plasmid copy number by about 10-fold compared to the original recombinant. The construction of T1 involved the transfer of a 13 kb *K. lactis* genomic sequence that included the genes *LAC4* and *LAC12* as well as their intergenic region (LACIR) (Domingues et al., 1999b). LACIR is an unusually large intergenic region that works as a promoter for the divergent transcription of both the *LAC* genes. This region contains four functional upstream activating sites (UASs) that synergistically contribute to the activation of both genes by providing binding sites for the transcriptional activator Lac9p, homologous to Gal4p of *S. cerevisiae* (Gödecke et al., 1991). Our results suggest that the intact promoter (endogenous *K. lactis* promoter) was unable to mediate induction by

lactose of the transcription of *LAC4* and *LAC12* in the original recombinant T1, whereas the deletion identified established transcriptional induction of both genes in the evolved recombinant T1-E. We proposed that tuning of the expression of the heterologous *LAC* genes in the evolved recombinant was accomplished by interplay between the decreased copy number of both genes and different levels of transcriptional induction for *LAC4* and *LAC12*, resulting from the changed promoter structure (Guimarães et al., 2008a).

Fermentation of high concentrations of lactose by the evolved recombinant strain

The performance of the evolved recombinant strain (T1-E) was studied in batch fermentations with high concentrations of lactose (up to 200 $g \cdot L^{-1}$). Since aeration has been reported to improve the performance of yeast in fermentations producing very high concentrations of ethanol (see e.g. Alfenore et al., 2004) we have tested T1-E in micro-aerated (shake-flasks) and in well-aerated (bubble column bioreactor) fermentations.

The fermentations were performed in defined mineral medium. Shake-flask fermentations were done in Erlenmeyer flasks filled with medium to 40% of the total volume and incubated at 30 ºC and 150 rpm. The initial pH was adjusted to 5.5 and 100 mM potassium hydrogen phthalate was added to the medium to avoid major drops in pH during cultivation. The bioreactor fermentations were done in a 600 mL bubble column (made in-house) filled with 440 mL of medium. The temperature was maintained at 30 ºC and the pH at 4.0. An air flow rate of 1 vvm was applied using a sintered porous plate located at the bottom of the column and a magnetic stirrer was used to aid in keeping the entire volume well-mixed (for details about the fermentations see Guimarães et al., 2008b).

The evolved recombinant strain consumed rapidly and completely 150 $g \cdot L^{-1}$ lactose in either well-aerated or micro-aerated batch fermentations, producing 5.5% (v/v) and 8.0% (v/v) of ethanol, respectively (Table 2). However, the yeast was unable to consume completely 200 $g \cdot L^{-1}$ lactose in the micro-aerated shake-flask fermentations, but, conversely, consumed totally the same concentration of lactose in well-aerated bioreactor fermentations, although taking a considerable time (about 60 h) to complete fermentation. This may be related with the yeast's inability to synthesize proper amounts of sterols and unsaturated fatty acids under the oxygen limiting conditions found in the shake-flask fermentations. It is well established that yeast needs oxygen in order to synthesise unsaturated fatty acids and sterols (see e.g. Guimarães et al., 2006), and lower amounts of these lipids in the plasma membrane have been correlated with lower ethanol tolerance (see Aguilera et al., 2006 and references therein).

Table 2 – Fermentation of high concentrations of lactose by T1-E in micro-aerated (shake-flasks) and in aerated (bubble column bioreactor) cultivations

Micro-aerated				Aerated			
Initial lactose ($g \cdot L^{-1}$)	Ethanol produced (% v/v)	Ethanol productivity ($g \cdot L^{-1} \cdot h^{-1}$)	Residual lactose ($g \cdot L^{-1}$)	Initial lactose ($g \cdot L^{-1}$)	Ethanol produced (% v/v)	Ethanol productivity ($g \cdot L^{-1} \cdot h^{-1}$)	Residual lactose ($g \cdot L^{-1}$)
114	6.1	2.0	< 1.5	100	4.1	1.2	< 1.5
150	8.0	1.5	< 1.5	150	5.5	1.6	< 1.5
200	8.4	1.4	50	200	7.2	0.95	< 1.5

The ethanol yields were much higher in the shake-flask fermentations (about 80% of the theoretical) than in the bioreactor fermentations (< 60%). This probably resulted from lower oxygen availability for yeast in the shake-flasks (conditions of micro-aeration), leading to

higher sugar flux towards fermentative metabolism. Therefore, under our conditions high aeration was not beneficial to the ethanol production performance of the yeast.

In the design of processes for ethanol production from cheese whey or whey permeate a compromise must be made between maximisation of ethanol titre and productivity and minimisation of the residual lactose concentration at the end of fermentation, since one of the major motivations for whey utilization is to reduce its polluting load. The results suggest that an initial lactose concentration of 150 $g \cdot L^{-1}$ represents the best compromise to obtain high ethanol titre (8% v/v) and productivity (1.5 $g \cdot L^{-1} \cdot h^{-1}$) at the end of fermentation (i.e. with a lactose residual < 1.5 $g \cdot L^{-1}$).

The ethanol productivity obtained in this work was higher than that reported for batch or fed-batch fermentations with other lactose-consuming recombinant *S. cerevisiae* strains: 0.3 $g \cdot L^{-1} \cdot h^{-1}$ (Rubio-Texeira et al., 1998); 0.14 to 0.6 $g \cdot L^{-1} \cdot h^{-1}$ (Ramakrishnan and Hartley, 1993); 1 $g \cdot L^{-1} \cdot h^{-1}$ (Compagno et al., 1995); 1.3 $g \cdot L^{-1} \cdot h^{-1}$ (Farahnak et al., 1986). The utilization of high initial lactose concentrations enabled also to attain higher ethanol titres than previously obtained with recombinant *S. cerevisiae*, with the exception of the work of (Farahnak et al., 1986) that reported an ethanol titre of 13% (v/v). The strain used here was also able to ferment concentrated cheese whey powder solution containing about 150 $g \cdot L^{-1}$ lactose in a batch fermentation with low (0.1 vvm) aeration, consuming nearly all lactose (residual lactose < 3 $g \cdot L^{-1}$) in about 120 h and producing 7% (v/v) ethanol, which corresponds to an ethanol productivity of 0.46 $g \cdot L^{-1} \cdot h^{-1}$ (Guimarães et al., 2008a). The performance of the yeast may be improved by supplementation of the cheese whey with cheap nutrient sources (e.g. corn steep liquor). To our knowledge, the recombinant strain used in this work is the most efficient lactose-fermenting *S. cerevisiae* strain reported in the literature. An additional important advantage of this strain is its highly flocculent phenotype, which makes it particularly suitable for the development of high cell density fermentation processes that, when operated in continuous with flocculated biomass retention, may allow to attain very high ethanol productivities (Domingues et al., 2000).

Studies of fed-batch operation mode on synthesis of short chain ethyl esters catalyzed by cutinase

Dragana P. C. de Barros, Susana M. S. A. Bernardino, Pedro Fernandes, Joaquim M. S. Cabral, Luís P. Fonseca,

IBB – Institute for Biotechnology and Bioengineering, Centre for Biological and Chemical Engineering, Instituto Superior Técnico, Av. Rovisco Pais, 1049-001 Lisboa, Portugal.

Abstract:

The goals of these studies are to determine and optimize the conditions of the synthesis of chain ethyl esters, a group of important fruit flavor compounds, by cutinase in organic media, in particular, isooctane an organic solvent recognized as safety ingredient in food and beverage industrial processes.

The possibility and success to operate in fed-batch operation mode and to determine how much substrate and concentration would be possible to add in consecutive pulse of substrate supply and how these variables affect the enzyme activity and stability were evaluated.

In order to avoid substrate inhibition and to improve the esterification yield a discontinuous feed pulse of substrates strategy (pulse fed-batch mode of substrates supply) was tested which allows achieve concentration of ethyl caproate, important flavor compound of apple and pineapple aromas, of 1.5M in isooctane media. By monitoring the concentration of the substrates this type of cutinase, biosynthesized with a *S. cerevisiae* strain, shows excellent properties on synthesis of short alkyl esters and special achieving very high ester concentration.

Keywords: Cutinase, ethyl caproate, enzymatic processes, fed-batch operation mode, short chain alkyl esters

Topic: Integration of life sciences & engineering.

1. Introduction

Short chain ethyl esters belong to a huge group of flavor compounds that are very important components of natural aromas for the most part used in various food, beverage, cosmetic and pharmaceutical industries. Flavor esters are usually produced by chemical synthesis of an alcohol with an organic acid in the presence of an acid catalyst or by extraction from natural sources. The chemical synthesis of these flavor esters has low-priced but, they are characterized by low purity and not classified like as natural products. Natural aromas obtained by the extraction are very expensive owing to low concentration in the natural product and low extraction yield (Hari-Krishna S. et al., 2002, Berger R.G, 1995).

Biotechnology processes based on enzyme synthesis, as alternative catalysts to chemical route, produce also those esters and other similar flavors. These enzymatic processes have technological and economical interesting characteristics as use mild reaction condition, synthesize flavors with high quality and purity due to the regio- and stereo-specificity of enzymes. The high purity of these flavors allows to be classified as *natural* by food regulatory agencies and better public acceptance as ingredients for food industry in relation to those synthesized by chemical processes (Welsh et al., 1990).

Cutinase are a group of enzymes that can be considered as a link between esterase and lipase. In recent years, the esterolytic activity of cutinase has been largely exploited and several applications in different industrial field have been presented. In the reaction of esterification cutinase showed selectivity for short-chain carboxylic acid esters (Carvalho et al., 1999).

2. Materials and methods

2.1. Materials and chemicals

The acetic, valeric, caproic and octanoic acids (Sigma-Aldrich, Germany), and ethanol 96% (AGA, Portugal) previously dried with were used for ester synthesis while *iso*-octane (Sigma-Aldrich, Germany) used as as organic solvent and n-decane as internal standard of Gas Chromatography (GC) (Merck, Germany). Anhydrous sodium sulfate, powder (Sigma-Aldrich, Germany) used to dry sample media after reaction of esterification and before GC analysis. All other chemicals used were analytical grade.

2.2. Production of cutinase

The *F. solani pisi* cutinase wild-type was biosynthesized by recombinant *S. cerevisiae* SU50 strain as described by Calado *et al*., 2003.. The cutinase producing *S. cerevisiae* SU50 strain (Mata, leu2-3, ura3, gall:URA3, ML-S, MAL3, SUC3) contains the expression vector pUR7320 constructed and provided by the Unilever Research Laboratory, Vlaardingen, the Netherlands. The strain was stored at -80°C in frozen tubes containing selective medium and 50% (v/v) glycerol (Merck, Dannstadt, Germany).

2.3 Purification of cutinase and production of lyophilized enzyme preparation

The isolation and purification of cutinase excreted by recombinant *S. cerevisiae* SU50 strain was carried out by expanded bed adsorption (EBA). Frontal adsorption experiments were carried out in a EBA column Streamline 25 with a settled bed adsorbent height of 15 cm and the column top adjusted to 45 cm. The cation adsorbent Streamline SP XL from Amersham Pharmacia Biotech, Sweden was used to isolate the cutinase directly from the fermentation broth. The cutinase activity and protein concentration of the collected effluent fractions from the column were determined after each run Calado *et al*., 2002. The pool of elution fractions exhibiting highest cutinase activity were previously dialyzed against 20mM phosphate buffer pH 7.0 and then frozen at -80°C and lyophilized (B. Braun Biotech. International CHRIST Alpha 2-4) overnight. Lyophilized pure cutinase was stored at freeze at -20°C before used in esterification reactions.

2.4 Characterization of the cutinase preparations

The cutinase esterolytic activity and protein content were assayed and lyophilized cutinase preparations characterized. The protein concentration was determined by the method of PEARCE (BCA assay). Protein concentrations were determined with reference to a protein standard, the Bovine Serum Albumin (BSA) (Merck).

The cutinase estereolytic activity was assayed using a spectrophotometric method, based on monitoring the hydrolysis of p-nitrophenylbutyrate (p-NPB) to nitrophenol (p-NP), a yellow compound easily identify and quantify by the absorbance at 400 nm Calado *et al*., 2002.

One unit of cutinase estereolytic activity was defined as the amount of enzyme required to convert 1μmol of p-NPB to p-NP per 1 min, under specific condition. The extinction coefficient of p-NP was considered to be 1.84×10^4 (M^{-1} cm^{-1}), as indicated by the supplier (Sigma).Specific activity of lyophilized cutinase preparations was of 170 U/mg protein and

these enzyme samples when loaded in an electrophoresis gel which shows basically only one band of 22kDa, i.e., pure cutinase Sambrook et al.,1989.

2.5 Methods for monitoring substrate and ester concentrations

The concentration of ethanol, carboxilic acids (acetic acid, valeric acid, caproic acid) and ethyl esters (ethyl acetate, ethyl valerate, ethyl caproate) was determined by a Hewllet-Packard model 5890 gas chromatography (GC) equipped with a flame ionization detector (FID). The WCOT Fused Silica coating CP Chirasil- Dex CB column, 25m x 0.25mm, DF=0.25 (Varian Inc.) was used. N-decane was used as the internal standard and to calculate ethyl esters and respective substrates concentrations in the reaction media based on the results of GC analysis according the following specific conditions applied for each particular ethyl ester and respective substrates:

Ethyl acetate: oven temperature was held at 50ºC for 4 min before being elevated to 140ºC for 3 min at 30ºC/min; injector temperature was set at 200 ºC; detector temperature was set at 250 ºC; carrier gas was nitrogen**.**

Ethyl valerate: oven temperature was held at 50ºC for 4 min before being elevated to 170ºC for 2 min at 30ºC/min; injector temperature was set at 200 ºC and detector temperature is set at 250 ºC; carrier gas was nitrogen**.**

Ethyl caproate: oven temperature was held at 50ºC for 4 min before being elevated to 160ºC for 1.67 min at 15ºC/min; injector temperature was set at 200 ºC; detector temperature was set at 250 ºC; carrier gas was nitrogen**.**

2.6 Esterification catalyzed by lyophilized cutinase

Esterification reaction of acid and alcohol by cutinase was carried out in isooctane as organic solvent. Unless otherwise stated a typical esterification reaction for ethyl esters synthesis was carried out in 7 ml of working volume inside of 10 ml capped flasks with rubber (EPDM stoppers, black, Sigma-Aldrich, Germany), used as appropriate reactors that minimizes evaporation or loss of volatile compounds. Alcohol, acid and n-decane were mixed thoroughly in isooctane which consists the reaction medium before the addition of enzyme (lyophilized form) with the objective to minimize enzyme inhibition by the substrates [Claon, P. A. et al., 1993]. First sample (zero point of the reaction) was withdrawn before enzyme addition. The enzymatic ester synthesis occurred in an incubator at 30ºC with multi magnetic stirrer(S.B.S. Instruments A-23). This device enables operation of multiple parallel experiments by simultaneous use of 6 to 12 reactors, as well as, using at least a blank (without enzyme) running in parallel for each ester synthesis reaction. During the reaction a magnetic stirring set at 300 rpm was performed. Samples were withdrawn periodically using a needle without to destroy the rubber cap and then dried before ester and substrates analyzed by GC. The esterfication conversion or reaction yield was calculated according the molar ratio between ethyl ester and respective limiting substrate, alcohol or acid.

The esterification reaction was performed in two different reaction operation modes: batch and discontinuous feed pulse of substrates (fed-batch). In the fed-batch operation mode, the composition of the substrates in the reaction media was assessed first and only then the feed of new substrates was performed in accordance with their observed consumptions

3. Results and discussion

Due to enzyme inhibition for high concentrations of fatty acids and ethyl alcohol and in order to attain high ethyl ester concentration in reaction media was tested a strategy of fed-batch operation mode of stepwise substrates addition because high ester concentrations has significant impact on production cost of any ester. The possibility and success to operate in fed-batch operation mode and to determine how much substrate and concentration would be

possible to add in consecutive pulse of substrate supply and how these variables affect the enzyme activity and stability were evaluated.

Studies of fed-batch operation mode on synthesis of ethyl caproate was initially performed using lower initial concentration of caproic acid (0.05 M) and keeping always the alcohol/acid molar ratio of 2 (Fig. 1). First addition on second day was done with ethyl caproate concentration of 0.054 M. Within the next 9 days of reaction, stepwise substrates additions with R = 2 were carried out for more 5 times. After 11 days, the conversion achieved was of 94 % in relation to caproic acid (limiting substrate) with the final ester concentration of 0.15M (Fig. 1). These results suggest that consecutive substrates supply during the production of caproate ethyl ester by cutinase could be possible to perform without significant effect on enzyme activity after 11 days.

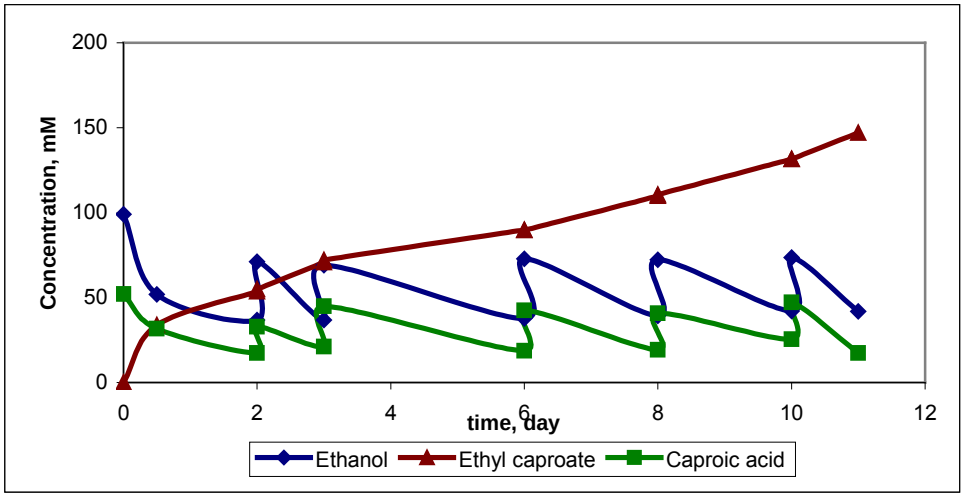

Fig. 1: The effect of the fed-batch operation mode by 5 stepwise additions on synthesis of ethyl caproate by cutinase. (Reaction conditions: Initial concentrations [ethanol] = 0.1M; [caproic acid] = 0.05M; t=30°C; 300 rpm; 2.1 mg/ml enzyme; cutinase specific activity 170 U/mg).

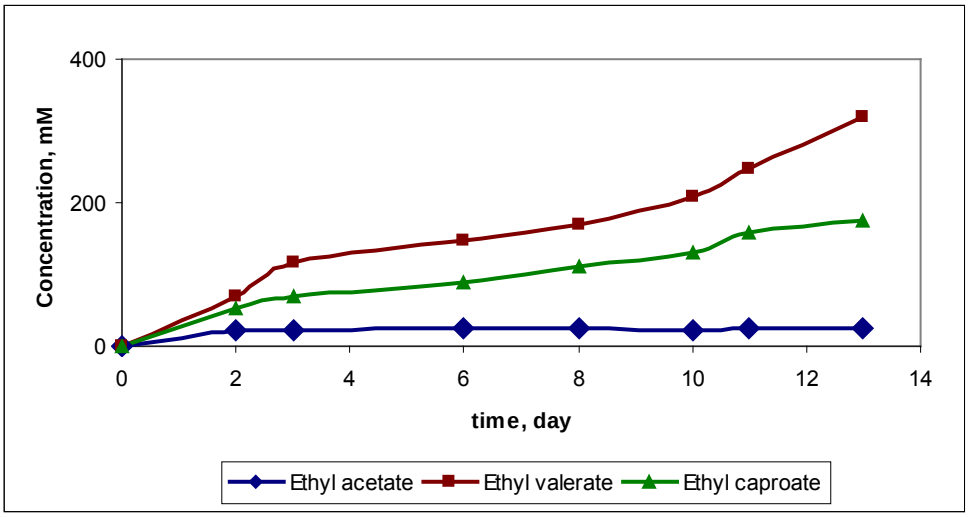

Fig. 2: Effect of acid chain length on synthesis of ethyl esters by cutinase using the fed-batch operation mode (7 stepwise substrates additions). (Reaction condition: [ethanol]=0.1M; 300 rpm, t=30^{0}C, 2.1mg/ml of enzyme, cutinase specific activity 170U/mg).

The same strategy was implemented and evaluated during 13 days for synthesis of acetate, valerate and caproate ethyl esters. Similar profiles of accumulation of ethyl valerate in relation to ethyl caproate was obtained but this strategy was not enough efficient for ethyl acetate. After the initial conversation and seven consecutive stepwise substrates additions

into the reaction medium have not produced more ethyl acetate as apparently the cutinase was deactivated especially due to low pH in the microenvironment surrounding enzyme preparation (Fig. 2)

3.1. Cutinase operational stability evaluated by long esterification reaction

The cutinase catalyzed synthesis of ethyl caproate was observed to evaluate the potential of fed batch reaction operation mode and stability of the lyophilized cutinase in the reaction media under agitation and in equilibrium with respective substrates and different concentrations of product.

a) b)

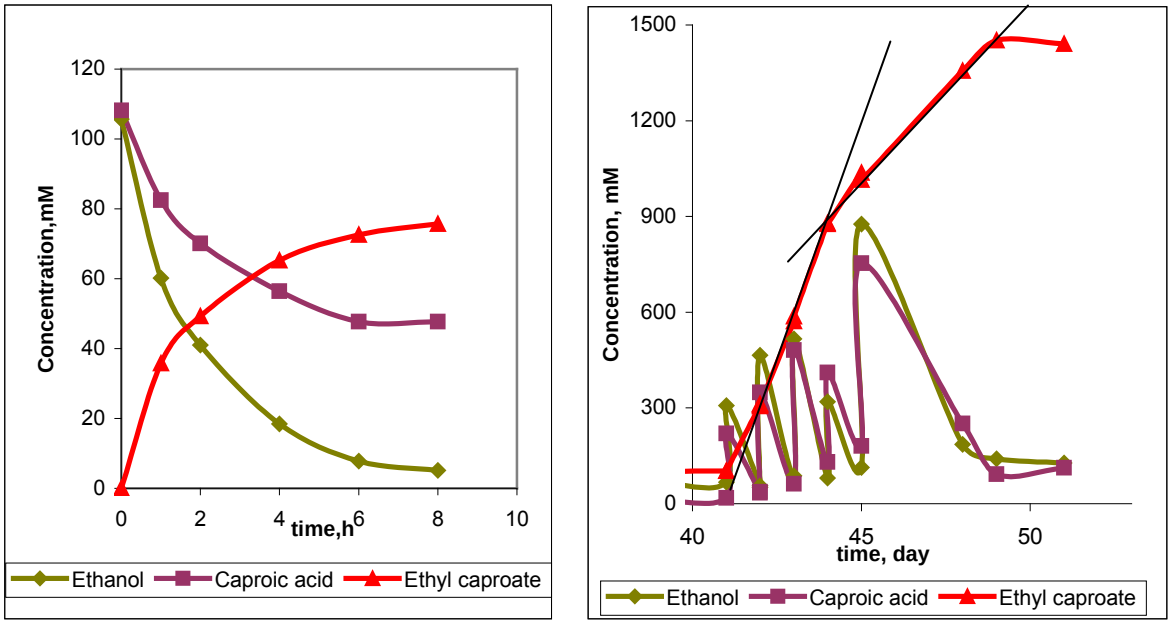

Fig. 3.a),b). Evolution of ester concentration in isooctane media obtained by discontinuous pulse of substrates (fed-batch mode). (Reaction conditions; equimolar alcohol/acid concentrations R=1; t=30°C; 300 rpm; 2.1 mg/ml enzyme; cutinase specific activity 170 U/mg).

The reaction start with equimolar concentration of substrates (0.1M) in batch mode, and after achieving an equilibrium 75.6M concentration of ester (7h) (Fig. 3a), the reaction was left to run 40 days. Between day 41 and 45 days, 5 new stepwise substrates were added (discontinuous feed pulse of substrates).

Monitoring the addition of the substrates was observed. At first 4 addition concentration of substrates was controlled between 0.2M-0.3M and at day 45 was added almost double concentration of substrates. It was noticed that the velocity of production of ester decrease 2.3 times (Fig. 3b), due to the inhibitory effect of substrates. However the yield of ester increase until total consumption of the substrates reaching equilibrium.

These results suggest a enzyme inhibition or deactivation occure with concentration of substrates higher than 0.3M, while the conversion to ethyl caproate was continuously increasing in the reaction medium with lower substrate concentrations.

With fed-batch reaction operation mode at day 45 was observed almost total consumption of substrates and ester concentration increased until about 1.5 M inside of the reaction medium if the substrates concentration was always controlled (Fig. 3b). A similar strategy was also used by Deng at al., 2003 and a good ester yield was also obtained 80.5% with *Candida sp.* 99-125 non-immobilized. By monitoring the concentration of the substrates, an optimal amount can be added in each supply that will not lead to the inhibition or deactivation of the enzyme but at end allows to achieve one of the highest concentration of ethyl caproate. As it was not observed significant accumulation of substrates in the reaction media and for this

reason is possible to think that higher ethyl caproate concentration could be achieved continuing the fed-batch process.

4. Conclusion

Feasibility of using consecutive feeding pulse of the substrates during the production of ethyl esters could be a very productive way to achieve great amount of the product and, at the same time, avoid the substrate inhibition. The feeding should be performed into reaction media to attain substrate concentrations lower than 0.3M and with this strategy minimizes inhibition of enzyme by the substrates.
Furthermore, the lyophilized cutinase showed to be active for long time (more than 50 days) in the reaction media without significant effect of isooctane on its stability. The fed-batch operation mode can be a very rational way to enhance the amount of the ester synthesized and, at the same time, avoid the substrate inhibition and enzyme desactivation since the substrate was added in accordance with its depletion from the reaction mixture.

Keywords: Glycerol; 1,3-propanediol; enzyme activities; immobilization
Topic: Integration of life sciences & engineering

Abstract

As glycerol is a nontoxic, edible, biodegradable compound, it will provide important environmental benefits to the new platform products. Glycerol can be utilized in various ways of biological transformation to industrially valuable products (Werpy and Petersen, 2004). There are some important derivatives among these such as 3-hydroxypropionaldehyde ((3-HPA) commercial name: reuterin), dihydroxyacetone (DHA), and 1,3-propanediol (PD). 1,3-PD has the largest potential (100.000 t/yr capacity). Several bacteria are able to ferment glycerol to 1,3-PD under anaerobic conditions. A new recombinant technology was worked out with the leadership of DuPont and Genecor in the last decade, in which a recombinant *Escherichia coli* converts glucose directly to 1,3-PD (DuPont Tate & Lyle Bio Products, 2007). Microbiological production of a molecule has always lower yield than an enzymatic method and usually produces a lot of byproducts, which also can be avoided using enzymatic bioconversion. For years we have been working on a new enzymatic process in order to produce 1,3-PD and DHA simultaneously from glycerol. For this enzymatic way three key enzymes are needed (Papanikolaou et. al, 2000). These enzymes must be produced by microbial fermentation. We would like to present the results of developing the fermentation media.

1 Introduction

Although glycerol has been a well-known renewable chemical for centuries, its commercial relevance has increased considerably in the last few years because of its rising formation as an inevitable by-product of biodiesel production. Glycerol can be utilized in various ways of biological transformation to industrially valuable products such as 3-hydroxypropionaldehyde ((3-HPA) commercial name: reuterin), dihydroxyacetone (DHA), and 1,3-propanediol (PD).
1,3-propanediol is mainly used as a starting material polymers, an important diol in the production of polyesters, polycarbonates and polyurethanes. Two examples of large scale applications of 1,3-propanediol are SORONA made by DuPont via biological way and CORTERRA, trade mark of Shell produced via chemical synthesis. Although the fermentative PD production of DuPont is much more environmental friendly then the chemical way, an enzymatic process would be more advantageous. It would not have an upper limit of product yield (decreased also with biomass formation), and would not produce any unwanted metabolites.
For enzyme source several bacteria can be used, which are able to ferment glycerol to PD under anaerobic conditions (Biebl et al. 1999).
We have been working for several years on a process, where glycerol can be converted into 1,3-PD and DHA simultaneously by the fermented enzymes of *Klebsiella pneumoniae* and *Clostridium butyricum*. The process for this method was patented (*P 05 00961*, 2005).
For the enzymatic production of 1,3-PD from glycerol, two key enzymes are responsible: Glycerol-dehydratase (GDHt, E.C.4.2.1.30) and a $NADH_2$-dependent 1,3-propanediol-oxydoreductase (PDOR, E.C.1.1.1.202). In our process the NAD^+ produced by PDOR can be

regenerated by a series of oxydoreductases (alcohol-dehydrogenase, formate dehydrogenase etc.), but we usually use glycerol-dehydrogenase (GDH, E.C. 1.1.1.6) which produces DHA.
It is known that enzyme inactivation can be reduced and its economic value is increased by immobilization. To carry out enzymatic bioconversions, we already used successfully a membrane reactor system retaining the enzymes. With the crude key enzymes of *K. pneumoniae*, we made several successful glycerol transformation to PD and set up a complex mathematical model to describe the whole process (Németh, Á., Sevella, B. 2008). Unfortunatelly acetic acid was always produced as an unfavored byproduct. This byproduct formation cannot be eliminated any way because it serves also the ATP, which is essential for the regeneration of the suicide inactivated key enzyme (B_{12}-dependent GDHt). To overcome this problem we choosed an other enzyme source namely *Clostridium butyricum* VPI 1718 because its GDHt is B_{12}-independent, thus it does not go under suicide inactivation (Raynaud et al., 2004). Crude enzyme solution of *C. butyricum* was obtained by ultrasonic desintegration of cells and were already tested in glycerol to PD bioconversion (Németh, Á. 2008).
Clostridium butyricum is to our knowledge the best natural 1,3-producer from glycerol (Saint-Amans et al., 1994) and the only microorganism identified so far to use a coenzyme B_{12}-independent glycerol dehydratase. Our pleriminary results indicated that the 2xYT medium described by Reynauld et al 2003 is perfect for our Clostridium strain. However in economic aspect the concentrations of yeast extract and bactotryptone are too high to scale-up this fermentation procedure. The first purpose of this study was to optimize the fermentation media.
The other aim of our research was to compare further immobilization technics with the membrane reactor experiments. We tried a covalent method applying chitosan matrix activated with glutaraldehyde. Chitosan – a natural polyaminosaccharide obtained from chitin – was chosen as support material to bind the three key enzymes from the crude enzyme solution.

2 Materials and Methods

Organism and medium

Clostridium butyricum NCIMB 8082 (the same as VPI 1718) was used as enzyme source. The strain were stored at 4°C on Petri dish on modified Reinfored Clostridial Medium (Difco, agar: 12,5 g). Batch cultures of *C. butyricum* were grown anaerobically at 37°C in 2xYT medium (yeast extract, 10 $g \cdot l^{-1}$; bactotryptone, 16 $g \cdot l^{-1}$; NaCl, 5 $g \cdot l^{-1}$), supplemented with 20 $g \cdot l^{-1}$ glycerol or glucose as carbon source (Reynaud et al., 2003). However, as described under "Results", the concentrations of yeast extract, bactotryptone, glycerol and glucose were varied.

Analytical methods

The cell concentations were estimated as cell dry weight using a predetermined correlation factor (K: 1,496 $g \cdot l^{-1}$) between optical density at 600 nm (Pharmacia LKB-Ultrospec Plus spectrophotometer, Pharmacia Co., USA) and cell dry weight.
Substrates and products concentrations were determined by Waters Breeze HPLC System (Waters 1515 Isocratic HPLC Pump, Waters 717 Plus Autosampler, Bio-Rad Aminex HPX 87H chromatography column, Waters 2414 Refractive Index Detector) using the following method: flow rate, 0,5 ml $\cdot$ min^{-1}; mobil phase, 0.01 N H_2SO_4 ; column temperature, 65°C; detector temperature 40°C; sample analyzing time, 30min.

Fermentation experiments

Batch cultivations are shown in Table 1.

Table 1

Number	Type	Anaerobic condition	Medium	Volume	pH regulation	Comment
1	TT	ANAEROSTAT	2xYT substrate: 30g/l Glu or Gly	10 ml	K-phosphates or CaCO3	inoculation: 50 ml cell suspension
2	SF	ANAEROSTAT	2xYT substrate: 30g/l Glu or Gly	50 ml	K-phosphates or CaCO4	inoculation: 1 fringe / flask
3	BQ (1-l)	N_2 gas (periodic)	1. stage: 2xYT; substrate: 20g/l Glu 2.stage: 20 g/l Gly, 10 g/l YE (final concentration) *	0,8 l	20% NH4OH and 25% H2SO4 (by automatic addition)	inoculation (10%): medium: 2xYT contained 20 g/l Glu
4	BQ (1-l)	N_2 gas (periodic)	2xYT substrate: 20g/l Gly	0,8 l	20% NH4OH and 25% H2SO4 (by automatic addition)	inoculation (10%): medium: 2xYT contained 20 g/l Gly
5	BM (2-l)	N_2 gas (periodic)	1. stage: YE: 6 g/l, BT: 4 g/l, NaCl: 5 g/l; substrate: 20g/l Glu 2.stage: 20 g/l GLY, 6 g/l YE (final concentration) *	1,5 l	20% NH4OH and 25% H2SO4 (by automatic addition)	inoculation (10%): medium: 2xYT contained 20 g/l Glu

*After glucose was tottally consumpted in the 1.stage, 20% of the broth was changed with fresh media
TT: test tube (shaked); SF: shaking flask; BQ (1-l): 1-l Bioreactor (B. Braun Biostat® Q DCU); BM (2-l): 2-l Bioreactor (B. Braun Biostat® M); Glu: glucose; Gly: glycerol; YE: yeast extract; BT: bactotryptone

Sampling (in the cases of test tubes) were realized from different parallel test tubes at the corresponding timepoint, because the need of anaerobic cultivation performed in a closed ANAEROSTAT system (Merck).
The growth temperature was 37°C, the agitation speed was 200 rpm.

Preparation of cell-free extracts
Fermentation broth's (number 3-5) were centrifuged at 6000 rpm for 40 min. For resuspending the harvested cells, HEPES buffer pH=7.4 containing 50 mM N-(2-Hydroxyethyl)-piperazine-N′-(2-ethanesulfonic acid) and 0.1 mM MnCl2, and 2 mM dithiothreitol was used. This centrifugation/resuspendation cycle was repeated twice.
Cells were disrupted by ultrasonic desintegration (Labsonic-P, 300W; Sartorius) using the following method: volume, 10 ml; time, 15 min at 0,5 s intervals; efficiency, 60%. Cell debris was separated by centrifugation (10 min at 13000 rpm). The enzyme activity of supernatant was determined.

Enzyme assays

1,3-propanediol-oxydoreductase (PDOR), glycerol-dehydratase (GDH) and glycerol-dehydratase (GDHt) activity was determined photometrically using the method described previously (Németh, Á., Sevella, B. 2008; Németh, Á., Kupcsulik, B., Sevella, B. 2003).

3 Results

Fermentation process development

To reach an economically feasible technology we tried to reduce the costly media components significantly (1. and 2. experiments results shown in Table 3).

Beside the maximum level of bactotryptone (BT;16 $g \cdot l^{-1}$) and two types of substrates we analyzed the effect of yeast extract (YE) concentraion (Figure 1.a). Biomass production decreased significantly below 6 $g \cdot l^{-1}$ YE. While BT concentration was reduced to 4 $g \cdot l^{-1}$ at constant YE (10 $g \cdot l^{-1}$), the biomass was not fallen remarkably (Figure 1.b).

The 0,72 mol/mol theoretical yield for PD limits the development of an economical fermentation process (Zeng et al., 1996). In the biological production of PD, a series of by-products (acetic acid, butyric acid, lactic acid etc.) decrease the yield of 1,3-PD.

Biebl et al. described the yield (mol/mol glycerol) of PD beside single byproducts such as acetic acid, butyric acid and lactic acid (0.72; 0.59; 0.66 mol/mol respectively). In our experiments the yield of PD did not decrease while BT concentration reduced to 2 $g \cdot l^{-1}$ at constant 10 $g \cdot l^{-}1$ YE (pH regulation with K-phosphates) but fall down beside constant 6 $g \cdot l^{-1}$ YE. However, BT concentration had no effect on PD yield beside pH regulation with $CaCO_3$ (at 6 $g \cdot l^{-}1$ level of YE) and the obtained PD yield approached the theoretical maximum described above.

*[2] near to the determination lower limit

For enzyme (PDOR, GDH) production we drove several fermentations in lab scale bioreactor (experiments 3-5). If glucose and glycerol were used consecutively as carbon sources (beside of maximum level of YE and BT) the obtained PDOR/GDH ratio was around 1, while in the case of glycerol as sole carbon source the PDOR/GDH ratio was 10 (Table 3). Applying the media with decreased YE and BT content (6 and 4 $g \cdot l^{-1}$ respectively) together with glucose and glycerol as consecutive carbon sources the enzyme activities were hardly measurable and their ratio was around 1 again. These results can be very interesting if we are going to apply the most appropriate enzyme ratio in the enzymatic bioconversion.

Topic: Integration of Life Sciences and Engineering.

Abstract

Arthrobacter viscosus biomass was used for Cr(VI) biosorption. The effect of biomass concentration on Cr(VI) reduction and removal from aqueous solution was studied in the range of 1.2 to 5.3 g/L. The removal of Cr(VI) and total chromium increased linearly with the increase of biomass concentration. The best removal efficiencies of Cr(VI) and total chromium were reached for the highest biomass concentration, 72.2 % and 44.0 %, respectively. The increase in biomass concentration did not produce significant changes in the uptake values. The maximum uptake value, 8.2 $mg_{Cr}/g_{biomass}$, was obtained for a biomass concentration of 2.3 g/L.

1 Introduction

Heavy metals derived from the release of industrial wastewater present an ongoing and serious hazard to human health and to the environment, because these elements are toxic, not biodegradable and can accumulate in food chain and living tissues (Gavrilescu, 2004; Deng et al., 2006).

Chromium is a common and very toxic pollutant introduced into natural waters from a variety of industrial wastewaters. The major sources of contamination are electroplating, metal finishing industries and tanneries (Agarwal et al., 2006). Among the several oxidation states of chromium, the main forms present in the environment are trivalent and hexavalent, Cr(III) and Cr(VI), respectively. These two oxidation states have widely contrasting toxicity and transport characteristics. Hexavalent chromium poses a greater risk due to its carcinogenic properties to living organisms, while Cr(III) is generally only toxic to plants at very high concentrations and is less toxic or non-toxic to animals (Dakiky et al., 2002; Anderson, 1997). Depending on the solution pH values, Cr(VI) species may be in the form of dichromate ($Cr_2O_7^{2-}$), hydrochromate ($HCrO_4^-$), or chromate (CrO_4^{2-}) and Cr(III) species may take the form of hydrated trivalent chromium, $Cr(H_2O)_6^{3+}$, and chromium hydroxide complexes, $Cr(OH)(H_2O)_5^{2+}$ or $Cr(OH)_2(H_2O)_4^+$. Due to the repulsive electrostatic interactions, Cr(VI) anion species are generally poorly adsorbed by the negatively charged soil particles and can move freely in the aqueous environments. In contrast, Cr(III) species normally carry positive electric charges and therefore can be easily adsorbed on the negatively charged soil particles (Silva et al., 2008 a; Deng et al., 2004).

The conventional methods used for heavy metals removal are generally expensive and potentially hazardous due to the generation of harmful by-products. Common methods include chemical precipitation, chemical oxidation or reduction, ion exchange, membrane filtration and carbon adsorption (Bailey et al., 1999). These technologies have significant disadvantages, such as incomplete metal removal and generation of huge volumes of toxic sludge, and are often inefficient and/or expensive mainly when applied to diluted solutions up to 100 mg/L (Sağ et al., 1995; Cossich et al., 2004).

As an alternative to traditional physicochemical treatments, a number of biological assays using microbial biomass have been studied and developed to treat chromium-contaminated waste streams and natural waters. Certain types of microbial biomass can retain relatively high quantities of metals by means of passive processes known as biosorption, which is dependent on the affinity between the metallic species and the binding sites on the cell wall (Raras, 1995). Biosorption is a metabolism-independent process and thus can be performed by both living and dead microorganisms. This adsorption is based on mechanisms such as complexation, ion exchange, coordination, adsorption, chelation and microprecipitation (Hu et al., 1996). The accumulation of metals by biological materials is a promising process that can reduce capital costs by 20%, operational costs by 36% and total treatment costs by 28%, compared with conventional systems (Loukidou et al., 2004).

The use of bacteria for biosorption is a fast growing field in metal remediation because of their ubiquity, ability to grow under controlled conditions and small size (Mohan et al., 2006). Many studies have demonstrated that various types of biomaterials such as bacteria are capable of transforming hexavalent chromium, Cr(VI), into the much less toxic and less mobile trivalent form, Cr(III). When Cr(VI) comes in contact with biomaterials, especially in an acidic solution, the Cr(VI) can easily or spontaneously be reduced to the Cr(III), because Cr(VI) has high *redox* potential value (above +1.3 V at standard conditions) (Park et al., 2004, 2005, 2007, 2008). *Arthrobacter* species are of particular interest because of its high potential for bioremediation (Asatiani et al., 2004). The bacteria used in this work, *Arthrobacter viscosus*, is a good exopolysaccharide producer, an aspect which would permit prediction of good metal ion entrapment (Figueiredo et al., 2008; Silva et al., 2008 b).

The purpose of the present work was to assess the potential of *A. viscosus* for the biosorption of hexavalent chromium and to study the effect of biomass concentration on its removal performance.

2 Experimental

2.1 Materials and reagents

Arthrobacter viscosus was obtained from the Spanish Type Culture Collection of the University of Valencia. Aqueous potassium dichromate solution was prepared by diluting $K_2Cr_2O_7$ (Panreac) in deionised water.

All glassware used for experimental purposes was washed in 10% nitric acid to remove any possible interference by other metals.

2.2 Preparation of the biomass

A medium with 10 g/L of glucose, 5 g/L of peptone, 3 g/L of malt extract and 3 g/L of yeast extract was used for the microorganism growth. The medium was sterilized at 121 ºC for 20 min, cooled to room temperature, inoculated with bacteria and kept at 28 ºC for 24 h with moderate stirring in an incubator. The cells were then harvested by centrifugation at 7000 rpm for 15 min and re-suspended in residual culture medium to obtain suspensions with different biomass concentrations to be used in the biosorption assays.

2.3 Biosorption assays

Batch experiments were conducted in 250 mL Erlenmeyer flasks using 15 mL of each suspension of *A. viscosus* and 150 mL of a potassium dichromate solution (100 mg_{Cr}/L). Biomass concentrations of 1.2, 2.3, 4.3 and 5.3 g/L were used and determined by dry weight measurement. The initial pH value of the dichromate solution was adjusted to 3, using a 4 M H_2SO_4 solution. The Erlenmeyer flasks were kept at 28 ºC, with moderate stirring. Samples of 1 mL were taken, centrifuged and analyzed for chromium determination.

2.4 Chromium analysis

Hexavalent chromium was analyzed by measuring absorbance at 540 nm of the purple complex of Cr(VI) with 1,5-diphenylcarbazide, in acidic solution (Eaton et al., 1995). For total Cr determination, the Cr(III) was first oxidized to Cr(VI) at high temperature by the addition of an excess of potassium permanganate previous to the reaction with 1,5-diphenylcarbazide. The Cr(III) concentration was calculated by the difference between the total Cr and Cr(VI) concentration.

3 Results

Cr(VI) removal and its reduction to Cr(III) was observed in the presence of *A. viscosus* cells. In Fig. 1 is shown the time-dependent concentration of Cr(VI) and the initial removal rates, for various biomass concentrations.

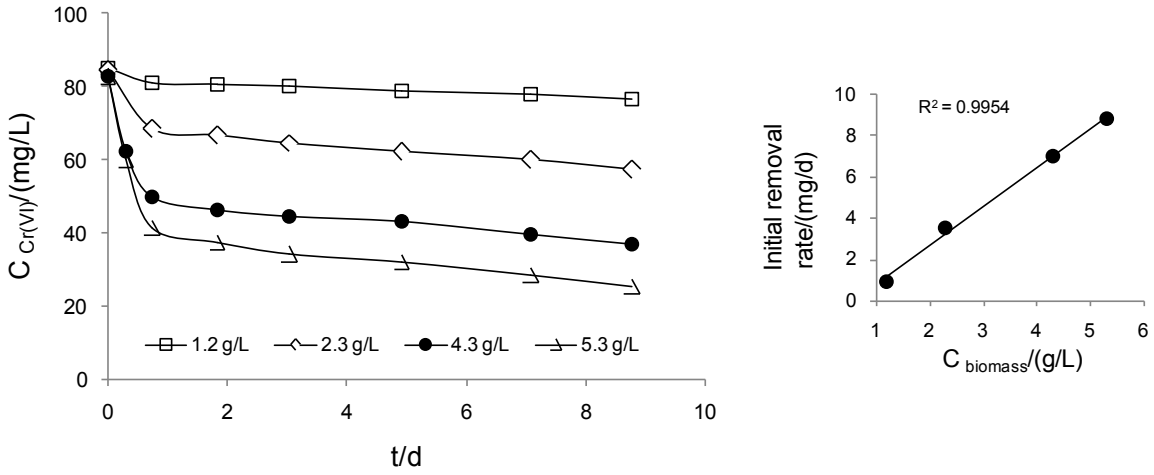

Fig. 1 Concentration of Cr(VI) as a function of contact time and initial removal rates, for biomass concentrations of 1.2, 2.3, 4.3 and 5.3 g/L.

It can be observed that the removal of Cr(VI) is enhanced with an increase in biomass concentration, as it was expected. The initial removal rates were plotted against biomass concentration, as presented in Fig. 1. The plot showed a good linearity, indicating that the reaction was pseudo-first-order with respect to biomass concentration. Total removal of Cr(VI) was not achieved, for the biomass concentrations in study. As the solution pH was not maintained at highly acidic values, the reduction of Cr(VI) to Cr(III) was restricted due to the high pH values of the solutions after 9 days of contact time, which varied from 4.6 to 5.1. Therefore, there was a deficit of protons in solution to allow the complete reduction of Cr(VI).

The concentration values of Cr(VI), Cr(III) and total chromium at the end of the contact time, are presented in Figure 2. It can be seen that the final chromium concentrations in solution showed a linear pattern with respect to biomass concentration, in the range of 1.2 to 5.3 g/L. Cr(VI) concentration decreased lienarly with the increase of biomass concentration, while Cr(III) concentration in solution increased proportionally with the increment of biomass. The lowest total chromium concentration was obtained for the highest biomass concentration, remaining in solution 25.4 mg/L of Cr(VI) and 24.6 mg/L of Cr(III).

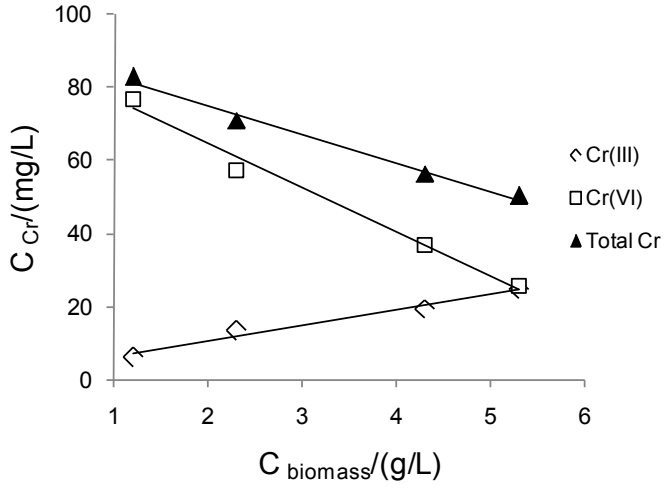

Fig. 2 Chromium concentrations in solution after 9 days of contact time, for different biomass concentrations.

In Fig. 3 are shown the removal efficiencies and the uptake of total Cr attained for the different biomass concentrations. As the biomass concentration increased, the removal efficiency of Cr(VI) and total Cr increased linearly, as discussed above. The best removal efficiencies of Cr(VI) and total chromium were achieved for a biomass concentration of 5.3 g/L, 72.2 % and 44.0 %, respectively. It can be observed in Fig. 3b) that the uptake values did not change significantly with the increase of biomass concentration. The highest uptake value, 8.2 $mg_{Cr}/g_{biomass}$, was obtained for a biomass concentration of 2.3 g/L.

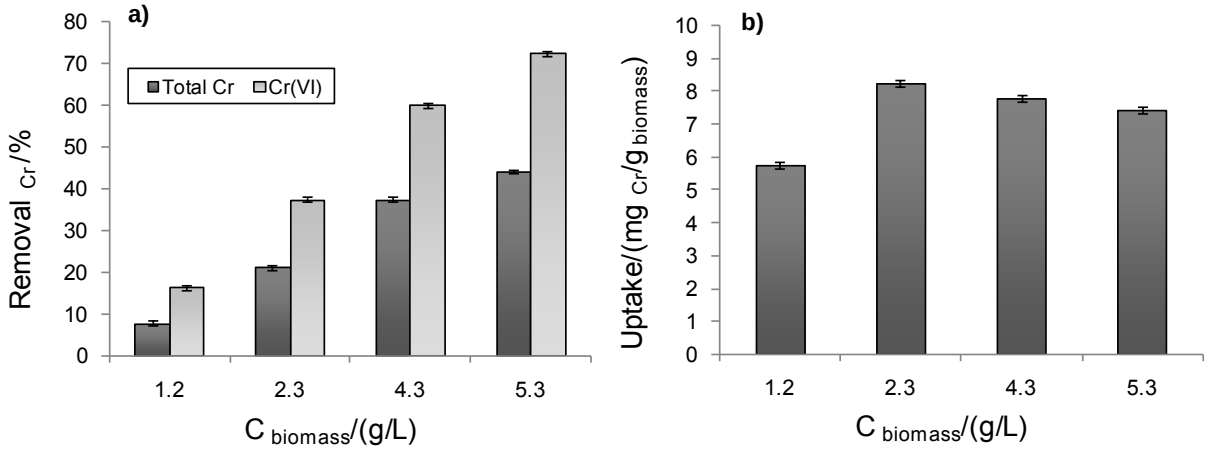

Fig. 3 Removal efficiencies of total Cr and Cr(VI) **(a)** and uptake of total chromium in terms of initial bacteria mass **(b)** after 9 days of contact time, for the different biomass concentrations tested.

4 Conclusions

This work demonstrate the ability of *Arthrobacter viscosus* biomass for the detoxification of Cr(VI) from contaminated wastewaters and highlights the efficacy of using biological agents as an alternative to conventional treatments.

The complete reduction of Cr(VI) was not attained for the biomass concentrations in study, due to the lack of protons in solution. For promoting the Cr(VI) reduction, it is necessary to work with highly acidic pH values. The removal efficiencies of Cr(VI) and total chromium increased linearly with the increase of biomass concentration, in the range 1.2 to 5.3 g/L.

Keywords: bioethanol, wood hydrolysates, xylose, biorefinary, *Eucalyptus globulus*
Topic: Integration of life sciences & engineering

Abstract

The main objective of this work is the valorisation of *Eucalyptus globulus* wood hydrolysates, rich in xylose, by using them as raw material for bioethanol production within the biorefinery concept. The hydrolysates were obtained from two distinct pre-treatments of eucalyptus wood chips: an auto-hydrolysis and an acid-hydrolysis. The liquid extracts resulted from the auto-hydrolysis needed a secondary acid-hydrolysis, which doubled the xylose content. Two treatment methods were tested to reduce the potential inhibitors concentration and to adjust the pH value in the liquid hydrolysates, either using NaOH or $Ca(OH)_2$. The treated liquid hydrolysates were fermented by the yeast *Pichia stipitis*, which was previously adapted to the treated wood extracts. The use of $Ca(OH)_2$ enabled a greater detoxification effect, leading to a better overall yeast performance. An ethanol concentration of 12 g L^{-1}, with a productivity of 0.22 g L^{-1} h^{-1} and a yield based on xylose equivalents of 0.48 g_{eth} $g_{xyl\ eqs}^{-1}$, was achieved so far when using the acid-hydrolysates.

1 Introduction

Several well known factors are leading to an increase in the demand of bioethanol as an alternative fuel. Its advantage as an ecological fuel, obtained from renewable resources, must be supported by non-food competitive materials. Lignocellulosic biomass is abundant, cheap and with a great potential to produce bioethanol, being composed of cellulose (40-50%), hemicelluloses (25-35%) and lignin (15-20%) (Knauf and Moniruzzaman, 2004).The hemicellulosic fraction of *Eucalyptus globulus* wood, the major wood species used in Portugal to produce pulp and paper, is mainly xylan which is partly dissolved during the cooking process and burned in the recovery boiler. For the production of value-added products, such as bioethanol, this fraction could be partly extracted before the cooking start up and undergo an ethanolic fermentation after hydrolysis into simple sugars. The hydrolysis of those polymeric chains releases xylose monomers which can then be fermented by few microorganisms, like *Pichia stipitis* (Pan *et al.*, 2004). Nevertheless, the fermentation efficiency of hemicellulosic sugars is strongly dependent on the hydrolysates inhibitors content coming from the raw material or produced during the hydrolysis reaction (Villareal *et al.*, 2005). Such compounds can stress fermentative microorganisms reducing their performance (sugar use and product formation efficiencies). The type and concentration of inhibitors in the hydrolysates obtained from wood chips depend on both hydrolysis operating conditions and raw materials used and may include sugar-derived by-products (furfural and hydroxymethylfurfural), aliphatic acids (like acetic acid), lignin and its degradation products as well as metals (Villareal *et al*., 2005). The inhibitory effects can be overcome by the hydrolysate detoxification prior to fermentation and several methods have been developed to reduce the inhibitors concentration, or even to convert them into inactive substances. Microbial adaptation, evaporation, solvent extraction, activated charcoal adsorption,

* Corresponding author: Tel +351-239-798746, Email: mgc@eq.uc.pt

enzymatic treatment, the use of ion exchange resins and pH adjustment are some of the most common procedures that can be employed separately or in different combinations, to achieve an efficient detoxification of the hydrolysate (Villareal *et al.*, 2005). pH adjustment is a low-cost treatment (Canilha *et al.*, 2003) and it was used in this work to detoxify the hydrolysates from *Eucalyptus globulus* wood. For that, two procedures with different alkali (NaOH and $Ca(OH)_2$) were tested. *Pichia stipitis* was selected to ferment the treated hydrolysates, due to its ability to ferment xylose and to produce ethanol with a high yield (in the range 0.24 – 0.47 g g^{-1}) over different sources of hydrolysates, including eucalyptus wood (Karimi *et al.*, 2006; Ferrari *et al.*, 1992).

2 Materials and methods

2.1 Wood hydrolysis and treatment methods

The hydrolysates were obtained by two different hydrolysis processes applied to eucalyptus wood chips, both with a solid to liquid ratio of 1:4 kg L^{-1}: 1) an auto-hydrolysis at 150 ºC for 180 min and 2) an acid-catalysed-hydrolysis with sulphuric acid (0.4% w/w) at 140 ºC, for 180 min. The hydrolysate obtained from the auto-hydrolysis process was further submitted to a secondary hydrolysis, also catalysed by sulphuric acid (4% w/w) at 100 ºC for 180 min, to increase monosaccharides content (Carvalho *et al*., 2007). The secondary hydrolysis was worthless for the acid-hydrolysates. The acid-, auto- and secondary-hydrolysates had, respectively, *c.a.* 40, 10 and 16 g L^{-1} of reducing sugars, being xylose the major one. As the optimum pH for *Pichia stipitis* activity is 6.5 (Ferrari *et al.*, 1992), two strategies for hydrolysates treatment by pH adjustment were carried out: the first one was a one-step method consisting in the addition of NaOH or $Ca(OH)_2$ until pH 6.5, being the precipitates removed by centrifugation and vacuum filtration; the second one was a two-steps method which comprised the increase in pH until 10 by adding NaOH or $Ca(OH)_2$, and, after the precipitates removal, the pH correction to 6.5 with concentrated sulphuric acid, followed by vacuum filtration.

2.2 Microorganism and fermentation conditions

Pichia stipitis DSM 3651 (DSMZ, Germany) was primarily grown in both liquid and solid synthetic media and kept in agar slants at 4ºC. The synthetic medium contained analytical grade xylose (10 g L^{-1}, Merck) and microbiological grade peptone (5 g L^{-1}, Fluka), yeast extract (3 g L^{-1}, Sigma) and malt extract (3 g L^{-1}, Fluka). The yeast was then progressively adapted to treated eucalyptus hydrolysates, hereafter referred to as natural media: it was gradually transferred from solid to liquid natural media (and *vice versa*) with increasing volumetric percentages of acid hydrolysate and consequently with higher concentrations of potential inhibitors - 15, 30, 50 and 75% (v/v) diluted in water and non diluted (100% (v/v)). The strain adapted to full strength natural media (100% (v/v) of acid hydrolysate) was kept in agar slants at 4ºC. This adapted strain was grown in liquid natural media, composed of acid-, auto- or secondary-hydrolysates, supplemented with peptone, yeast extract and malt extract in the concentrations referred above. Batch fermentations were carried out in 250 mL erlenmeyer flasks (with cotton stoppers covered by aluminium sheet) using 150 mL of liquid natural media, at 130 rpm and 30 ºC. 10 mL of fresh inoculum, previously prepared under the same conditions of the culture, and at exponential phase were used.

2.3 Analytical methods

Cultures were followed by cell density, reducing sugars consumption and ethanol production. Total reducing sugars, evaluated as xylose equivalents, were determined by a colorimetric method using the dinitrosalicylic acid reagent (DNS) and a UV-VIS spectrophotometer at 540 nm. Optical density of cells suspension was measured at 540 nm in order to follow the yeast growth. Ethanol and xylose concentrations in the cultures were both determined by HPLC, with a PL Hi-Plex Ca 8 μm column, at 85 ºC, using ultra-pure water as eluent at a flow rate of 0.6 mL min^{-1}. The same chromatographic column was used to characterize the hydrolysates.

3 Results and discussion

Besides carbohydrates, the wood hydrolysates also contain other compounds which could inhibit the yeast metabolism. From previous results (Rocha *et al*., 2007; Mendes *et al*., 2008), the yeast growth rate was not limited by furfural (0.1 to 0.8 g L^{-1}) but had a 20-30% reduction in the presence of lignin (1.3 to 7.0 g L^{-1}) and was strongly inhibited by acetic acid (4 to 8 g L^{-1}) since the pH media was lowered to 4. The range of concentrations tested was selected according to the wood hydrolysates composition. In the latter case, the pH correction of the media with NaOH or NH_3 restored the yeast activity, confirming the major influence of pH in a fermentation process. Therefore, two different strategies to adjust the pH value of hydrolysates and to reduce their toxicity level were studied. In addition, microbial cells adaptation to natural media is essential to avoid long lag phases. The adaptation to full strength natural media must be progressive by reducing the dilution rate with water. The level of adaptation was observed to be very dependent on the strategy adopted to adjust the pH of the hydrolysates. All the results regarding the hydrolysates treatment are listed in table 1.

Table 1 – Influence of both treatment method and alkali on the fermentation of eucalyptus wood hydrolysates by *Pichia stipitis* (P – productivity; Y – yield).

(1) – type of inoculum growth media and strain adaptation (50% means strain adapted to 50%(v/v) natural media); (2) – Rocha *et al*., 2007.

3.1 pH adjustment by one-step method

Regarding the one-step method, *i.e.* the addition of an alkali (NaOH or $Ca(OH)_2$) to reach the required pH in acid-hydrolysates, our previous work has shown that the use of $Ca(OH)_2$ led to a faster yeast growth and to higher ethanol yield and productivity (Rocha *et al*., 2007). However, using this procedure, the strain adaptation was only achieved for solid media containing up to 50% (v/v) of acid-hydrolysate. Both original and adapted strains were used to inoculate half-strength natural media. The corresponding fermentation evolution for cell density and ethanol and xylose concentrations is shown in figures 1a) and 1b). The main differences between the two assays are the ethanol and xylose equivalents profiles at the beginning of the fermentation. A lag phase of 50 h in ethanol production was observed with the original strain, while an ethanol concentration of 3 g L^{-1} was achieved and 88% of initial xylose equivalents were consumed with the adapted yeast, at the same time (50 h). Using this adapted strain, fermentation of natural media was only feasible till 75% (v/v) as shown in table 1.

The lag phase was also observed at the beginning of auto- and secondary-hydrolysates fermentation both treated with either $Ca(OH)_2$ or NaOH. The ethanol production rate achieved in the fermentation of auto-hydrolysates was very low and was associated to the low initial sugar concentration (table 1). In addition, only half of the reducing sugars were consumed by the yeast, being the xylose monomers totally used. The secondary hydrolysis applied to the auto hydrolyzed extracts did increase the initial reducing sugars (table 1), and particularly xylose content, even though the ethanol concentration obtained was still very low (2 g L^{-1}), corresponding to a rate production of 0.017 g (L h)$^{-1}$ and a yield of 0.19 g_{eth} $g_{xyl\ eqs}^{-1}$ based on the reducing sugars consumed (Rocha *et al*., 2007).

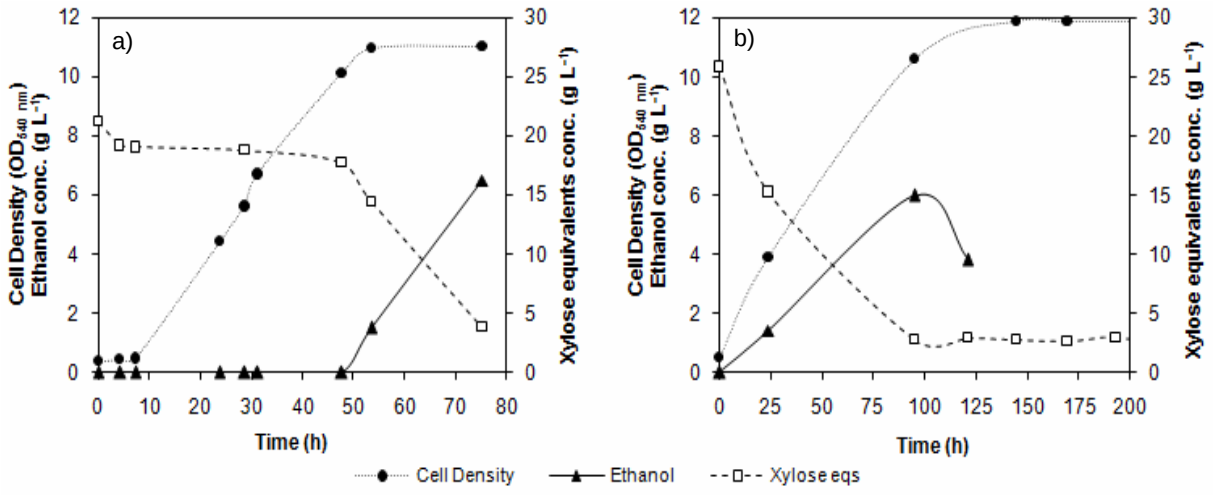

Figure 1 – Cell density, ethanol and xylose equivalents evolution in the fermentation of liquid natural media consisting of 50% (v/v) acid hydrolysate diluted in water, using a) the original strain and b) the strain adapted to half strength natural media.

3.2 pH adjustment by two-steps method

The other pH adjustment method, which consisted in the addition of an alkali to pH 10 followed by its decrease to 6.5 with concentrated acid (sulphuric acid), was then carried out in an attempt to reach a better purification of hydrolysates. According to the results presented above, $Ca(OH)_2$ was the first choice. Using this two-steps method, the strain adaptation and the fermentation of full strength acid-hydrolysate (100% (v/v)) was successfully achieved (table 1). The fermentation of acid-hydrolysates, as depicted in figure 2a), led to a maximum ethanol concentration of 12 g L^{-1}, a productivity of 0.22 g L^{-1} h^{-1} and a yield based on xylose equivalents of 0.48 g_{eth} $g_{xyl\ eqs}^{-1}$. These results are similar to some of the data in the literature

(Ferrari *et al.*, 1992) allowing some expectations on the energetic valorisation of *Eucalyptus globulus* wood hemicelluloses extracted prior to pulping.

The experiments carried out show that a better yeast performance is achieved when acid-hydrolysates are treated with $Ca(OH)_2$ by the two-steps method, due to a greater detoxification effect. However, a decrease up to 9% on the initial sugars concentration was observed. A stronger influence of $Ca(OH)_2$ addition upon sugar content reduction was even registered in the treatment of the auto-hydrolysates (table 1). A decrease up to 35% was verified which, consequently, led to lower ethanol concentrations (1.1 g L^{-1}). Even though, higher productivity (0.036 g L^{-1} h^{-1}) and yield on reducing sugars (0.41 g_{eth} $g_{xyl\ eqs}^{-1}$) were obtained when compared to the one-step method.

Similarly, the secondary-hydrolysates treated with $Ca(OH)_2$ suffered a reduction of the initial xylose equivalents up to 44%. As a consequence, a low ethanol concentration was also obtained (2.1 g L^{-1}), as shown in figure 2b), with a productivity and yield of 0.072 g L^{-1} h^{-1} and 0.43 g_{eth} $g_{xyl\ eqs}^{-1}$, respectively. The fermentation profiles in figures 2 a) and 2 b) show that ethanol production is proportional to xylose equivalents consumption. Therefore, to avoid the sugar content decrease, the treatment procedures must be optimized, particularly for the auto- and secondary-hydrolysates.

The decrease in ethanol concentration latter in all the fermentations assays can be due to its metabolisation when the other nutrients are exhausted, or to its loss by vaporization during the long fermentation period. The remaining reducing sugars at the end of fermentations probably cannot be fermented by the yeast although xylose was totally consumed as confirmed by HPLC analysis.

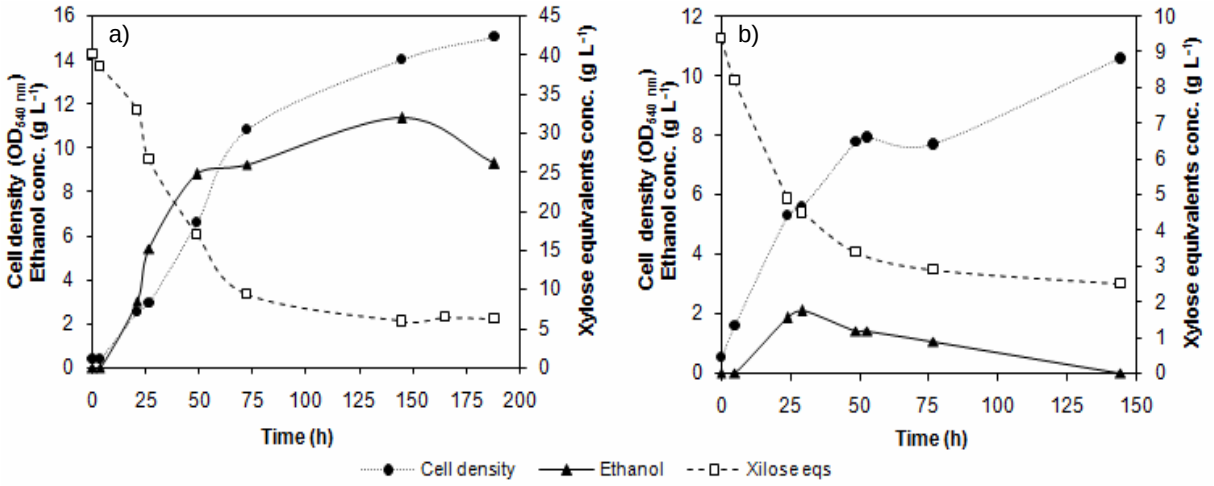

Figure 2 - Ethanol production, xylose equivalents concentration and yeast growth profiles obtained in the fermentation of 100% (v/v) a) acid-hydrolysate and b) secondary-hydrolysate, both treated with $Ca(OH)_2$ by the two-steps method and using the strain adapted to full strength natural media.

A few experiments using NaOH in the two-steps method were carried out with acid- and secondary-hydrolysates as illustrated in table 1. Since this alkali did not promote a significant loss on the initial reducing sugars concentration, a higher amount of sugars was available and the fermentation of the secondary-hydrolysate led to a higher ethanol concentration (3.3 g L^{-1}) than the one achieved when using $Ca(OH)_2$. However, the productivity and the yield were smaller (0.046 g L^{-1} h^{-1} and 0.30 g_{eth} $g_{xyl\ eqs}^{-1}$, respectively). On the other hand, no yeast activity was detected when using the acid-hydrolysate treated with NaOH (table 1) like in the pH adjustment by the one-step method. A greater toxicity level of the acid-hydrolysates when compared to the auto- and the secondary-hydrolysates, not sufficiently reduced by the addition of NaOH, may explain this result.

4 Conclusions

Hydrolysates obtained from eucalyptus wood auto-hydrolysis or acid-hydrolysis have a low pH value and contain a broad range of compounds, including reducing sugars (xylose is the major one) and potential inhibitors, like acetic acid, furfural and lignin. These hydrolysates must be submitted to a detoxification treatment and pH adjustment before fermentation by *Pichia stipitis*, whose metabolic activity is strongly dependent on pH. As different hydrolysis conditions were used to produce the hydrolysates, these did not present equal toxic levels nor composition and therefore different responses were obtained when they were treated by different methods (one-step or two-steps) using two alkalis (NaOH or $Ca(OH)_2$).

The treatment of acid-hydrolysates by the addition of $Ca(OH)_2$ up to pH 10, followed by pH adjustment to 6.5 with concentrated sulphuric acid (two-steps method) promoted a higher detoxification effect. The strain adaptation was achieved with success in 100% acid-hydrolysates, thus enabling the reduction or even the absence of the initial lag phase during their fermentation. The best set of results achieved in the fermentation of the treated acid-hydrolysates comprised a maximum ethanol concentration of 12 $g_{eth}\ L^{-1}$, corresponding to a productivity of 0.22 $g_{eth}\ (L\ h)^{-1}$ and a yield of 0.48 $g_{eth}\ g_{xyl\ eqs}^{-1}$ on reducing sugars.

On the other hand, a significant reduction of the initial sugars concentration was observed in both auto- and secondary-hydrolysates treated by this method and, consequently, the ethanol concentration accomplished was very low (1.1 and 2.1 $g_{eth}\ L^{-1}$, respectively), even though higher yields on the reducing sugars consumed were obtained. Therefore, better procedures must be studied within this treatment strategy, using for example other types of alkali, in order to decrease the percentage of reducing sugars lost when processing auto- and secondary-hydrolysates.

Biopolymers Production by Microbial Fermentation on Glycerol-Rich Product

Filomena Freitas, Vitor D. Alves, Joana Pais, Nuno Costa, Mónica Carvalheira, Rui Oliveira, M. A. M. Reis*
CQFB-Requimte, Chemistry Department, FCT/Universidade Nova de Lisboa, 2829-516 Caparica, Portugal.

Keywords: Biopolymer, Fermentation, Exopolysaccharide (EPS), Polyhydroxyalkanoates (PHA), Glycerol-Rich Product (GRP)
Topic: Sustainable process-product development through green chemistry.

Abstract

The objective of this work was the conversion of glycerol-rich byproduct (GRP), obtained in biodiesel production facilities, into biopolymers using ***Pseudomonas oleovorans***. Two distinct biopolymers were simultaneously produced: an extracellular polysaccharide (EPS) and intracellular polyhydroxybutyrate (PHB). Under optimized EPS production conditions in fed-batch mode, the cellular PHB content was 21 % of the cell dry weight (CDW) and the EPS concentration was 11.6 g L^{-1}. The use of glycerol as carbon source greatly reduces production costs of the process, since it allows for the valorization of GRP by its conversion into high-value products.

1 Introduction

Microorganisms are generally better suited for biopolymers production than plant or algae, because they usually exhibit higher growth rates and are more amenable to manipulation of conditions for enhancing growth and/or production (Moreno et al., 1998). However, the high cost of the carbon sources used, mainly sugars such as glucose, sucrose and fructose (Kumar et al., 2007) limits the market potential of these biopolymers. As a consequence, less expensive carbon sources must been searched in order to decrease production costs.

Glycerol, a byproduct of biodiesel production, is generated in quantities far beyond current consumption in traditional applications. The development of new routes to convert crude glycerol, which is now considered as a waste with associated disposal costs, into higher value products is an urgent need (Çelik et al., 2008). The use of glycerol rich byproduct (GRP), a low cost substrate, for microbial production of biopolymers presents an advantageous strategy since it allows for the reduction of production costs (Ashby et al., 2005).

Polysaccharides are used in a variety of industrial applications, including food, painting, cosmetic, paper and pharmaceutical, as emulsifiers, stabilizers or thickening agents. Currently, polysaccharides obtained from plants (ex: Guar gum, Arabic gum), algae (ex: alginate, carrageenan, agar) and crustacean (ex: chitin) still dominate the market, with microbial polysaccharides (ex. xanthan, gellan gum, dextran, pullullan) representing only a small fraction of the biopolymers commercialized (Moreno et al., 1998).

Polyhydroxyalkanoates (PHA) are natural polyesters synthesized by bacteria and stored inside the cell. These biopolymers exhibit properties that range from semicrystalline to elastomeric, making them biocompatible substitutes for petrochemical-based polymers (Ashby et al., 2005).

The objective of this work was the conversion of the GRP obtained in biodiesel production facilities into high-value microbial biopolymers. When grown on GRP as the sole carbon source, ***Pseudomonas oleovorans*** produced two distinct biopolymers: a new extracellular polysaccharide (EPS) and intracellular polyhydroxybutyrate (PHB).

2 Materials and Methods

Pseudomonas oleovorans NRRL B-14682 was grown on a slightly modified Medium E* (pH 7.0), with the following composition (per liter): $(NH_4)_2HPO_4$, 3.3g; K_2HPO_4, 5.8g; KH_2PO_4, 3.7g; 10mL of a 100mM $MgSO_4$ solution and 1mL of a micronutrient solution. The micronutrient solution had the following composition (per liter of 1N HCl): $FeSO_4 \cdot 7H_2O$, 2.78 g; $MnCl_2 \cdot 4H_2O$, 1.98g; $CoSO_4 \cdot 7H_2O$, 2.81g; $CaCl_2 \cdot 2H_2O$, 1.67g; $CuCl_2 \cdot 2H_2O$, 0.17g; $ZnSO_4 \cdot 7H_2O$, 0.29g) (Brandl et al., 1988). Glycerol-rich product (GRP) was added to give a concentration between 30 g L^{-1}.

Inoculums for the bioreactor experiments were prepared by incubating the culture in Medium E* supplemented with GRP (50 g L^{-1}), in shake flasks, for 72 h at 30ºC in an incubator shaker (200 rpm). Fed-batch experiments were performed in a 2L bioreactor (BioStat B, Sartorius), operated with controlled pH (6.75 – 6.85) and temperature (30ºC), constant air flow rate (0.25 slpm, standard liters per minute) and automatic variation of the stirrer speed (400-800 rpm) for controlling the dissolved oxygen (DO) concentration in the culture broth. The inoculum culture (200 mL) was inoculated into the medium described above supplemented with 50 g L^{-1}. Starting around 24 hours of cultivation, a feeding solution was fed to the bioreactor at a constant rate of 5mL h^{-1}. The feeding solution composition was identical to the culture medium described above, with a higher glycerol concentration (200g L^{-1}).

Glycerol concentration in the cell-free supernatant was determined by liquid chromatography (HPLC) with an Aminex HPX-87H column (BioRad), coupled to a refractometer. The analysis was preformed at 50ºC, with H_2SO_4 0.01 N as eluent, at a flow rate of 0.6 ml/min. Ammonium concentration was determined using a potentiometric sensor (Thermo Electron Corporation, Orion 9512).

For EPS quantification, the cell-free supernatant was subjected to protein removal (addition of trichloroacetic acid at a final concentration of 10%), prior to ethanol precipitation. The precipitated EPS was dissolved in deionised water, frieze dried and weighted. For the identification and quantification of the constituent monosaccharides, the EPS samples were dissolved in deionised water and hydrolyzed with trifluoroacetic acid 99%, at 120ºC, for 2 hours. The hydrolysate was analyzed by HPLC with a CarboPac PA10 column (Dionex), equipped with an amperometric detector. The analysis was preformed at 30ºC, with sodium hydroxide (NaOH 4 mM) as eluent, at a flow rate of 0.9 ml/min.

3 Results and Discussion

When cultivated on mineral medium containing GRP as the sole carbon source, ***Pseudomonas oleovorans*** grew, produced extracellular EPS and accumulated intracellular PHB (Figure 1). Bacterial cell growth stopped due to nitrogen limitation, as the ammonium concentration in the culture broth dropped below 0.1 g NH_4^+/l.

Following 1 day of cultivation, the bioreactor was continuously fed with a mineral medium containing glycerol and ammonium, thus keeping a high carbon/nitrogen (C/N) ratio. As a result, the glycerol concentration in the bioreactor was maintained above 25 g L^{-1} throughout the cultivation (Figure 1).

Under these conditions, the culture produced extracellular EPS, reaching a concentration of 11.6 g/l after 6 days of fermentation. Concomitant with EPS production, there was a sharp raise of the culture broth viscosity, which induced mixing limitations decreasing mass and heat transfer. Thus, the experiment shown in Figure 1 was terminated at 6 days of fermentation, because it was no longer possible to maintain appropriate mixing, aeration or

control of bioreactor parameters. Simultaneously with EPS production, the culture accumulated intracellular reserves of PHB, reaching a cellular content of 21% (Figure 1).

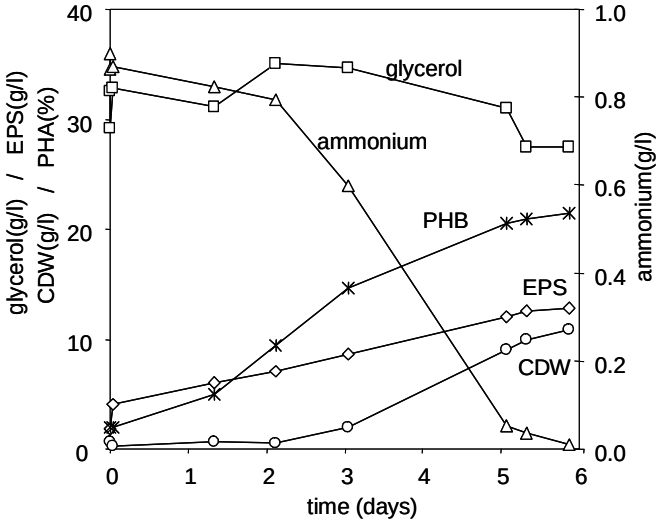

FIGURE 1. Bacterial growth on glycerol and production of PHB and EPS.

The EPS was extracted and its physical-chemical characteristics where studied. The chemical analysis of the EPS revealed that it is composed by galactose (50-90%), glucose (1-25%), rhamnose (1-25%) and mannose (0.5-20%), with an average molecular weight of $2x10^6$. The presence of galactose residues in microbial polysaccharides is rather common, even though it may be present in variable amounts ranging from 21-63 mol%, in galactose-rich heteropolysaccharides produced, for example, by several bacteria of the Genera ***Erwinia*** (Eastgate et al., 2000) and ***Pseudomonas*** (Osman et al., 1989; Hung et al., 2005). Microbial galactose-rich EPS frequently contain other monosaccharides such as glucose, mannose, rhamnose, arabinose and fucose. The unusual high galactose content of the EPS produced by ***Pseudomonas oleovorans*** grown on GRP, distinguishes it from other microbial EPS. Also, many of the known microbial EPS contain, besides neutral sugars, acidic sugars (ex. glucuronic acid, galacturonic acid) or amino sugars (ex. glucosamine, galactosamine) that are absent from the EPS obtained in this study.

Results have also shown that the EPS contains non-saccharide components, namely, acyl groups, which accounts for 3-15 wt% of the polymer's mass. Three different organic acids were identified in the acid hydrolysate: pyruvate (3.35 wt%), succinate (1.04 wt%) and acetate (0.38 wt%). These components are frequently found in microbial EPS and they greatly influence polymer's properties, namely, solubility and rheology (Rinaudo, 2004). As shown by its pyrolysis at 550ºC, the purified polymer had an inorganic content of about 11.6 wt%, which was attributed to the presence of ions, such as potassium (4.7 wt%), magnesium (0.2 wt%) and sodium (0.9 wt%), as detected by ICP analysis. These inorganics were probably remnants of the contents of the culture broth, being present in the polymer after its purification as counter ions for the anionic groups of the polymer (pyruvil and succinyl groups).

The EPS forms highly viscous aqueous solutions with pseudoplastic fluid behavior (Figure 2). The viscosity of an EPS 0.1% (w/v) solution is higher than that of pectin and alginate for the same range of shear rate, and higher than that of carrageenan for shear rates below 30 s^{-1}. It is insoluble in organic solvents and has both flocculating and emulsifying activities, as well as film-forming capacity.

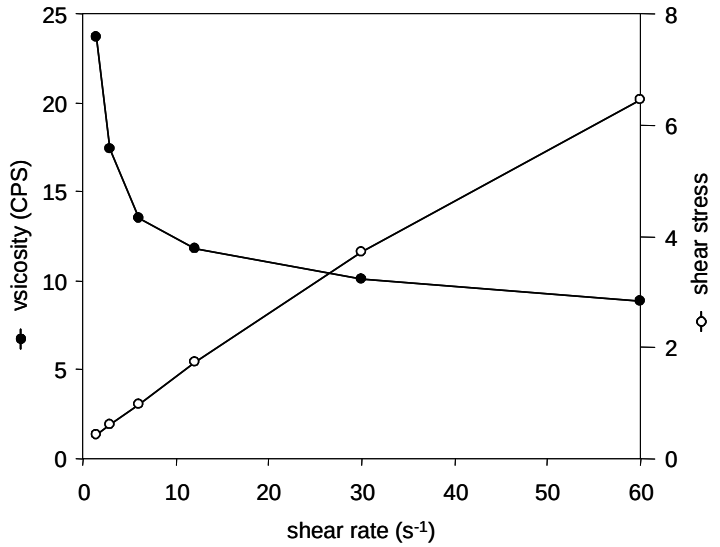

FIGURE 2. Rheological properties of a 0.1% w/v aqueous solution of the EPS.

These chemical and physical properties suggest a broad range of applications in the food, textile and paper industries, in the formulation of pharmaceutical and cosmetic products, for metal recovery in the mining industry, wastewater treatment and many others. The EPS may be used alone or blended/mixed with other polymers as a suspending, thickening, flocculating, emulsifying or film-forming agent.

4 Conclusions

The process described in this work allows for the valorization of GRP, which is currently a waste generated by several industrial processes, especially the biodiesel industry, converting it in high-value products. Thus, glycerol is used as a low cost substrate for the microbial fermentation of ***Pseudomonas oleovorans*** that efficiently converts GRP, a low cost substrate, into two distinct biopolymers, namely extracellular EPS and intracellular PHB. The process may be controlled to favor the production of either or both biopolymers, which makes it very versatile. This new process constitutes a promising technology for the valorization of GRP, since it allows for the production of two biopolymers with relatively low production costs. In addition, the EPS is a novel product with characteristic chemical composition and physical properties which are very competitive when compared to commercially available algal and plant polysaccharides.

Keywords: Biotrickling filter, Hydrogen sulfide, Bacterial community diversity, Clone library, T-RFLP
Topic: Integration of life sciences & engineering

Abstract

The diversity and spatial distribution of bacteria in a lab-scale biotrickling filter treating high loads of hydrogen sulfide (H_2S) were investigated. Community patterns were obtained by means of terminal restriction fragment length polymorphism (T-RFLP) at two locations in the reactor. A 16S rRNA gene clone library was established. Clones were clustered into 24 operational taxonomic units (OTUs). Only 48% of the 16S rRNA gene sequences in the clone library exhibited similarities of more than 96% to classified bacterial species, indicating that a considerable fraction of the clone sequences were derived from unknown taxa. Approximately 45% of the sequences retrieved were affiliated to bacteria of the sulphur cycle including *Thiothrix spp., Thiobacillus spp*. and *Sulfurimonas denitrificans*. Sequences related to *Thiothrix lakustris* accounted for 38% of the collection. Differences in the microbial community were observed among the zones investigated. Although aerobic species were predominant in the reactor, facultative anaerobes had a major relative abundance at the inlet of the reactor, where the sulfide to oxygen ratio is higher.

1 Introduction

With increasingly strict regulations for air pollution control, the necessity for treating gas pollutants is critical. Biogas, produced in multiple industrial processes like the anaerobic treatment of wastewater treatment plant sludge, contains variable amounts (1000-20000ppm$_v$) of hydrogen sulfide (H_2S), which is a corrosive, toxic and odorous gas. Biological processes have proven to be suitable, environmental-friendly, and cost-effective alternatives for low H_2S concentration treatment, but only a few references address biological treatment of high concentrations of H_2S in biotrickling filters (Fortuny et al., 2008). In biofiltration, the gas to be treated is forced through a filter bed where microorganisms are attached. Gaseous pollutants are transferred to a moisturized biofilm, where the transformation of the compounds takes place, involving several physical, chemical and biological interactions.

A thorough study of the microbial community in bioreactors has been shown to be critical to the improved understanding of the underlying biochemical processes. It has been estimated that as many as 99% of all microorganisms are not cultivable by standard methods, biasing cultivated community diversity studies. However, this problem can be overcome by using the novel molecular biology tools targeting the small subunit rRNA-encoding genes. Terminal restriction fragment length polymorphism (T-RFLP) is a molecular technique for characterizing environmental microbial communities and for studying changes in their

* Corresponding author. Tel + 34935811587. E-mail: david.gabriel@uab.es

structure and diversity (Liu et al., 1997). Clone libraries have been extensively used for microbial communities analysis since it provides a collection of the species present in the sample.

In the present work, the microbial diversity in a biotrickling filter treating H_2S was studied using a combination of T-RFLP and clone libraries of the 16S rRNA gene. This combination allowed more accurate identification of individual T-RFLP peaks. Although a few studies have characterized the microbial community of such gas-phase bioreactors, mainly biofilters, using molecular techniques (Friedrich et al., 2002), this work is the first to characterize the populations in a biotrickling filter treating H_2S by constructing an extensive clone library and by using T-RFLP as the fingerprinting technique for studying H_2S-degrading communities.

2 Materials and Methods

Experimental setup. In this work, an experimental reactor based on a conventional biotrickling filter was used. The reactor was initially inoculated with activated sludge from a municipal wastewater treatment plant and then continuously operated for six months in upflow mode at an empty bed residence time of 180 s, an average liquid retention time of 54 ± 7 h, an inlet H_2S concentration of 2,000 ppm_v (load of 55.6 g H_2S m^{-3} h^{-1}) and a liquid recirculation velocity of 3.6 m h^{-1}. Under these conditions, elimination capacities of 53±1 g H_2S m^{-3} h^{-1} were achieved for the whole experimental period, except for few days after the start up. Metered amounts of H_2S, N_2 and air (0.2, 77.3 and 22.4 %, respectively) were used to simulate a controlled biogas inflow. Details of the reactor, mineral medium, other operational conditions and analytical methods can be found elsewhere (Fortuny et al., 2008).

DNA isolation and 16S rRNA gene amplification. Biomass samples were withdrawn from two sampling ports situated at different heights in the reactor, 17 cm and 34 cm out of 50 cm. The first one will be referred as inlet part and the second one as outlet part. For library construction biomass samples from the inlet and the outlet part of the reactor were mixed in a 1:1 ratio (w/w).The DNA was extracted and tested and preserved at -20ºC. The small subunit (SSU) rRNA gene was polymerase chain reaction (PCR) amplified from genomic DNA extracted from the environmental samples and two isolates using universal primers for the Bacterial domain (8F/1492R). These two isolates were obtained from the same reactor and then tested as sulfur oxidizers (data not shown). For isolate identification and clone library generation, the PCR reactions were performed as described elsewhere (Chi-hua and Banks, 2006) but contained 100 ng of template DNA. For isolate identification, PCR products were sent for direct sequencing. For clone libraries, the 16S rRNA gene fragments were cloned with the TOPO TA Cloning® Kit for Sequencing (Invitrogen, CA, USA) according to the manufacturer's instructions.

T-RFLP analysis. For T-RFLP analysis, the labeled forward primer Fam-8F and the unlabeled reverse primer 926R (Molbiol, Germany) were used. T-RFLP was performed as described in Ho and Banks, (2006) with some modification as described by Egert and Friedrich (2005) to reduce partially single-stranded amplicon. The T-RFLP digests (digested with HhaI) were analyzed on an ABI automated sequencer (Model 3100). Duplicates from the initial step of DNA extraction were performed through the whole process to evaluate the reproducibility of the methodology. The distribution of the peaks from the collected profiles was performed using ABI Genemarker 1.51.71 (Softgenetics, PA, USA). A level of 80 fluorescence units was used as a minimum threshold value for all peaks in the selected size range. To assess community similarity, terminal restriction patterns were standardized based on T-RF peak area (Kaplan et al., 2001). Once the samples were normalized, peaks below the threshold were deleted, and new peak area percentages were calculated. Duplicate sample results were grouped, and consensus terminal-restriction fragments (T-RFs) and average peak areas were obtained by using the web tool T-align (http://inismor.ucd.ie/~talign/).

Sequencing and phylogenetic reconstruction. One hundred clone inserts were sequenced in full with pUC/T3-T7 primers by Macrogen (Korea). All sequences were

checked for chimeric artifacts by using the CHIMERA_CHECK program of the Ribosomal Database Project and for similar sequences with the ClustalW program. Near full-length sequences (approximately 1500bp) were compared with similar sequences of the reference organisms by a BLAST search (Altschul et al., 1997). Sequences with the same first accession number were grouped into clusters. Thus, the clustering process was based on the BLAST results obtained for every clone. Similarity among clones within the same cluster was studied by sequence comparison using ClustalW.

Phylogenetic trees - ARB and rarefaction analysis. Sequences were subjected to a BLAST search (Altschul et al., 1997) to get a first suggestion of the phylogenetic affiliation. Sequences were aligned using the automatic alignment tool in the ARB program package (http://www.mikro.biologie.tu-muenchen.de). Then, nearly-complete sequences were inserted into the optimized tree derived from the complete sequence data by the ARB neighbour-joining method. The rarefaction analysis, which indicates if the community diversity is well represented by the number of clones that have been sequenced, was calculated using the defined OTUs. The software Analytic Rarefaction (version 1.3, S.M. Holland, http://www.uga.edu/~strata/software/) was used to perform rarefaction analysis. The 16S rRNA gene sequences of the clones have been submitted to the Genbank /EMBL/DDBJ to obtain the corresponding accession numbers.

3 Results and Discussion

Bacterial diversity. In the present work, a lab-scale biotrickling filter degrading high loads of H_2S was investigated. On the one hand, the high loads of hydrogen sulfide may constrain the bacterial diversity of the biofilter. Besides, comparing to organic packing materials, the inert plastic grid used could decrease the microenvironments available for bacterial communities. On the other hand, the presence of a biofilm enhances bacterial diversity due to the different microenvironments that exist in the biofilm.

A 16S rRNA gene clone library was constructed with near full-length 16S rRNA gene sequences for all the clones. After eliminating putative chimeric sequences, the remaining 75 clones were clustered into 24 groups. Rarefaction analysis demonstrated that the clone library constructed was suitable to describe the vast majority of the bacterial diversity of the reactor since the rarefaction curve almost achieved a plateau (data not shown). Seventy four percent of the sequences were related to the phylum Proteobacteria and 26.0% to Bacteroidetes. Among clones analyzed and clustered, 10 clusters, including 45 clones, were closely related to known sulfur-oxidizing bacteria (SOB) species: *Thiothrix lakustris* (γ-Proteobacteria), *Thiothrix sp. CT3* (γ-Proteobacteria), *Sulfurimonas denitrificans* (ε-Proteobacteria), *Thiobacillus denitrificans* (β-Proteobacteria), *Thiobacillus sajanensis* (β-Proteobacteria) and *Thiobacillus plumbophylus* (β-Proteobacteria) (Fig.1). Thiotrichales was the most predominant order among γ-Proteobacteria (almost 90%). The remaining orders of this class represented in the clone library were related to Xanthomonadales (clones were affiliated with *Dokdonella koreensis* and *Xanthomonas axonopodis*). All clones belonging to ε-Proteobacteria were exclusively related to Campilobacterales (clones were affiliated with *Sulfurimonas denitrificans*). Regarding class β-Proteobacteria, the order most frequently represented was Hydrogenophilales (clones were related to *Thiobacillus spp*.). Concerning the phylum Bacteroidetes, it comprised 26% of the clone library, and the clones were affiliated with *Haliscomenobacter hydrossis*.

Molecular phylogenetic analyses can suggest, but not definitively demonstrate, what metabolic roles are being played by the organisms present in the reactor. *Thiothrix* is a filamentous genus in the γ-Proteobacteria. It can grow under heterotrophic, chemolithoautotropic, and mixotrophic conditions. This could explain the predominance of *Thiothrix* in the bioreactor since it had been operated for 6 months after inoculating with activated sludge from a wastewater treatment plant, and there was a considerable quantity of biomass accumulated in the packing material. *Thiothrix spp*. have been described as a component of biofilms in sulfide-containing flowing water in natural systems and wastewater treatment plants. These filamentous bacteria are believed to be one of the major causes of

activated sludge bulking and foaming.

The genera *Thiobacillus* and *Sulfurimonas*, both found in the library, have been described previously as sulfur-oxidizers (Kelly et al., 1997). The genus *Thiobacillus* is represented in the clone library by the chemolithoautotrophic species *T. denitrificans*, *T. sajanensis* and *T. plumbophilus*. *T. denitrificans* is a facultative anaerobe, and *T. sajanensis* and *T. plumpophilus* are aerobes. Also, the genus *Sulfurimonas* is represented in the collection by the chemolithoautotroph facultative anaerobe *Sulfurimonas denitrificans*. Although both genera represent less than 20% of the clones in the collection, they are presumably playing an active role in the sulfur oxidation process, mostly in microenvironments where oxygen levels are extremely low. These microenvironments are present in thick biofilms like those in this bioreactor.

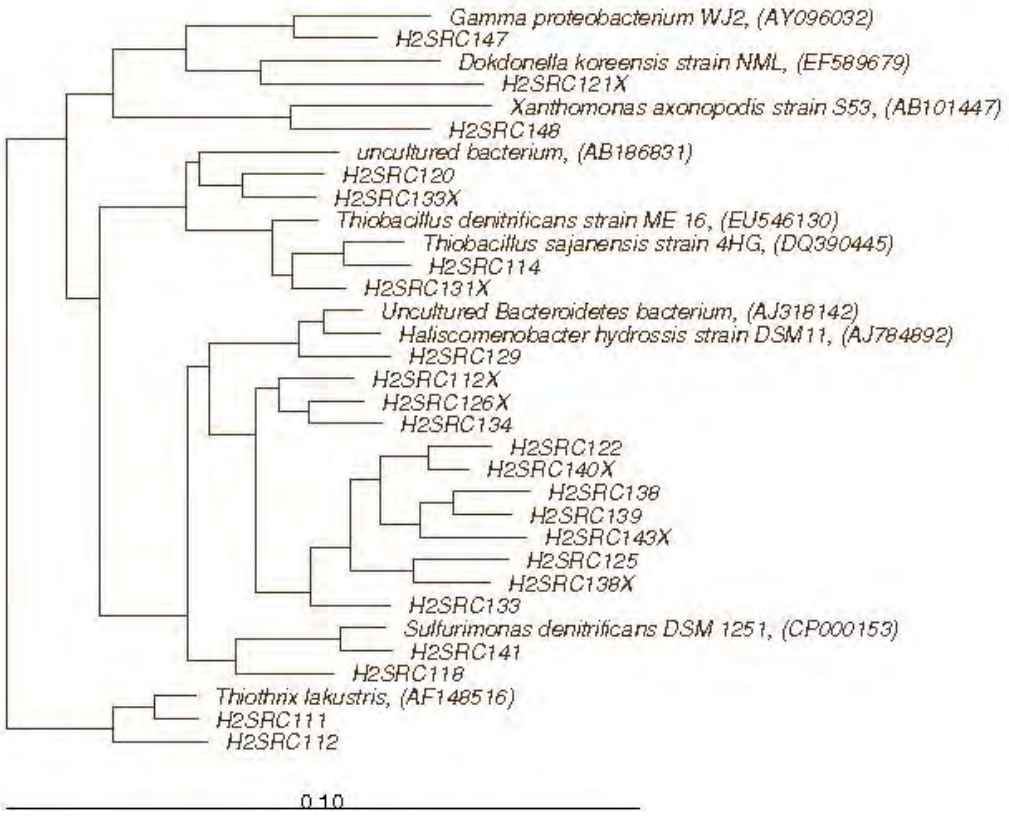

Figure 1. Bacterial phylogenetic tree based on near complete 16S rRNA gene sequences showing the affiliation of the representative clones for each OTU and its closest phylogenetic relatives. Clone names are shown with the code H2SRC1#. The symbol # indicates the number assigned to every clone and in some cases it has an X (clones are organised into two subcollections 1-50 and 1-50X).

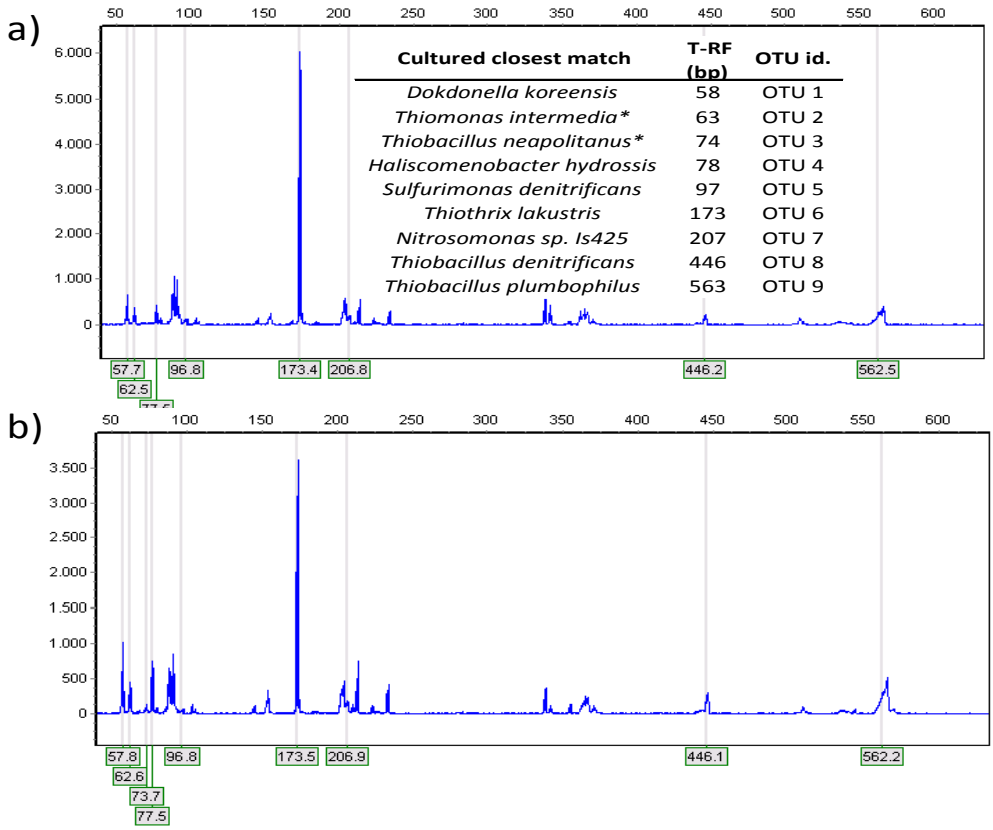
Microbial spatial distribution through T-RFLP. T-RFLP is not considered a quantitative methodology, but a comparison between samples can be performed based on the areas of the peaks representing different OTUs. T-RFLP was used for the samples of biomass withdrawn at two different heights of the reactor. Since the most significant clones of the clone library, either in abundance terms or in relation to sulfur cycle, were subjected to T-RFLP analysis, it was possible to identify the populations represented by some of the OTUs found in the T-RFLP patterns (Fig. 2). Clones affiliated with *Thiothrix lakustris* were digested with HhaI and yielded a terminal restriction fragment of 173 bp. Two species isolated from the reactor during the second month of operation also were studied by T-RFLP. Genomic DNA from *Thiobacillus denitrificans* strain DSMZ 807 was used through the whole T-RFLP process as a positive control. This organism has been also described as an SOB previously (Beller et al., 2006). When it was subjected to T-RFLP analysis, it showed a T-RF of 563 bp,

which corresponds to the same OTU as *Thiobacillus plumbophilus* (OTU 9).

Species abundance in the PCR amplicon is related to peak area percentage. It is possible to observe that OTU 6, which was confirmed to include the clone affiliated with *Thiothrix lakustris*, is the most abundant OTU found in the T-RFLP patterns, in accordance with the results obtained in the clone library. It was found that the clones and isolates used for OTU identification by T-RFLP only comprised 30% of the total peak area of the patterns, meaning that there is at least 70% of the peak area represents other OTUs. The distribution this 30% peak area studied is represented in Fig. 3.However, the clones used for OTU identification represented 65% of the clone library diversity.



*Two species isolated from the reactor

Figure 2. Electropherograms showing T-RFLP patterns in a) outlet part, and b) inlet part of the reactor. Main OTUs studied are labeled with their respective restriction fragment lengths.

Figure 3. Distribution of studied OTUs in microbial communities of A) outlet part of the reactor and B) inlet part of the reactor. Distribution is based on % peak area from T-RFLP.

OTU 6, related to *Thiothix lakustris*, is predominant among the species studied in both parts of the reactor. It could be hypothesized that this species would be the most adapted to the operational conditions throughout the reactor, most probably because of its mixotrophy. In

the inlet part of the bioreactor, the otherOTUs increased in relative abundance at the expense of OTU 6. This means that the physiological advantage of *Thiothrix lakustris* over the rest of species is reduced near the inlet of the reactor where there is higher sulfide to oxygen ratio. Here, it can be highlighted that OTUs that increment their significance near the inlet of the reactor are related to mainly facultative anaerobic species (*Thiobacillus denitrificans*, *Sulfurimonas denitrificans* and *Haliscomenobacter hydrossis*) so they could use another electron acceptor if oxygen was lacking. It is remarkable that OTUs 2 and 3, linked to the two isolates *Thiomonas intermedia* and *Thiobacillus neapolitanus*, represent a low proportion of peak area. These results agree with those obtained through the clone library where clones affiliated to these species were not even found. This could indicate that either the clone library should be extended to cover a higher portion of the bacterial diversity and/or that in the OTUs where they are represented, there could be other species that we have not analysed individually by T-RFLP.

4 Conclusions

In this study, a molecular approach has been used to characterize the microbial diversity in a biotrickling filter. A clone library potentially representing the most abundant species present was created, and T-RFLP was used to study the differential microbial distribution at two different heights in the reactor. The use of both molecular tools improves the knowledge about the microbiology of gas-phase bioreactors. To our knowledge, this is the first research to retrieve an extensive number of near full-length 16S rRNA gene sequences from a biotrickling filter treating H_2S and to construct a collection representative of the existing diversity. Approximately 45% of the sequences retrieved were affiliated with bacteria of the sulphur cycle including *Thiothrix spp.*, *Thiobacillus spp*. and *Sulfurimonas denitrificans*. Although clones related to aerobic species were predominant in the reactor, facultative anaerobes had a major relative abundance at the inlet of the reactor, where the sulfide to oxygen ratio is higher. Even though these results may help to break new ground in the biofiltration field, further research about the microbial composition and distribution in biotrickling filters is needed in order to fully understand the underlying processes that take place in these systems. Quantification of populations would help to hypothesize about the causes of changes in the microbial community composition and to understand the relation between phylogeny and reactor efficiency.

Keywords: sequencing batch biofilm reactor (SBBR), support, nitrogen removal, poly-β-hydroxybutyrate (PHB)
Topic: Integration of life sciences & engineering (Improvement of environmental remediation processes).

Abstract

The aim of this work was to assess the feasibility of a Sequential Batch Biofilm Reactor (SBBR) to perform carbon and nitrogen removal: from support design to reactor operation. The experimental part was conducted in two phases. In the first phase, different supports were tested to select the most suitable one for SBBR operation. In the second phase, the most appropriate support was used in a SBBR to perform carbon and nitrogen removal. The results demonstrate that the support with the highest internal surface area presented a higher biomass accumulation. Time profiles of nitrogen ions and acetate concentration showed the typical behaviour of a SBBR performing carbon and nitrogen removal. Poly-β-hydroxybutyrate (PHB) was formed immediately after acetate depletion and was subsequently consumed for biomass growth, owing to the high oxygen concentration in the reactor.

1. Introduction

The Sequential Batch Reactor (SBR) has been used to remove organic carbon and nutrients from wastewater in one single unit under properly controlled conditions (Brito et al., 1997; Rodrigues et al., 2001). The SBR can be combined with biofilm growth on the surface of a support material, originating the Sequencing Batch Biofilm Reactor (SBBR). In SBBR systems high concentrations of biomass can be maintained independently of the sedimentation characteristics of the biological aggregates and the hydraulic retention time of the reactor. SBBRs are particularly suitable when the required microbial population grow very slowly or when the biomass yield is low (Vieira et al., 2008).

Microorganisms in SBRs are exposed to continuous periodic environmental changes, namely varying liquid volumes and substrate concentrations (donors and receivers of electrons). When confronted with such interchanging periods of high ("feast period") and low ("famine period") substrate concentrations, bacterial populations adopt specific survival strategies. In particular, they often accumulate and set aside organic carbon as internal polymers such as poly-β-hydroxybutyrate (PHB). While such storage phenomena are well studied for suspended biomass systems, as for example SBRs, they are still poorly documented in literature for systems using biofilms, such as the SBBRs (Alves et al., 2004). Nevertheless, they do play an important role in the optimization of operating strategies, which holds particularly true for multiple and interlinked degradation pathways, such as the nitrogen and carbon removal by biological nitrification and denitrification. Therefore, the aim of this work was to assess the feasibility of a SBBR to perform carbon and nitrogen removal: from support design to reactor operation.

2. Materials and methods

2.1. Experimental set-up

In the first phase of the experimental work, biomass adhesion and biofilm formation was evaluated in a new developed thermoplastic support (*DupUM*) and in two supports currently available on the market (*Biolox10* and *Bioflow30*) (Table 1). Three SBBRs with working volumes of 2.5 L filled with different supports were operated in parallel. The bed formed by the supports occupied 47 % of the reactors volume. The reactors were operated with a constant cycle time of 6.2 h, a volume exchange ratio of 0.8 L/L and a resulting hydraulic retention time (HRT) of 7.75 h. The duration of the individual operating phases was: 102 min mixed fill, 150 min aerated, 114 min settle and 10 min draw. During the aerated phase airflow was applied through membrane diffusers, causing the reactor contents including the carrier bed to circulate. In the first operation period (days 0 – 127), a synthetic wastewater with acetate as the only carbon source and ammonium as nitrogen source was used. The carbon and nitrogen ratio (C/N) used was 6.25. At day 127, the carbon and nitrogen concentration in the system was increased from 500 mg/L and 80 mg/L to 750 mg/L and 120 mg/L, respectively. The SBBRs were inoculated with biomass from a nitrification/denitrification unit treating effluent from a brewery industry.

Table 1. Characteristics of supports.

Support	Material	Dimensions (mm)	Nº pieces/m^3	Specific surface area (m^2/m^3)
 *DupUM*	PE [a]	height: 10.0 Diameter: 17.0	324 900	407
 *Bioflow30*	PP [b] Recycled	height: 30.0 Diameter: 32.0	21 910	320
 *Biolox10*	PE Recycled	height: 10.0 diameter: 9.5	538 922	640

a) Polyethylene; b) Polypropylene

In the second phase, a SBBR with a working volume of 28 L was operated with a constant cycle time of 5 h, a volume exchange ratio of 0.36 $L \cdot L^{-1}$ and a HRT of 14 h. The duration of the individual operating phases was: 115 min mixed fill, 165 min aerated and 20 min draw. The biofilm was formed on the support selected in the previous phase of the experimental work. The SBBR was operated with synthetic water. The composition of the synthetic substrate solution was: 643 $mg \cdot L^{-1}$ $NaCH_3COO \cdot 3H_2O$, 130 $mg \cdot L^{-1}$ NH_4Cl, 210 $mg \cdot L^{-1}$ $NaHCO_3$, 44 $mg \cdot L^{-1}$ KH_2PO_4, and 1 $mL \cdot L^{-1}$ of a trace element solution in accordance with Vishniac and Santer (1957). The reactor was inoculated with the selected supports coming from the previous phase.

2.2. Analytical methods

The thermodynamic characterization of the interaction support material-biomass was evaluated using contact angle measurements. Contact angles were measured using sessile drop method at 20ºC with distilled water, formamide and 1-bromonaphthalene.The measurements were carried out in a standard contact angle apparatus (Kruss-GmH, Hamburg).

Grab samples were taken and analyzed for ammonium, nitrite, nitrate and chemical oxygen demand (COD) according to *Standard Methods*. The biofilm accumulation on supports was

estimated as dry weight measurements. PHB content of suspended biomass and biofilm (external and internal) was measured by gas chromatography (GC) using the method developed by Smolders et al. (*1994*).

2.3. Calculations

The Extended Derjaguin-Landau-Verwey-Overbeek theory (XDLVO) was used to assess the affinity of the individual support materials to biomass adhesion (van Oss, 1989).

Mass balance calculations were based on an assumed elemental composition of $CH_{1.8}O_{0.5}N_{0.2}$ for 1 Cmol biomass (Beun et al., 2002). The carbon consumption of hereotrophic growth was calculated based on the observed ammonium consumption and a biomass formation rate per mole of acetic acid of 0.40 Cmol·Cmol^{-1} (Beun et al., 2002). Stoichiometric considerations for energy production lead to the following rates of acetate consumption with respect to nitrate, nitrite, and oxygen: 1.25 Cmol acetate·mol^{-1} NO_3^-, 0.5 Cmol acetate· mol^{-1} NO_2^- and 1 Cmol acetate·mol^{-1} O_2, respectively. It was assumed that nitrification is performed by ammonium and nitrite oxidizing bacteria with a biomass formation yield of 0.057 Cmol mol^{-1} NH_4^+ and 0.034 Cmol mol^{-1} NO_2^-, respectively (Henze et al., 1995).

3. Results and Discussion

3.1. Supports surface properties

The free energy of adhesion between the biomass and the support surface immersed in water was calculated to foresee the biofilm adhesion on the supports. According to the results obtained, the surface properties of *Biolox10* and *DupUM* (with values of ΔG of -34.60 mJ.m^{-2} and -30.16 mJ.m^{-2}, respectively) are more favourable to biomass adhesion than the one of *Bioflow30* (-4.04 mJ.m^{-2}) due to their lower free energy of adhesion (Salerno et al., 2004).

3.2. Biofilm formation in supports

The biofilm accumulation profile expressed as dry weight per specific surface area is presented in figure 1.

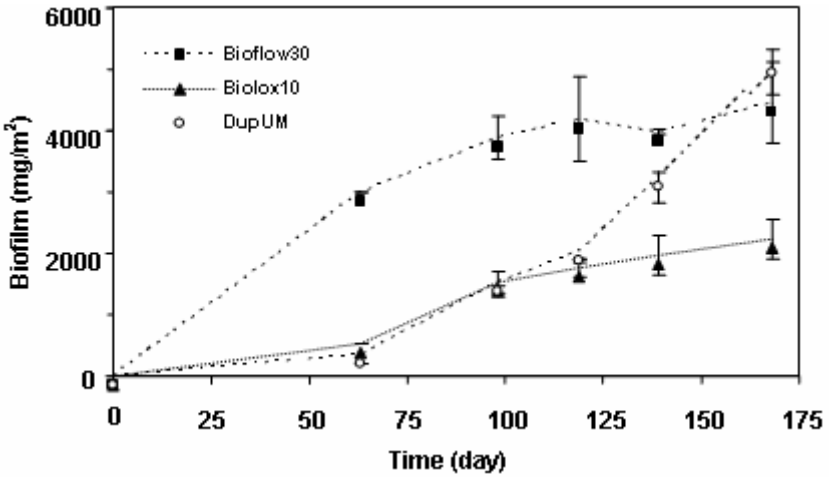

Figure 1. Biofilm accumulation on supports surfaces expressed as dry weight per specific surface area.

Biolow10 and *DupUM* displayed a very slow biofilm growth, whereas *Bioflow30* presented an initial biofilm growth about six times higher. This may be related to the different detachment forces in the reactors as a result of the support geometry. For the same fraction of support

(47 %) and as a result of the different dimension of the supports, the number of support pieces was considerably different in each reactor. This difference is higher for *Biolox30*, where there were only 26 support pieces in the reactor, which is much less than the number of pieces in the reactors with *Biolox10* and *DupUM* (around 633 pieces and 381 pieces, respectively). Hence, the occurrence of collisions and their intensity are expected to be different in the reactors. Probably, the abrasion forces which result from the collisions caused by the high number of pieces of *Biolox10* and *DupUM* in the respective reactors have conditioned initially the biofilm formation on the respective supports.

From day 127, the concentration of carbon and nitrogen in the reactors was increased. Biofilm accumulation on *Bioflow30* and *Biolox10* did not change significantly compared to the increase of biofilm mass observed on *DupUM*. These results have shown that biofilm accumulation on *DupUM* was limited by the amount of available substrate. After 168 days, *DupUM* presented a higher biomass accumulation per unit of surface area (5096 $mg.m^{-2}$) than *Biolox10* and *Bioflow30* (2231 $mg.m^{-2}$ and 4454 $mg.m^{-2}$, respectively). Based on these experimental results *DupUM* was selected for the next phase of the experimental work.

The thermodynamic approach did not allow us to foresee the biofilm formation on the supports. The results obtained through the thermodynamic characterization indicated that *Bioflox10* and *DupUM* had more favourable surface properties to the initial adhesion of biomass than *Bioflow30.* However, after 120 days of reactors operation, *Bioflow30* showed higher biofilm accumulation than the other supports. According to Gjaltema et al. (1997), in airlift reactors the biofilm adhesion and formation is dominated by the reactor hydrodynamic conditions and by collisions among particles. The results from biomass adhesion and biofilm formation studies obtained in the present work suggest that the hydrodynamic conditions established in the reactors and the geometry of the supports played a crucial role in biofilm formation. Biofilm growth was favoured in the supports that presented a higher internal surface area that protected biofilms from erosion and abrasion detachment mechanisms.

3.3. Reactor performance

Figure 2 depicts profiles of nitrogen ions, acetate as COD and dissolved oxygen (DO), during a typical SBBR cycle.

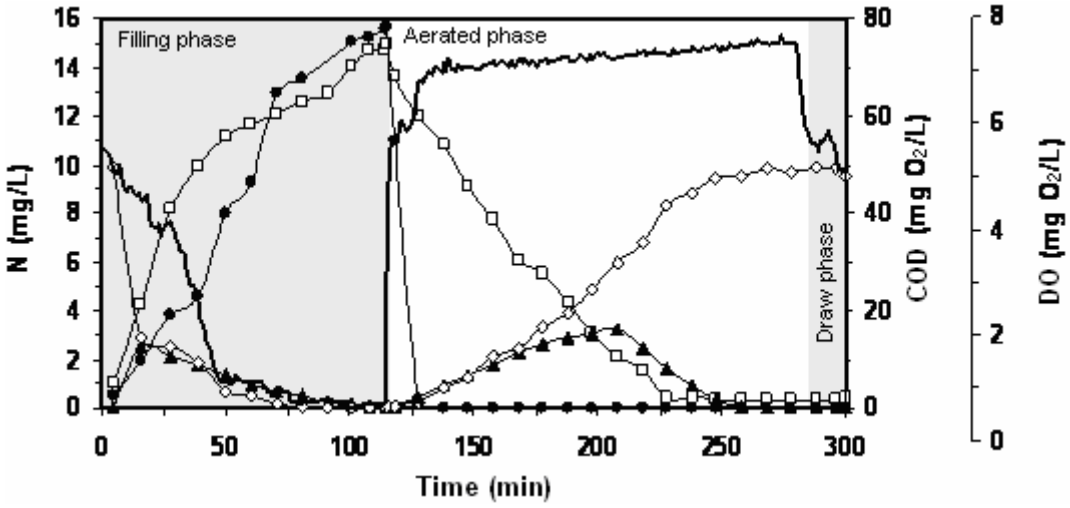

Figure 2. COD (●), DO (-), ammonium (□), nitrite (▲) and nitrate (◊) profiles during a SBBR cycle.

During the mix fill phase, the nitrate left over from the previous cycle was completely denitrified with acetate, so that no nitrite accumulation was observed. Time profiles of ammonium, nitrite and nitrate concentration in the aerated phase showed the typical behaviour of nitrification reactions, via nitrite formation and subsequent oxidation to nitrate. A

nitrogen balance of this phase showed that 66 % of ammonium supplied was oxidized to nitrate with the remainder being used for biomass growth.

According to these results, 46 % of carbon supplied was consumed during the mixed fill phase with the remainder being consumed in the aerated phase. Based on mass balances in the fill phase, it was possible to estimate that 15 % of carbon was used to the growth of biomass, 25 % was used as a source of energy and the remaining 60 % were removed by unknown mechanisms. The quantification of PHB in the biomass has allowed complementing the balance of carbon during the operation cycle illustrated in figure 2. Figure 3 presents schematically the main carbon fluxes in the SBBR.

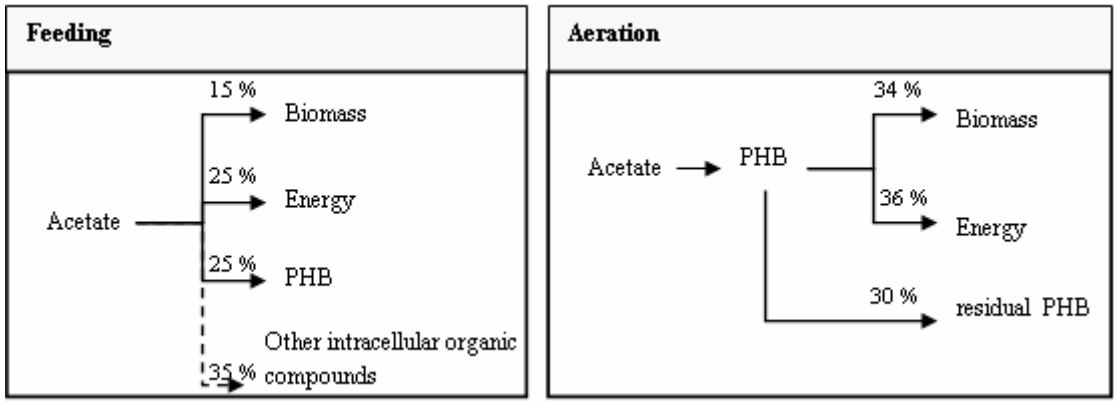

Figure 3. Fate of carbon added as acetate in the feeding and the aeration phase of the SBBR.

As illustrated, the carbon portion missing at the end of the feeding phase was stored as PHB (25 %), while the remaining 35 % were removed by another mechanism such as conversion to intracellular intermediary composts of a low molecular weight or storage as another PHA, besides PHB (Dionisi et al., 2001).

The acetate present at the beginning of the aeration phase is quickly converted and stored in the biomass as PHB. After acetate depletion, a part of the PHB (70 %) is consumed as a source of carbon and energy, while the rest is stored in the biomass (30 %). According to the reactions' stoichiometry, the organic carbon transformed into PHB during the aeration phase would be sufficient to denitrify the entire nitrate previously produced. This did not occur, however, probably due to the high concentration of oxygen dissolved in the liquid. Instead the PHB was consumed in the production of biomass and in energy needs.

Suspended biomass was revealed to play a significant role in the carbon removal mechanism: about 79 % of the total PHB formed was stored in the suspended biomass, although this biomass represented only 20 % of the total biomass present in the reactor. This important result might be attributed to the higher accessibility of suspend biomass to acetate, due to existence of lower mass transfer limitation.

4. Conclusions

Biomass adhesion and biofilm formation studies suggest that the hydrodynamic conditions established in the reactors and the geometry of the supports played a crucial role in biofilm formation. Biofilm growth was favoured in the supports that presented a higher internal surface area that protected biofilms from erosion and abrasion detachment mechanisms.

According to the operation phase of the SBBR, there are two relevant mechanisms in the removal of acetate in the SBBR: (1) use of the acetate simultaneously with the growth of biomass and in the metabolism of PHB storage (feeding phase); and (2) direct storage of the acetate as PHB which is later on used in the growth of biomass (aeration phase). The consumption of acetate and its storage as PHB is mostly carried out by the biomass in suspension. Although the biomass in suspension represented only 20 % of the total biomass

present in the reactor, 79 % of the total PHB formed was stored in the biomass in suspension. This result is due to the lower mass limitations of the biomass in suspension in comparison with the biofilm.

Lignocellulosic Materials as a Feedstock for Polymer Synthesis

Matjaž Kunaver[1*], Edita Jasiukaityte[1], Vesna Tišler[2], Sergej Medved[2]
[1] National Institute of Chemistry, Hajdrihova 19, SI-1000 Ljubljana, Slovenia.
[2]University of Ljubljana, Biotechnical Faculty, Wood Science Department, Rožna dolina Cesta VIII/34, SI-1000 Ljubljana, Slovenia

Keywords: Liquefied wood, polyester synthesis, adhesives,
Topic: Sustainable process-product development through green chemistry.

Abstract

Wood is one of the most abundant natural polymer, and despite its complex composition it can be used as a potential renewable feedstock for polymer production. The first step is the liquefaction of wood with multifunctional alcohols. The products are low molecular mass liquid oligomers. Liquefied wood can be prepared using all kind of wood biomass, like wood meal and wood residues from wood furniture industry, wood waste from building industry, broken furniture, waste paper and other materials based on cellulose. Glycerine, the industrial byproduct from the production of biodiesel can be utilized in some experiments as the main reactant. Such a reaction mixture is made of 97% of waste material.

In our research native hardwoods and softwoods were liquefied with different glycols and acidic catalyst. The liquefaction took place at 150 – 180 °C for 0.5 - 3 h with more than 95% yields. We have been the first worldwide to utilize the liquefied wood as the feedstock for the synthesis of different polyesters where the liquefied wood is been incorporated into a large polymeric molecule. Such polymers have a potential use in composites, adhesives and polyurethanes. Unsaturated polyesters were prepared by reacting liquid wood with maleic and phthalic acids. Polyester polyols were prepared by using adipic acid. These polymers were reacted with isocyanates to give a series of polyurethane foams that were comparable with commercial foams and could be used for isolation purposes.
Such utilization of lignocellulosic materials can reduce the crude oil consumption and might increase the use of the renewable resources in large extent.

Introduction

Biomass conversion to ethanol, diesel fuel and bio based chemicals are recently the most intensive research goals. However, much remains to be done in synthesis, analysis and characterisation if these materials are to replace the materials, otherwise produced from crude oil. Several attempts to elucidate the mechanisms associated with the liquefaction of lignin, of cellobiose and of cellulose have been published. The liquefaction of lignin with phenol has been studied on the basis of the behaviour of model substances, such as guaiacylglycerol-β-guiacyl ether (Lin et al., 2001), (Lin, Nakagame et al., 2001) . According to Lin et al. the reaction starts with hydrogen ion from acid catalysis attack of β-hydroxyl groups of lignin and it is followed by substitution reaction in C-β of obtained intermediates after scision of unstable β-O-4 linkage. The cellulose behaviour in acidic ethylene glycol was studied by Yamada and Ono (2001). In their paper, the authors proved the formation of ethylene glycol – glucosides in the early stage of liquefaction. These later decomposed into the 2-hydroxyethyl levulinate.
The preparation of low-cost polyols from biomass materials has been investigated by several research groups using different reagents. Kržan and Kunaver (2006) applied microwaves

* Corresponding author. Tel + 386 1 476 0363. E-mail: matjaz.kunaver@ki.si

radiation as the heating source. Cellulose and cellulose derivatives can be considered to be polyhydric alcohols. In the liquefaction process, the presence of hydroxyl group-containing species in the wood components can be used as the polyols for several different purposes. The polyhydric units that are present in the resulting liquefied/derivatised wood can be used in the creation of polyurethane foams, polyurethane resin precursors (Wei et al., 2004) and in the recently developed wood-polyalcohol based urethane adhesives (Tohmura et al., 2005). Lee et al. (2005) have studied the thermal stability, biodegradability and genotoxicity of a range of polyurethane foams that were produced from polyols made from waste paper. They found that the foams possessed the same thermal stability as those made from liquefied starch or wood. The hydroxyl value of the liquefied wood has been determined by several authors and is generally determined to be between the equivalent of 200 and 500 mg of KOH/g. The actual value depends on the liquefaction time. This high number of hydroxyl group sites means that the products have application in those areas in which the hydroxyl component can be used in complex polyester synthesis. Some benefits could be expected from such systems. These include the incorporation of the biomass components into the polymeric compositions and consequently, the provision of a certain degree of biodegradability. The work presented here offers a new approach to the utilisation of the liquefied/derivatised wood in the creation of novel polymeric composite materials.

Materials and methods

Materials

Wood saw dust of poplar (Populus *spp*.), oak (Quercus *spp*.), spruce (Picea *spp*.) and beech (Fagus Sylvatica) were sieved through 1.25 mm^2 screens and dried at room temperature to a constant water content. Waste corrugated board was cut into 10 mm to 10 mm pieces and used without further modification.

Glycerol, diethylene glycol, p-toluene sulfonic acid (pTSA), sulphuric acid, adipic acid, phthalic acid anhydride, dimethylacetamide, styrene and dibutyl tin oxide of reagent grade were used without further purification.

Liquefaction/derivatisation of wood saw dust and waste corrugated board

The respective polyhydroxy alcohol (300g), p-toluene sulphonic acid (9g) and wood saw dust or pieces of corrugated board (100g) were placed into the 1000 cm^3 three necked glass reactor, equipped with the mechanical stirring. Liquefaction was conducted with constant stirring at 150^{o}C to 160^{o}C for 90 minutes. The extent of liquefaction was evaluated by determining the residue after the washing out the reaction mixture with N,N-dimethylacetamide and acetone. The residue was dried in an oven at 110^{o}C to constant weight. The residual ratio was calculated as the weight percentage based on the starting wood material.

Synthesis of polyester polyols and unsaturated polyesters from the liquid/derivatised wood

The liquefied/derivatised wood or corrugated board mixture (400g) was introduced into the four-necked 1000 cm^3 glass reactor, equipped with a water condenser and mechanical stirrer. The reactor was placed in an electric jacket heater. 300g of adipic acid or of phthalic acid anhydride (depending on the required product) were added and 0.6g of dibutyl tin oxide as the transesterification catalyst. The mixture was heated gradually up to 220^{o}C under stirring and was held at this temperature. Water was continuously distilled from the reaction system. A sample was withdrawn periodically from the reaction system and its acid value was determined. After completion of the reaction, when the acid value was reduced to less than 30mg KOH/g, the reaction mixture was cooled to an ambient temperature.

Similar procedure was used for the synthesis of unsaturated polyesters. The formulations are shown in Table 1.

Table 1. Typical formulations for the synthesis of unsaturated polyesters and polyester polyols

Polyester Polyol	Unsaturated polyester
400g Liquid wood	400g Liquid wood
300g Adipic acid	224g Maleic anhydride
0.6g Dibutyl tin oxide	320g Diethylene glycol
	160g Phthalic anhydride
	1.1g Dibutyl tin oxide

Unsaturated polyester was inhibited with 100ppm of hydroquinone and diluted to 60% solids with styrene.

Polyester characterization

Measurement of hydroxyl number and acid number of liquid wood and liquid/derivatised wood species

The hydroxyl numbers of liquid wood and its derivatives were determined according to the method described elsewhere (ASTM).

FTIR Spectroscopic analysis

All of the spectra were obtained using a Perkin-Elmer Spectrum-1 FTIR spectrophotometer. The liquid/derivatised wood samples were applied on NaCl crystal as a thin film. Transmittance spectra were measured in the wavelength range from 4000 cm^{-1} to 500 cm^{-1}.

GPC measurements

Gel permeation chromatographic representations were obtained on an HP – AGILENT system, consisting of isocratic pump HP 1100, a refractive index detector AGILENT 1100 and a Perkin Elmer LC235 diode array detector. Two PLgel columns, connected in series (Plgel 100Å, 5um, Plgel 50Å, 5µm), were used. Poly(styrene) standards were used for the calibration curve. The mobile phase was prepared from N,N-dimethylacetamide containing 0,05M LiBr. The latter was added in order to prevent interaction between the sample molecules and stationary phase. The mobile phase flow rate was 1cm^3/min.

RESULTS AND DISCUSSION

The liquefaction process gave yields of the liquefied wood that were in excess of 98%. The typical reaction yields are shown in Figure 1 for two different wood meals. It is clear that at least 90 minutes of reaction time, under the specified heating regime, is needed if unwanted residues are to be minimised. Apparent further condensation occurs with longer reaction time, increasing the amount of the residue formed in lignocellulosic materials where lignin is also present. The liquefaction of waste corrugated board was completed in 90 minutes with 100% yield.

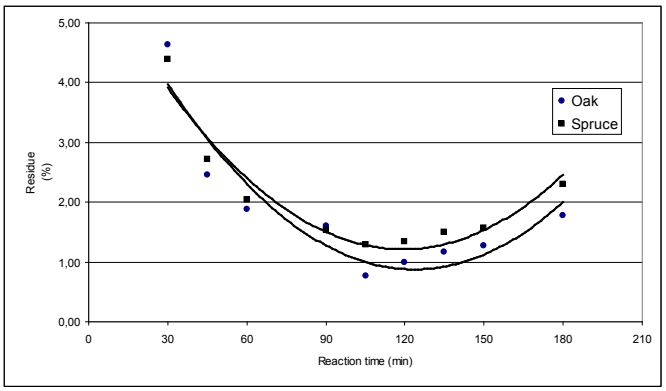

Figure 1: Reaction yields: Liquefaction of Oak and Spruce wood meals. Wood meal to glycerine ratio 1:4; 3% pTSA acid catalyst.

Each of the liquefied wood species was characterised using FTIR spectroscopic evaluations and by gel permeation chromatography/size exclusion chromatography (GPC/SEC). The results of this characterisation and analysis showed that each of the liquefied/derivatised wood products gave very similar FTIR spectroscopic profiles and GPC/SEC characteristics. For the reaction product arising from the liquefaction/derivatisation of the poplar wood meal, at different reaction times, the spectral information shown in Figure 2 was obtained.

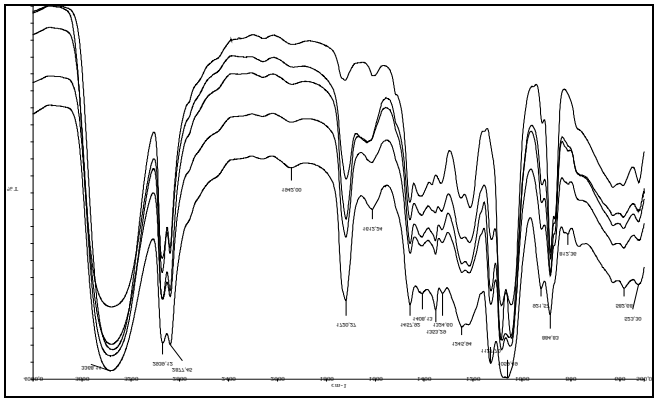

Figure 2: FTIR spectrum of products derived from the liquefied poplar wood samples that were isolated every 15 minutes of reaction: top spectrum - after 30 minutes, lower spectrum – after 120 minutes

With respect to the influence of the time of reaction, the intensity of the 1721 cm^{-1} (C=O stretching) band increased during such reaction because of the formation of the levulinic acid ester of diethylene glycol, (DEG) which is produced by solvolysis of cellulose through cleavage of the β-1,4-glycosidic linkage. The presence of this compound was also verified by identification using GC/MS analysis. The concentration increased during the process of liquefaction.

Liquid wood readily reacted with appropriate dibasic acids to yield a higher molecular mass resin of acceptable viscosity and with appropriate OH numbers. Acid addition was adjusted to either theoretical or experimentally determined OH numbers. The solid remains after liquefaction could be kept in the mix as a filler.

Theoretically all of the hydroxyl groups could be esterified during the polyester synthesis. A liquefied wood with a hydroxyl value 500 mg of KOH/g for complete esterification would need 8.9 mM/g of organic acid. However, such a complete reaction is never achieved due to differences in reactivity of the hydroxyl groups. A certain proportion of the hydroxyl groups are left unreacted since in the case of the polyurethane synthesis they are needed for the polycondensation reaction with the polydiiocynate.

In our studies we have reduced the hydroxyl value from between 500 and 600 mg of KOH/g to values between 10-25 for unsaturated and 150-200 for saturated polyester. As a result of the utilization of liquefied wood in polyester-polyol synthesis, 45% to 25% of polyhydric alcohols were replaced with liquefied wood. The reactivity and the hydroxyl value remained in the range of commercial products.

The liquefied/derivatised wood meals (based on oak meal, beech meal, spruce meal and poplar meal) and the corresponding polyester based materials that were derived from reaction between the liquefied/derivatised wood meal and phthalic acid were subjected to GPC/SEC analysis. The resulting chromatograms were all very similar. Figure 3 gives the chromatogram of the unsaturated polyester derived from the liquefied poplar wood meal and Figure 4 the chromatogram of the liquefied poplar wood and its corresponding phthalate ester.

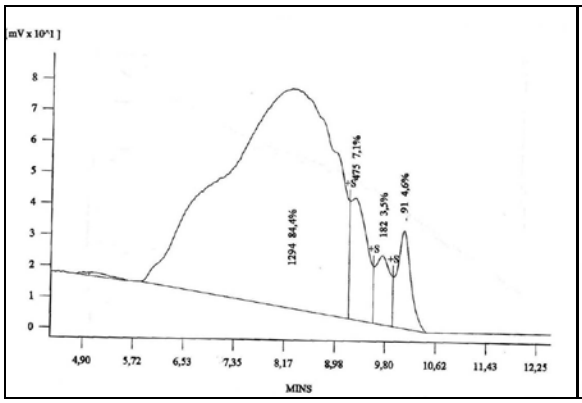

Figure 3. SEC curve of unsaturated polyester resin

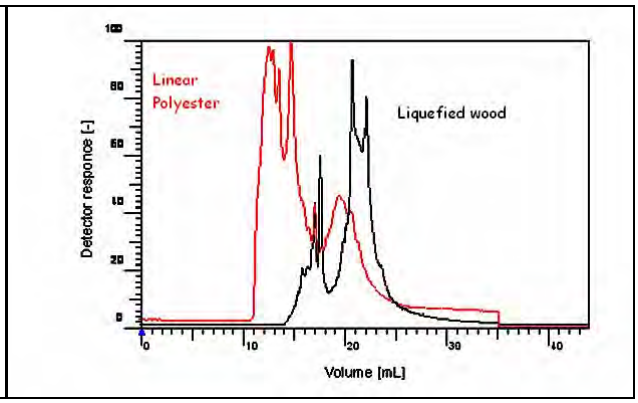

Figure 4. SEC curve of liquefied poplar wood and polyester polyol

Resin use

Unsaturated polyesters were dissolved in styrene and resins were crosslinked with a peroxide initiator and showed normal reactivity. The liquefied wood concentration in 100% unsaturated polyester resin was from 22% to 29%. Saturated polyesters were reacted with MDI isocyanate in the presence of standard foam forming additives. Compressive strength at 10% strain was 46kPa – 74kPa and density from 0.03 g/cm^3 to 0.05g/cm^3. Polyurethane foams appeared less hydrophilic than foams derived directly from liquefied wood.

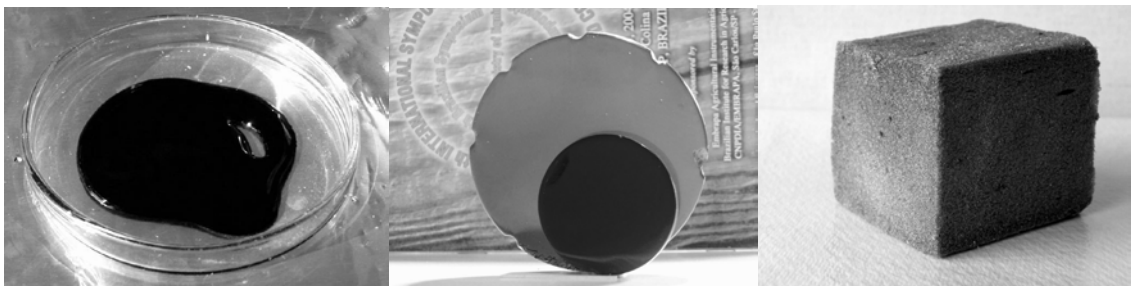

Figure 5: Liquefied wood (left), unsaturated polyester (middle), polyurethane foam (right)

Conclusions

Liquefied/derivatised wood can be used as one of the components in polyester synthesis due to the large number of hydroxyl groups available in the liquefied/derivatised wood. By using adipic acid and phthalic acid anhydride as reagents in the polyester synthesis, polyesters

have been synthesised that have a molar mass distribution that is similar to that of the commercial linear polyesters that are used for polyurethane foam production. 45% of the raw materials that would otherwise be in the linear polyester creation were, thus, replaced with wood. This amount varies according to product requirements.

Linear polyesters that are based on liquid wood species show similar application properties to those of commercial wood composites. They can be used in combination with melamine resin precursors, as wood adhesives in fibre-wood boards production and in plywood boards production as well as in polyurethane foam preparation. The properties of wood based linear polyester and unsaturated polyester products and their potential use are the subject of current further research.

Keywords: *Saccharomyces cerevisiae*, bioethanol, transporter, xylose, xylose isomerase
Topic: Integration of life science & engineering

Abstract

We constructed *Saccharomyces cerevisae* strain with the xylose isomerase (XI) as the xylose metabolic pathway by multicopy integration of the XI overexpression cassette into the yeast genome. Resulting yeast MT8-1/XKSδXI successfully produced ethanol from xylose as the sole carbon source. Furthermore, MT8-1/XKSδXI strain could also produce ethanol from the mixture of glucose and xylose. These results indicated that MT8-1/XKSδXI strain could be applied to ethanol production from lignocellulose hydrolysate.

1 Introduction

Bioethanol production from lignocellulosic biomass, such as wood, is one way to avoid the problem of competition with food. Glucose and xylose are major components of the lignocellulosic biomass, and the efficient utilization of not only glucose but also xylose is advantageous for large-scale ethanol production. Since the wild type strain of *Saccharomyces cerevisiae* could not metabolite xylose, the engineering of recombinant strains having xylose metabolic pathway has been well investigated previously by various research groups. To be more precise, many research groups introduce xylose reductase (XR)-xylose-xylose dehydrogenase (XDH) as the xylose metabolic pathway. However, the difference of cofactor preference between XR and XDH frequently causes xylitol accumulation and limits the xylose metabolic flux (*Rizzi et al.*, 1989a, b, Toivari *et al.*, 2001). In this study, we selected xylose isomerase (XI) pathway and integrated XI overexpression cassette in yeast genome. The recombinant yeast strain having XI pathway was applied to the fermentation of ethanol from xylose and the mixture of xylose and glucose.

2 Materials and methods

Strains and media

Escherichia coli NovaBlue (Novagen Inc., Madison, WI.) was used as the host strain for recombinant DNA manipulation. *S. cerevisiae* MT8-1 (*MAT**a** ade his3 leu2 trp1 ura3*) (Tajima *et al.*, 1985) was used for introduction of xylose metabolic pathway and fermentation. *E. coli* was cultivated in Luria-Bertani (LB) medium (1% (w/v) tryptone, 0.5% yeast extract and 0.5% sodium chloride) containing 100 μg/ml ampicillin. Yeast was cultivated in YPD medium (1% (w/v) yeast extract, 2% peptone and 2% glucose) or SD medium (0.67% (w/v) yeast nitrogen base supplemented with appropriate amino acids and nucleotides and 2% glucose). For solid media, 2% (w/v) agar was added to the media described.

Construction of plasmids

The pLXKS for overexpression of *S. cerevisiae* xylulokinase (XK) *XKS1* was constructed as follows. A DNA fragment composed of the glyceraldehyde-3-phosphate

* Corresponding author. Tel + 81-78-803-6199. E-mail:ohmura@kobe-u.ac.jp

dehydrogenase (GAPDH) promoter, XK and GAPDH terminator from *S. cerevisiae* was prepared by polymerase chain reaction (PCR) with the following primers: SacII-pGAP (5'-ATTACCGCGGACCAGTTCTCACACGGAACACC-3') and tGAP-XhoI (5'-GCCCGCCTCGAGTCAATCAATGAATCGAAAATGTC-3'), with plasmid pWX1X2XK (Katahira et al., 2004) as template. The amplified fragment was digested *Sac*II and *Xho*I; it was inserted into *Sac*II and *Xho*I site of pRS405 (ATCC87516).

The pδWOXYLA1 for δ integration of XI from *Orpinomyces* sp. *OXYLA1* (under preparation) overexpression cassette into the yeast genome was constructed as follows. Three DNA fragments containing 167 bp of 5' region of□ sequence, 167 bp of 3' region of δ sequence and *TRP1* deficient marker (*TRP1*d) were amplified from the genome of *S. cerevisiae* BY4741 by PCR with the following primers: DS1-(F)-SacI (5'-ATGCGAGCTCTGTTGGAATAGAAATCAACT-3') and DS-167+AscI(R)-SacI (5'-GCATGAGCTCGGCGCGCCATGTTTATATTCATTGATCCTA-3'), DS168+AscI(F)-KpnI (5'-ATGCGGTACCGGCGCGCCATAAAATGATGATAATAATATT-3') and DS-334(R)-KpmI (5'-GCATGGTACCTGAGAAATGGGTGAATGTTG-3'), and TRP1d(F)-XhoI (5'-ATGCCTCGAGTGGAGTATGTCTGTTATTAA-3') and TRP1 (R)-XhoI (5'-GCATCTCGAGTGCAGGCAAGTGCACAAACA), respectively. The amplified fragments were digested *Sac*I, *Kpn*I and *Xho*I, respectively; they were sequentially inserted into *Sac*I, *Kpn*I and *Xho*I sites of pBluescript II KS+ (Agilent Technologies, Inc., Santa Clare, CA.). The resulting plasmid vector was named p□W. A DNA fragment composed of the GAPDH promoter, *OXYLA1* and GAPDH terminator was prepared by PCR with following primers: pGAP-SacI-F (5'-cggccgcggACCAGTTCTCACACGGAACACCACTAATGGA-3') and tGAP-NotI-R (5'-ATTTTAATGACATTTTCGATTCATTGATTGAgcggccgccgg-3') with plasmid pWOXYLA1 (under preparation) as template. The amplified fragment was digested *Sac*I and *Not*I site; it was inserted into *Sac*I and *Not*I site of pδW. The resulting plasmid vector was named pδWXI.

Yeast transformation

The expression plasmid pLXKS was digested with *Hpa*I at *LEU2* maker loci and transformed into *S. cerevisiae* MT8-1 cells using YEAST MAKER™ (Clontech Laboratories Inc.) according to the protocol specified by the supplier. The resulting transformant was named MT8-1/XKS. Subsequently, the expression plasmid pδWXI was also digested with *Asc*I and transformed into MT8-1/XKS using YEAST MAKER™. The resulting transformant was named MT8-1/XKSδXI.

Fermentation

The xylose-utilizing yeast MT8-1/XKSδXI was aerobically culticated in SDC medium (0.67% (w/v) yeast nitrogen base supplemented with appropriate amino acids and nucleotides, 0.5% glucose and 2% Casamino acids) for 48 h at 30°C. The cells were collected by centrifugation for 5 min at 3,000 x g and washed with distilled water twice. Two g wet cell weight of collected cells was inoculated into 50 ml of fermentation medium, containing 1% (w/v) yeast extract, 2% peptone and various concentrations of glucose and xylose. Ethanol fermentation was carried out in 100-ml closed bottles equipped with a bubbling CO_2 outlet. All fermentations were performed at 30°C with mild agitation. Ethanol and sugars were measured by HPLC analysis described in the next section.

HPLC analysis

HPLC analysis of fermentation medium was performed by using a refractive index detector (model RID-10A; Shimadzu, Kyoto, Japan). The column used for separation was a Shim-pack SPR-Pb column (Shimadzu). The HPLC apparatus was operated at 80°C with water at a flow rate of 0.6ml/min as the mobile phase.

3 Results

Fermentation from xylose

For introduction of the xylose metabolic pathway to the *S. cerevisiae* MT8-1 strain, one copy of XK overexpression cassette and multicopy of XI overexpression cassettes were introduced into the MT8-1 strain genome. To confirm the xylose fermentation ability, MT8-1/XKSδXI was applied to the fermentation from xylose as the sole carbon source without adaptation. Figure 1 shows the time course of the fermentation. MT8-1/XKSδXI consumed xylose and produced ethanol and byproduct, xylitol and glycerol. This result shows that MT8-1/XKSδXI have xylose fermentation ability. Ethanol productivity of up to 104 h of fermentation was 0.13 g per liter per h, and the ethanol yield was 0.30 g per g of xylose-consumed consumption.

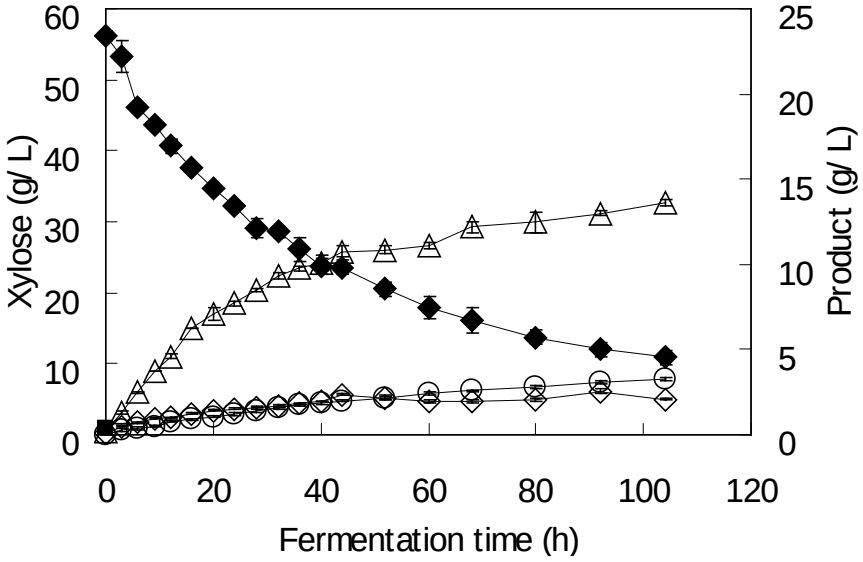

Figure 1. Time course of fermentation from xylose as the sole carbon source by MT8-1/XKSδXI. Xylose (closed diamonds), ethanol (open triangles), glycerol (open diamonds) and xylitol (open circles) contents were measured by HPLC.

Ethanol production in a mixed culture medium consisting of mixture of glucose and xylose

Figure 2 shows the time course of the ethanol production using MT8-1/XKSδXI strain in a mixed culture medium consisting of mixture of the same amount of glucose and xylose. Ethanol and byproduct productions from the mixed culture medium were observed. Ethanol production associated with the glucose consumption was rapidly finished (12 h). In contrast, ethanol production associated with the xylose consumption was slow, but comparably slow rate of ethanol production was observed.

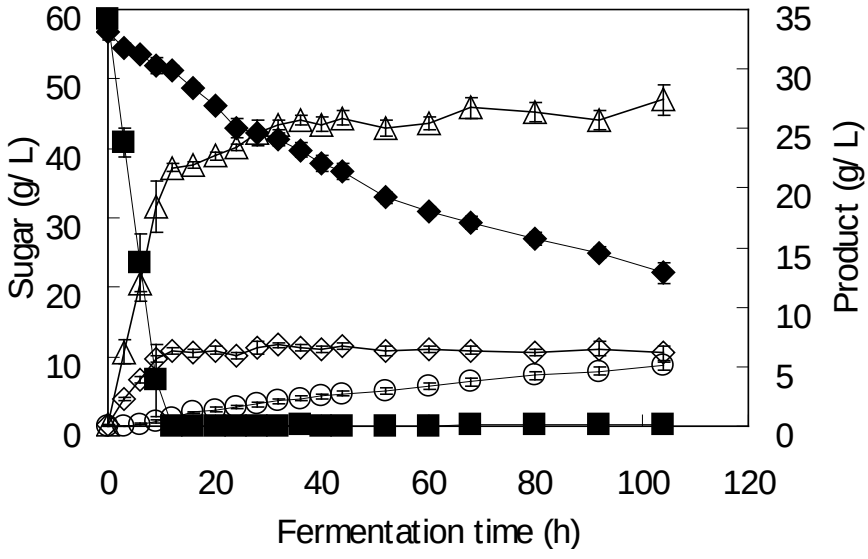

Figure 2. Time course of fermentation from mixture of glucose and xylose by MT8-1/XKSδXI. Glucose (closed squares), Xylose (closed diamonds), ethanol (open triangles), glycerol (open diamonds) and xylitol (open circles) contents were measured by HPLC.

4 Discussion

In the present study, we constructed xylose metabolic yeast with XI pathway by the multicopy integration of XI overexpression cassettes into the genome of *S. cerevisiae* MT8-1 strain. The resulting strain MT8-1/XKSδXI successfully produced ethanol from xylose as the sole carbon source without adaptation (Fig. 1). To the best of our knowledge, this is the first report of xylose metabolic *S. cerevisiae* with the XI pathway by the integration of XI expression cassette into the genome. However, the ethanol yield is very low and a relatively large amount of xylitol (0.07 g per g consumed xylose) was produced. The xylitol production results from the unspecific aldose reductase *GRE3*, and the deletion of *GRE3* is important for the decrease of xylitol production (Träff *et al.*). Kahumaa introduced *Piromyces* sp. XI into the TMB 3044 strain by multicopy plasmid and achieved the ethanol yield 0.43 g per g consumed xylose with 0.04 g per g consumed xylose (Kahumaa *et al*. 2007). The TMB 3044 strain contains deletion of *GRE3* and additional over expressed non-oxidative pentpse phosphate pathway (PPP) (Kahumaa et al. 2005). To achieve a higher ethanol yield in our XI integration system, these genetic modifications would be important.

MT8-1/XKSδXI strain could produce ethanol from the mixture of the glucose and xylose (Fig. 2). This result indicates that MT8-1/XKSδXI strain could be applied to ethanol production from lignocellulose hydrolysate.

Further research including study of the genetic modification of metabolic pathway and xylose uptake are under investigation.

Keywords: Penicillin acylases, β-lactamic antibiotics, immobilization, sol-gel
Topic: Sustainable process-product development through green chemistry

Abstract

Biocatalysis presents a sound alternative to chemical synthesis in the field of drug production, given the highly selective nature of biological catalysts. The use of immobilized biocatalysts in antibiotic production is one of the most relevant. Penicillin G Acylase (PGA) from *E. coli* is currently used to hydrolyze penicillin G (PG) and catalyze the synthesis of β-lactam antibiotics. The enzymatic synthesis of these semi-synthetic antibiotics on a commercial basis is only feasible if immobilized biocatalysts are used, given the cost of enzyme production. In this work, particular emphasis is given to advances in penicillin G acylase immobilization by entrapment in a silica matrix with magnetic properties. A mechanically stable carrier based on porous xerogels silica matrixes, starting from tetramethoxysilane (TMOS), was produced. Diffusion limitations were minimized given the diameter (25 nm- 30 μm) of the nano- and micro-carriers obtained. Immobilization of PGA in these carriers allowed a protein immobilization yield of 95-100%, whereas the recovered activities were 50-65% at 37 ºC, as determined by PG hydrolysis (pH STAT method). These values of activity were kept constant during at least six months. Cephalexin (CEX) synthesis was performed at 14 ºC and pH 8.0, using the immobilized PGA in sol-gel in aqueous medium. Phenylglycine methyl ester (PGME) was used as acyl donor and 7-aminodeacetoxycephalosporanic acid (7-ADCA) was the limiting substrate at 30 mM. Cephalexin stoichiometric yield after 1 hour incubation was close to 65% (19 mM CEX/h), with respect to the limiting nucleophile. Immobilized PGA (682 U/g_{dry} at 37 ºC) retained high specific activity throughout 10 consecutive runs for penicillin G hydrolysis, suggesting adequate biocatalyst stability.

1. Introduction

Penicillins are the most widely used β-lactam antibiotics, but the excessive and too often inadequate use of these antibacterials has led to the development of resistant pathogens. Currently, the only method of overcoming the resistance problem is the use of newer semi-synthetic antibiotics. These penicillins (e.g. amoxicillin, ampicillin, ticarcillin) and cephalosporins (e.g. cephalexin, cefaclor, cefadroxil) correspond to 65% of the ever rising worldwide production

of antibiotics, exceeding 45000 tons in 2000 (Giordano et al., 2006).

The conventional processes of manufacturing these drugs demand harsh conditions. The industrial production of β-lactam antibiotics and their intermediates is, however, undergoing a remarkable transformation where the traditional chemical conversions based on stoichiometry are being replaced by enzyme-catalyzed processes – the so-called "green chemistry" approach. In contrast to the complex solvent-based chemical approach, the one-step enzymatic conversion is regio-and stereo-specific and can be performed under mild conditions (Kim and Lee, 1996).

Penicillin acylases (PACs) (penicillin amidohydrolase, EC 3.5.1.11) are a group of enzymes which are mainly involved in the industrial synthesis of semi-synthetic β-lactam antibiotics and production of 6-aminopenicillanic acid (6-APA), 7-aminodesacetoxycephalosporanic acid (7-ADCA) or 7-aminocephalosporanic acid (7-ACA). The application of PAC in the production of β-lactam antibiotics has been extensively studied by many research groups (Alkema et al., 2002, 2003; Alvaro et al., 1990; Guisan et al., 1998; Grooten et al., 1998; Fernandez-Lafuente et al., 1998; Hernandez-Justiz et al., 1998; Kasche et al., 1986; Kim and Lee, 1996a,b; Svedas et al., 1996; van Langen et al., 1999; Youshko et al., 2000, 2004). PAC is a heterodimeric protein synthesized as an inactive preprotein that contains a leader peptide and a spacer peptide separating the α- and β- subunits. The PAC enzyme belongs to the family of N-terminal nucleophile (Ntn) hydrolases, a class of enzymes that have a catalytic nucleophile at the N-terminal position and a fold around the active site consisting of a four layered catalytically active αββα-core. This core is comprised of two anti-parallel β-sheets packed against one another and covered by a layer of anti-parallel α-helices. In PAC the catalytic nucleophile is an N-terminal serine of the large β-subunit. PAC from *Escherichia coli* is the most studied and used enzyme for commercial purposes (Serenovic et al., 2005). Although PACs have proved effective in their role, better biocatalysts and higher yields than those actually obtained are required (Illanes et al., 2004).

In semi-synthetic antibiotic production, synthesis can be performed under thermodynamic or kinetic control. In both cases the reduction of water activity in the reaction medium will improve it, by displacing the equilibrium towards synthesis (Illanes et al., 2007).

The first strategy considers the direct condensation of the nucleophile and the acyl donor. Non-ionic forms of the substrates are required for the condensation reaction, so that pH will be an important variable in this strategy by altering the ionic equilibrium of the nucleophile and the acyl donor by the substrates. In this strategy, the yield is determined by the thermodynamic equilibrium of the reaction (which is largely independent of the biocatalyst used) and drastic conditions are usually required to displace it in favor of synthesis, so that very robust biocatalysts are required to perform adequately (Schröen et al., 2001).

Synthesis under kinetic control requires an activated acyl donor, in the form of an ester or an amide. It is usually a better strategy when product yield is the main goal, since product concentration is not limited by the equilibrium of the reaction. In kinetically controlled synthesis of β-lactam antibiotics, the reaction of synthesis (synthetase activity) will occur simultaneously with the hydrolysis of both the activated acyl donor (esterase activity) and the antibiotic product (amidase activity). Yields will be favored by reducing water activity, since the rates of the hydrolytic reactions will be reduced (Illanes et al., 2004,2007).

The advantages of using immobilized PGA over the soluble form, e.g., easier handling of the

biocatalyst, facilitated separation of the biocatalyst from the product, lesser product contamination, possible continuous use or re-use of the biocatalyst and enhanced stability and productivity, allow for significant cost saving in the production. However, immobilization brings along some drawbacks, such as loss of activity upon immobilization and diffusion limitations, which reduce the productivity of the immobilized enzyme system (Schroën et al., 2001).

A relatively recent approach for enzyme immobilization is based in the sol-gel process, which allows the room temperature synthesis of silica glasses, although suitably modified to exclude the typical harsh conditions that would cause enzyme denaturation. The concomitant material offers the same beneficial properties as traditional silica based matrices and allows a high biocatalyst load, since the enzyme is entrapped within the polymeric matrix as it forms (O'Neil et al., 2002).

A well-established sol-gel processing technique consists of hydrolyzing the adequate precursors in aqueous solutions to produce soluble hydroxylated monomers, followed by polymerization and phase separation to produce a hydrated metal or semi-metal oxide hydrogel. Removal of water from the wet gel, which is usually accompanied by changes in the structure of the pores and of the gel network, results in a porous xerogel. The most widely used precursors are alkyl-alkoxysilanes (Reetz et al., 1998).

Such materials offer the same beneficial properties as traditional silica based matrices. However, the amount of enzyme that can be immobilized is not limited by the available surface area on the matrix, because the enzyme is also entrapped within the polymeric matrix as it forms and becomes homogeneously throughout the material (O´Neil et al., 2002). This method has been employed for entrapment of a wide range of enzymes, antibodies, and whole cells.

The aim of this study was the development of a suitable methodology for the immobilization of PGA in a sol-gel silica matrix with magnetic properties and the concomitant application of this new biocatalyst on cephalexin synthesis.

2. Material and Methods

PGA solution (26.6 mg mL^{-1}, 35 U mg^{-1}) from *Escherichia coli*, tetramethoxysilane (TMOS), sodium dioctyl sulfosuccinate (AOT), magnetite nanopowder, were all purchased from Sigma-Aldrich. Isooctane was supplied from Riedel de Haën. Penicillin G was obtained from Fersinca Gb. All other reagents used were either laboratory or analytical grade.

Enzyme assay and Operational stability- pH STAT method

One unit of PGA activity (U) for the soluble and immobilized enzymes is defined as the amount of enzyme required to produce 1 μmol of 6-APA (6-Amino Penicillanic Acid) per minute. Enzyme activity was determined in a small batch stirred reactor with automatic pH correction by the pH STAT method (Cardoso and Costa, 1986), using a 4% (w/v) penicillin solution in 0.02 mol dm^{-3} pH 8.0 phosphate buffer at 37ºC. To evaluate the operational stability of the biocatalyst, Penicillin G hydrolysis was performed during 10 minutes at 37 ºC and pH 8.0 (pH STAT method), using the immobilized PGA in sol-gel in aqueous medium.

Assay for protein concentration

The concentration of protein in the enzyme solution before immobilization and in the supernatant and washings, after immobilization, was determined through mass quantification

based on a calibration curve of PGA absorbance at 280 nm. The amount of protein linked to the support was calculated by mass balance.

Activity retention

The percentage of activity retention was calculated as the ratio between the specific activities of the enzyme immobilized on the support and of the free enzyme solution.

Sol-gel

A solution containing 100 μL TMOS (2.32 mol dm^3) and 40 μL HCl (1.37 mmol dm^3) was sonicated in a Transsonic T 460 sonicating water bath for 10 min until the hydrolysis reaction was complete. In a typical immobilization procedure, 75 μL of PGA was suspended in 85 μL of magnetic suspension -10% (w/v) in 100 mmol dm^{-3} phosphate buffer, pH 7.5 - and the whole was mixed with the sol solution. To obtain micro-particles and minimize diffusion limitations, 300 μL of the sol-gel solution with enzyme was immediately added to 6 mL of 150 mmol dm^{-3} AOT/isooctane solution, before gelation. The resulting mixture was placed under vortex for 2 min, washed twice with 100 mmol dm^{-3} phosphate buffer, pH 7.5 and aged at 2-8 ºC during one week. The micro-particles obtained were suspended in 1 mL of the same phosphate buffer. The particles are either used or stored at 2 – 8 °C.

SEM

Dry particles of biocatalyst were put on a double carbon tape and analyzed in a Field Emission Scanning Electron Microscope (Jeol JSM-7001F).

Analysis

Substrates (7-ADCA and PGME) and products (CEX and PG) of synthesis were identified and analyzed by HPLC using a Merck Hitachi delivery system L-6000 with a Perkin Elmer LC 90 UV UV-vis detector and a Merck Hitachi D-2500 (Chromato-Integrator) integrator. The column used was a ChromSpher 5 C18 S250x4.6 from Varian. Samples were eluted isocratically with a mixture of 40% (v/v) acetonitrile, 60% (v/v) 5 mM phosphate buffer and 0,2% (m/v) SDS, pH 3.1, at a flow rate of 1 $mL.min^{-1}$, and analyzed in the UV detector at 214 nm. Elution times were 3.21, 3.91, 8.61 and 10.85, for PG, 7-ADCA, CEX and PGME, respectively. Concentration of substrates and products were calculated from calibration curves using stock solutions with internal standard (acetaminophen).

Synthesis of CEX with immobilized PGA

Synthesis of CEX was performed in temperature controlled, magnetically stirred reactors with 10 mL of reaction medium. Substrate concentrations were 30 mM 7-ADCA, and 90 mM PGME. 20 mg of biocatalyst per mL of reaction, corresponding to 97 U/mmol 7-ADCA, were used). The reaction was performed at 14 ºC and pH 8.0. During synthesis, pH and temperature were monitored and samples were taken to analyze product and substrates to determine yield and volumetric productivity. Yield was defined as the maximum molar conversion of 7-ADCA into CEX (%) and productivity as the amount of cephalexin produced per unit time and unit reaction volume at maximum yield ($mM.h^{-1}$). Specific productivity was determined per gram of dry biocatalyst ($mM.h^{-1}g^{-1}$). Experiments have variations below 5% among them.

3. Results and Discussion

In this work, particular emphasis was given to advances in penicillin G acylase immobilization by entrapment in a silica matrix with magnetic properties. Mechanically stable xerogel carriers

containing magnetite were produced from tetramethoxysilane (TMOS), to yield an immobilized biocatalyst in the form of nano- and micro-carriers, with sizes roughly ranging from 25 nm to 30 μm, as determined by SEM. A typical SEM micrograph of micro-carriers is given in figures 1 and 2. The presence of magnetite considerably eased the recovery of the biocatalyst, from the reaction media, through the use of a magnetic concentrer (figure 3).

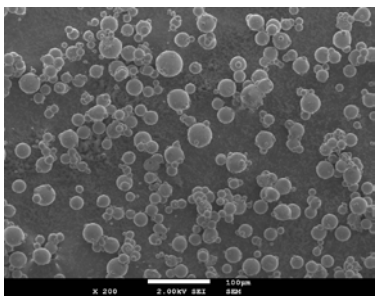

Figure 1: SEM micrograph of the sol-gel matrices (micro-particles) with encapsulated magnetite and PGA (bar match 100 μm).

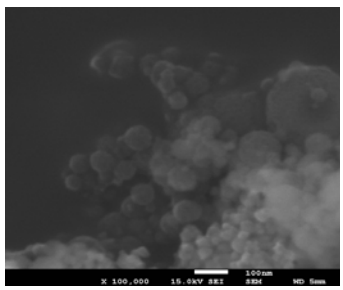

Figure 2: SEM micrograph of the sol-gel matrices (nano-particles) with encapsulated magnetite and PGA (bar match 100 nm).

Figure 3: Magnetic particles recovery on a magnetic concentrer.

Immobilization of PGA in these carriers allowed for an immobilization yield of 95-100%, whereas the recovered activity was 45-70% at 37 ºC, as determined by the pH STAT method, depending on aging. This clearly exceeds results reported in a previous work on PGA immobilization in sol-gel where only 10 % of activity was recovered (Kallenberg et al., 2005). Temperature and pH dependency are similar to soluble and immobilized PGA. The energy of activation also remained roughly unchanged following immobilization, for 10.5 and 10.8 kcal mol^{-1}, for soluble and immobilized enzyme, respectively, were determined from Arrhenius plots. The enzyme can carry out hydrolytic and synthesis reactions efficiently, in aqueous media (Figures 4 and 5).

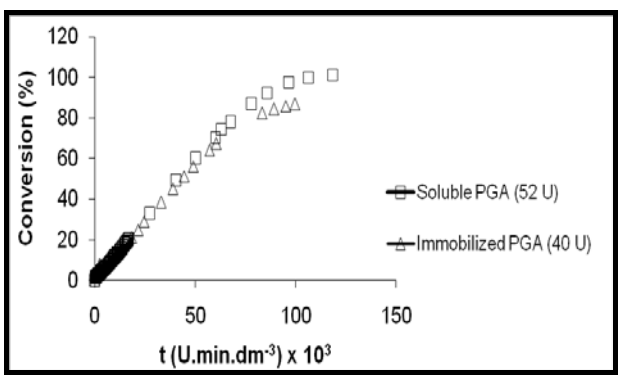

Figure 4: Penicillin G hydrolysis (pH STAT method). T = 37 °C; pH = 8.0; Penicillin G = 4% (m/v); 20 mM phosphate buffer (microparticles).

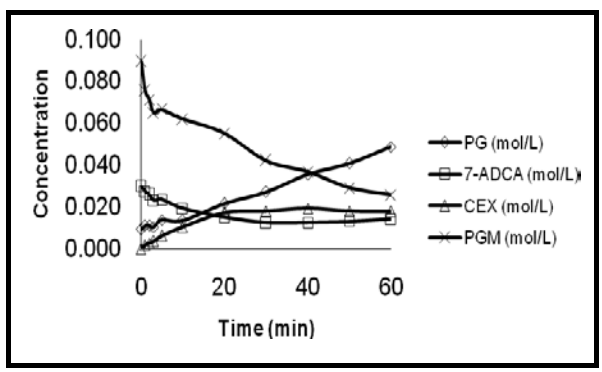

Figure 5: Cephalexin synthesis. T = 14 ºC; pH = 8.0; 29 U; reaction medium = 10 mL Y = 65%; P = 19 $mM.h^{-1}$; P_{sp} = 95 $mM.h^{-1}.g^{-1}$ (microparticles).

Immobilized PGA retained 65% specific activity throughout 10 consecutive runs for penicillin G hydrolysis (data not shown) suggesting adequate biocatalyst stability.

At low substrate concentrations (30 mM 7-ADCA, 90 mM PGME) and low enzyme load (97 $U.mmol^{-1}$ 7-ADCA) a maximum conversion yield of 65% was obtained with a productivity of 19 $mM.h^{-1}$ and a specific productivity of 95 $mM.h^{-1}.g^{-1}$. Illanes et al. (2005) obtained a similar result

for specific productivity (93 $mM.h^{-1}.g^{-1}$) but in organic medium at high substrate concentrations (150 mM 7-ADCA; 450 mM PGME) and low enzyme load (80 $U.mmol^{-1}$ 7-ADCA). The results obtained are thus encouraging and are likely to allow for substantial process improvement in terms of costs and environment.

4. Conclusions

Enzyme immobilization was carried out using penicillin G acylase from *Escherichia coli* in a silica xerogel matrix with magnetic properties. The enzyme is catalytically active and can carry out hydrolytic and synthesis reactions efficiently, but it is necessary to optimize the synthesis reaction conditions in order to depress hydrolytic activity. To prevent some biocatalyst degradation caused by dissolution and abrasion of magnetic agitation, novel developments such design and project an enzymatic reactor compatible with the developed magnetic biocatalysts are being tested, aiming to develop a system in which the biocatalyst can be recycled many-fold, a mandatory feature to render enzymatic catalysis economically feasible.

Keywords: polyhydroxyalkanoates, PHB, *Ralstonia eutropha*, biopolymers
Topic: Integration of life sciences & engineering.

Abstract

Several fermentation conditions were studied to optimize the biological production of polyester by *Ralstonia eutropha* and its posterior extraction. The highest biopolymer concentration obtained was 11 g L^{-1} in fermentor and 7.5 g L^{-1} in Erlenmeyer flasks. Both culture systems showed similar yields but higher productivity in fermentor, in fed-batch operation with a glucose concentration not higher than 10 g L^{-1} (seven supplies of glucose). Oxygenation rate must be low and pH close to neutral is advantageous. Cane molasses were shown to be a good substrate because of the price and its natural buffer ability. The adaptation lag phase of *R. eutropha* can be reduced if molasses are pre-treated by a biocatalytic hydrolysis driven by yeast cells at 45ºC, in bioprocess integration. Polymer extraction by ethanol precipitation favours the selective separation of large polymeric chains.

1. Introduction

The production of environmentally friend ecological plastics, since its manufacture from renewable raw materials till its degradation by biological processes, taking in mind that Nature always knows how to recycle what it is able to synthesize, it is a main contribution to mankind sustainability. The biocompatibility of natural materials enlarges their application to medicine, agriculture, food industry and other quotidian uses. The challenge is to explore Nature gifts without degrading its quality level, creating conditions to biological production in large scale, and economically competitive with traditional chemical synthesis. The polyesters from polyhydroxyalkanoates family (PHAs) are biopolymers that can be processed and used as a change of common petrochemical based plastics (Choi and Lee, 1997). They play the role of reserve compounds in many bacterial strains, such as *Ralstonia eutropha*, and their biosynthesis can be stimulated in fed-batch fermentation, under appropriate incentives and driven stress conditions, like the limitation of an essential growth nutrient and the excess of a carbon and energy source (Braunegg et al., 1998). These biopolymers are produced as discrete inclusions localised in the cell cytoplasm of the fermentative microorganism, being *R. eutropha* the most widely chosen bacterium due to its ability to accumulate large amount of poly-3-hydroxybutyrate (PHB), a particularly PHA, from simple carbon sources, such as glucose or fructose (Khanna and Srivastava, 2005). The large scale production of biopolymers still has several bottlenecks to be overtaken (Luengo et al., 2003) being so far their commercialization strongly limited by high production costs compared with the oil-derived plastics. Their net price is indeed extremely affected by the costs of substrates and by downstream procedures. Therefore, efforts have been made to reduce the production costs through the development of genetic modified bacterial strains, more efficient fermentation strategies using inexpensive and renewable substrates (*e.g.* molasses, sucrose, lactose or glycerol) and more effective downstream processing methods, allowing high levels of productivity and yield (Khanna and Srivastava, 2005). Although a great demand of new and more ecological extraction processes, PHA's are mostly separated from

* Corresponding author. Tel + 351-239-798731. E-mail:jrocha@eq.uc.pt

the producing cells by using solvents or mixtures of them that are toxic to the environment. The non-polymer cell material is degraded by acetone or alcohols, and the polymer, once liberated, is dissolved in chloroform or other chlorinated hydrocarbons, which can be separated from the solvent by evaporation or precipitation, using a polymer non solvent, usually an alcohol (Braunegg et al., 1998).

The large number of references found in literature, but the shortage of new experimental results, led to a set of experiments to test or confirm the effect of several factors in the production of PHB. The aim of this work was to study the fermentation of residual carbon sources and to improve the polymer extraction methods, optimizing the operational conditions in order to achieve high values of productivity and yield.

2. Material and methods

2.1 Microorganism and media

Ralstonia eutropha (DSM 545) was grown on agar slants and kept at 4ºC. The growth medium consisted of **a)** 4.5 g L^{-1} Na_2HPO_4, 1.5 g L^{-1} KH_2PO_4, **b)** 2.5 g L^{-1} $(NH_4)_2SO_4$, 0.2 g L^{-1} $MgSO_4.7H_2O$, **c)** 0.05 g L^{-1} Citrato-NH_4-Fe(III), 0.02 g L^{-1} $CaCl_2.2H_2O$, 0.1 mL trace metal solution and **d)** 10 g L^{-1} glucose. The trace metal solution was prepared with 3 g L^{-1} H_3BO_3, 2 g L^{-1} $CoCl_2.6H_2O$, 1 g L^{-1} $ZnSO_4.7H_2O$, 0.3 g L^{-1} $MnCl_2.4H_2O$, 0.3 g L^{-1} $Na_2MoO_4.2H_2O$, 0.2 g L^{-1} $NiCl_2.6H_2O$ and 0.1 g L^{-1} $CuCl_2.2H_2O$. Solutions a), b), c) and d) were sterilized separately in autoclave to avoid the medium composition degradation.

Liquid media for polymer production were prepared with the same mineral salt composition, varying the carbon source supplied. Cane molasses, sucrose and glucose with initial concentrations in the range 10-40 g L^{-1} were used as carbon source.

2.2 Fermentation conditions

2.2.1 Erlenmeyer flasks

Fed batch fermentations were carried out in 500 mL Erlenmeyer flasks (working volume 200-400 mL), at an orbital incubator (30 ºC;100-125 rpm). 10 mL of fresh inoculum, previously prepared under the same conditions, was used. Additional carbon source was supplied when necessary, to guarantee an excess to stimulate PHB production (trying to regain the initial composition).

In Erlenmeyer flasks the oxygen supply is just by air diffusion through the cotton stopper. In order to evaluate the effect of air accessibility, a set of fermentations with different medium volumes (200, 300, 400 mL) were carried out. The larger the medium volume (consequently smaller the superficial area in the conic flasks), the lower was the oxygenation of the microbial cells.

Mineral salts and the carbon source were dissolved in water (with and without some rough pH adjustment with NaOH 1M), and in buffers like Tris-HCl (0.1, 0.3 and 0.6 M) and HEPES, to provide a buffer environment to the bacterial metabolism.

In a set of assays, cane molasses were previously submitted to a biocatalytic hydrolysis by the action of *Saccharomyces* yeasts (making use of their intracellular enzyme invertase). The biocatalytic hydrolysis of cane molasses was realized by yeasts from a two days culture of 150 mL of a standard yeast growth medium (yeast extract 3 g L^{-1}, malt extract 3 g L^{-1}, peptone 5 g L^{-1} and glucose 10 g L^{-1}) at 30ºC and 125 rpm, that were centrifuged and added to 200 mL of cane molasses solution (100 g L^{-1}, that is equivalent to 50 g L^{-1} of sucrose) and kept in an orbital incubator at 45ºC for 2 h. After the molasses sucrose hydrolysis the suspension was centrifuged to remove the yeast cells (that can be reused) and the hydrolysate liquid was used as carbon source for *R. eutropha* growth. One volume of this sterilized hydrolysate was added to four volumes of the above described growth medium

(without carbon source) and also previously sterilized. This means a dilution 1:5 of molasses solution that was compared with non hydrolysed equivalent molasses solution of 20 g L^{-1}.

2.2.2 Fermentor

Fed-batch fermentation was also carried out in a Biostat® Bplus 5 LCC fermentor, with 5 L of working volume (B. Braun Biotech International, Germany). pH was set at 7.0 and automatically controlled by addition of NaOH 1M and H_2SO_4 1M. Air flow rate was adjusted manually by the air flow valve and the rotameter. Liquid volume was 3 L and culture was done at 30 ºC and 150 rpm (mechanical stirring).

2.3 Extraction methods

Culture broth was centrifuged (3500 rpm, 20 min) to separate the cells that were afterwards mixed with pure acetone, in order to degrade the non-polymer cell material. This suspension was stirred for 24 h at room temperature, filtrated under vacuum and the cellular residues were kept. Chloroform was added to the cellular residues, and the suspension was kept at room temperature in a well closed recipient under constant and magnetic stirring for 24 h, to promote the polymer dissolution in the organic solvent. The cellular residues were removed by filtration and the organic phase with the dissolved polymer was kept. Three procedures were tested to separate PHB from the organic solvent: i) chloroform evaporation, where the solution was submitted to a natural evaporation process; ii) chloroform distillation, where the solution was distilled permitting the chloroform recovery; and iii) ethanol precipitation, where ethanol was slowly added to the solution, acting as a counter solvent and thus promoting the polymer precipitation (the mixture was then filtrated and the polymer recovered).

2.4 Analytical methods

Cell growth was monitored by measuring the optical density of cells suspension at 540 nm on a Beckman D.U. 650 spectrophotometer, after suitable dilution with distilled water. Cell mass concentration was determined by standard plot between optical density and dry cell mass. Cells suspension was centrifuged, washed with water and dried till constant weight. Glucose, sucrose and cane molasses were evaluated by a colorimetric method for total sugars, using phenol and sulphuric acid (485 nm). Glucose and reducing sugars present in cane molasses were also determined by the dinitrosalicylic acid (DNS) method, measuring the optical density at 540 nm. After its removal the biopolymer mass was evaluated and the product was analysed by an infra-red spectroscopy method (FTIR). Its molecular weight was determined by a viscosimetric method, using an Ubbelohde nº1 viscometer.

3. Results and discussion

The use of cheap substrates as carbon source, the increase of their yield conversion into polymers, the use of simple fermentation systems and the development of more efficient and ecological extraction methods, will be the main items to make bioplymers production economically competitive. Simple reaction systems were carried out with *Ralstonia eutropha*, always with the purpose of reducing overall costs of the production process. The temperature control and the culture medium homogenization were relatively easy to achieve, either in small and simple scale, like Erlenmeyer flasks in an orbital incubator, or in larger scale in (more or less sophisticated) fermentor.

PHB production was obtained in all assays, although the productivities and yields varied, as a consequence of changing the operational variables, such as the type of carbon source and its initial concentration, the pH value of the culture, the oxygen supply, and the pretreatment of residual substrates, which affected the metabolic activity of the bacteria. Productivities were reported to the period of polymer accumulation; yields have the mean of real yields, that is, reported to consumed (and not supplied) carbon source.

3.1 The effect of oxygenation

The effect of oxygen in PHB production was initially studied in Erlenmeyer flasks (500 mL capacity). The oxygen supply is simply provided by superficial diffusion of air through the cotton stopper. The availability of oxygen to the cells was changed by varying the working volume in the Erlenmeyer flasks. The higher the culture volume (consequently lower

superficial area), the less was the oxygen supplied to the cells. Table 1 shows the PHB concentration achieved in the fermentation of different initial culture volumes, as well as the corresponding productivity and yield. In the assay D, the culture broth was transferred to an Erlenmeyer flask with a lower capacity (250 mL) after the exponential growth phase and at the beginning of PHB accumulation phase, reducing the superficial area and thereby the air supply.

Table 1. The effect of oxygen supply rate by air superficial diffusion (initial concentration of glucose 10 g L^{-1}, 100 rpm, no pH adjustment, additional supply of glucose)

	A	B	C	D
Volume (mL)	200	300	400	200
PHB conc. (g L^{-1})	0.67	1.42	2.31	1.15
Productivity (g_{PHB} $L^{-1}h^{-1}$)	0.0143	0.0189	0.0257	0.0247
Yield ($g_{PHB}/g_{glucose}$)	0.0733	0.136	0.374	0.1187

The highest PHB concentration, productivity and yield were obtained in assay C, showing the advantage of lower oxygenation rates. In fed-batch D, where the reduction of oxygenation was introduced in PHB production stage, the PHB concentration obtained was higher and productivity and yield almost doubled, when compared to the values registered in assay A where no change of oxygenation was induced. These evidences may have practical advantages in simple reaction systems (it is well known the difficulty to supply enough oxygen to aerobic cultures). Comparing assays C and D it is also evident that oxygen restriction must occur since the fermentation beginning.

3.2 The effect of pH

Cell growth and polymer accumulation are favored by pH close to neutral. The best results were obtained when pH 7 was kept constant during the fermentation either roughly by adding manually NaOH 1M in assay J or automatically in the fermentor (Table 2). The use of buffers was not very efficient in pH control, except with Tris-HCl 0.6 M. However, the presence of a foreign compound in the culture did not favor the polymer productivity. Better results were achieved with cane molasses as carbon source due to their natural buffer effect.

Table 2. The effect of culture pH (initial concentration of glucose 10 g L^{-1})

	E	F	G	H	I	J	Fermentor
Buffer Solution	Water	Tris-HCl 0.1 M	Tris-HCl 0.3 M	Tris-HCl 0.6 M	HEPES 0.1 M	NaOH	NaOH/H_2SO_4
PHB conc. (g L^{-1})	0.55	0.76	0.74	1.57	0.63	7.54	10.9
Productivity (g_{PHB} $L^{-1}h^{-1}$)	0.022	0.056	0.0077	0.0043	0.0209	0.0279	0.1344
Yield ($g_{PHB}/g_{glucose}$)	0.056	0.056	0.045	0.031	0.053	0.2292	0.2601

3.3 The effect of carbon source type and concentration

The kinetic of cell growth and biopolymer production is dependent from the type and concentration of carbon source used. Glucose is the easiest sugar for cells to metabolize but both very low and very high glucose concentration can inhibit the cell metabolism. According to Table 3 initial glucose concentrations in the range 20-40 g L^{-1} (also being the limit in glucose additions) lead to good results on PHB production. The highest molecular weight of polymer obtained (1.8×10^6 Da) was coming from this range of glucose supply. Sucrose, as a disaccharide, either purified or as the main component of cane molasses (residual carbohydrates from sugar industry) can be directly used by *R. eutropha*, with similar polymer production from the same amount of sugar supplied. However, a longer adaptation phase

was observed. In fact, the use of cane molasses is advantageous since they are less expensive and, on the other hand, the culture pH is much more stable, compared to glucose as carbon source, where the pH decrease deeply from 7 to 3-4, and this is not good for polymer production, as reported above.

Table 3. The effect of carbon source concentration (volume 400 mL, 125 rpm, no pH adjustment; additional supply of glucose in assays K and L when its concentration was reduced to zero)

	K	L	M
$[Glucose]_{initial}$ ($g\ L^{-1}$)	10	20	40
PHB conc. ($g\ L^{-1}$)	4.73	7.75	6.2
Productivity ($g_{PHB}\ L^{-1}h^{-1}$)	0.02363	0.0484	0.0620
Yield ($g_{PHB}/g_{glucose}$)	0.1382	0.2194	0.1721

3.4 Biocatalytic hydrolysis integration

A better profit of cane molasses can be made by a previous biocatalytic treatment, using *Saccharomyces sp*. yeasts, with the aim of hydrolysing the sucrose content into reduced sugar, easier to ferment by the bacteria. In fact, at 45ºC the yeasts are not able to reproduce, but their intracellular invertase is active for hydrolysis. The time evolution of this pre-treatment was followed by the DNS method. The reduced sugar content increased till a plateau was reached at 120 min. Table 4 and Figure 1 show the advantages of reducing the lag phase of the bacterial culture and to increase the biopolymer productivity, without a significant reduction of the molasses natural buffer ability. Cane molasses do not need to be sterilized before hydrolytic treatment with yeast cells (a very high concentration of yeasts and a high temperature are enough to avoid contamination).

Table 4. The effect of pretreatment with yeasts over molasses (previously sterilized or not) on polymer production; conditions described in Material and Methods.

	N	O	P
Carbon Source	**Cane Molasses (non hydrolysed)**	**Cane Molasses (sterilized and hydrolysed)**	**Cane Molasses (non sterilized but hydrolysed)**
PHB conc. ($g\ L^{-1}$)	0.13	2.01	2.19
Productivity ($g_{PHB}\ L^{-1}h^{-1}$)	-----	0.0111	0.0177
Yield ($g_{PHB}/g_{glucose}$)	-----	0.1088	0.1663

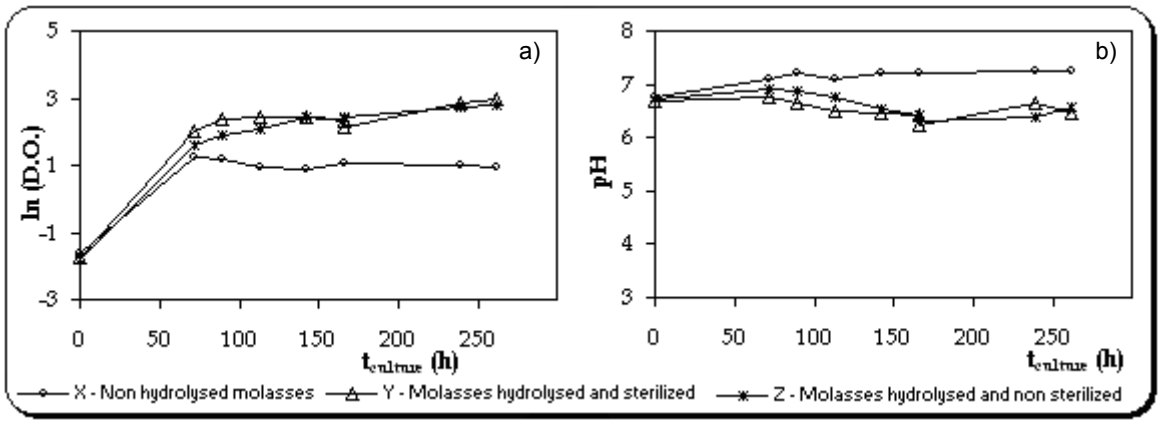

Figure 1. Profiles of a) *R. eutropha* growth and b) pH during fermentation, of non-hydrolysed molasses and hydrolysed molasses (previously sterilized or not).

3.5 Biopolymer extraction

PHB recovery was more efficient when using chloroform, followed by the organic solvent evaporation, or by ethanol precipitation. The mass of polymer obtained by the two methods was similar, but the latter is more advantageous because it is possible to recover both chloroform and ethanol by distillation. Polymer characterization was made by viscosimetric evaluation of molecular weight, making use of Mark-Houwink equation (Figure 2a)) and by FTIR, where the ester bond peak at *c.a.* 1750 cm^{-1} is well evident (Figure 2b)). Molecular weights were greater for polymers recovered by ethanol precipitation, when compared to the fraction recovered by chloroform evaporation. This fact must be ascribed to the loss of small polymeric chains that do not precipitate with ethanol, while in chloroform evaporation all molecular weight range of chains is recovered. So, ethanol precipitation induces a selective extraction of the largest polymeric chains.

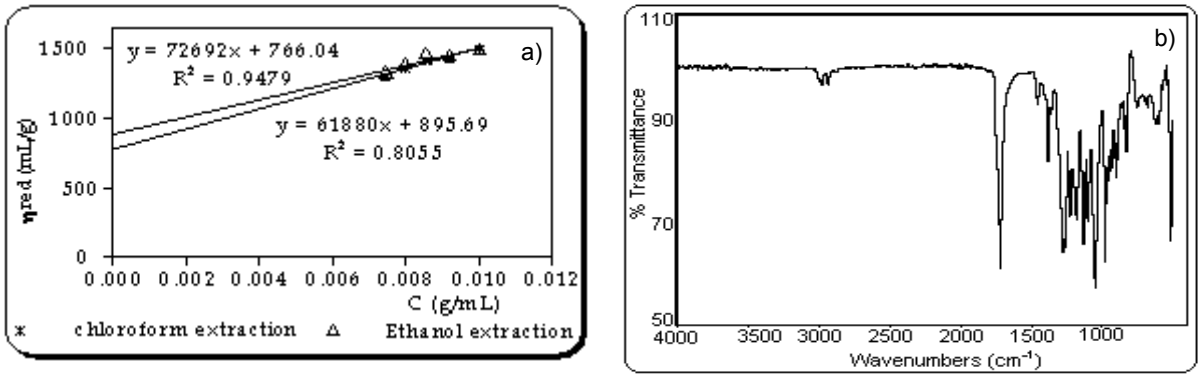

Figure 2 - Characterization of PHB polymer after its recovery by a) viscosimetric determination of molecular weights and b) FTIR.

4. Conclusions

Although cell densities achieved in this work had been quite low, probably due to a nitrogen limitation, with the consequence of low polymer productivities, some insight with practical application was obtained. The need of a low oxygenation rate, the adverse effect of pH reduction during the fermentation, that can be diminished by using cane molasses (a cheap substrate with a natural buffer ability), preferably if submitted to a biocatalytic hydrolysis, can contribute to the simplification of the bioprocess.

The highest PHB concentration registered was *c.a.* 11 g L^{-1} in the fermentor and 7.5 g L^{-1} in Erlenmeyer flasks, but these values are expected that can be increased significantly, to make the bioprocess more competitive. The lower productivity of simple reaction systems can eventually be compensated by the reduction of operation costs. It was achieved a biopolymer content of *c.a.* 80% of cell dry weight.

Topic: Systematic methods and tools for managing the complexity

Abstract
Elementary modes (EMs) are the simplest pathways within a metabolic network connecting substrates to end-products, which are able to operate coherently in steady-state. In this work, it was developed an algorithm to identify the set of active EMs which best describe the dynamics of the envirome. The algorithm combines the projection to latent structures (PLS) method with the elementary modes (EMs) analysis and aims at the maximisation of the covariance between the EM fluxes and the environmental factors.
The PLSEM algorithm was applied to identify, from a total of 251 EMs, the active subset during different fed-batch cultures of recombinant Baby Hamster Kidney (BHK) cells. A high degree of correlation was obtained between the observed transmembranar fluxes and the ones calculated through the fluxes of the selected EMs, confirming the potential for a macroscopic control of the intracellular fluxes. Therefore, the PLSEM algorithm can be used to design macroscopic control strategies, with its regression coefficients providing specific information of how the envirome impacts EM fluxes.

1. Introduction
The concept of elementary modes (EMs) has been widely applied for metabolic pathway analysis (Schuster et al. 1999; Klamt and Stelling 2003; Palsson et al. 2003). From a biological point of view, these pathways correspond to enzyme subsets that define a solution space circumscribing the functional capabilities of the biochemical network. Particular solutions found within this solution space are achieved by non-negative linear combinations of the EMs. In general, the number of EMs within metabolic networks is very high denoting their innate adaptability and robustness properties. The envirome can reduce the allowable steady-state flux distribution through the network. The knowledge of which of these pathways are carrying higher fluxes under particular envirome conditions is advantageous to understand how cells meet their metabolic “objectives”.
In this work, an algorithm was developed based on the projection to latent structures (PLS) including metabolic constraints to identify the active subset of elementary modes given a set of measured macroscopic fluxes. We demonstrate the potential of the algorithm to map the operation of the metabolic network of BHK cells during different fed-batch cultures.

2. Proposed Methodology
The PLSEM algorithm developed in this study combines two well-known methods: projection to latent structures (PLS) and Elementary modes (EMs) analysis. The objective of this algorithm is to identify a subset of EMs whose fluxes are highly correlated with environmental factors and, at the same time, to eliminate redundancy by excluding all non active EMs. In other words, the design principle is to maximise covariance between EMs fluxes and

environmental factors. Bellow we describe briefly the principles behind EMs analysis followed by the integration of PLS and EMs into the PLSEM algorithm.

2.1. Elementary Modes Analysis

Considering a metabolic network with *m* metabolites and *q* reactions such as the network represented in Figure 2, the following steady state material balance equations can be formulated assuming balanced growth and negligible dilution:

$$\begin{cases} \mathbf{N}\mathbf{r} = \mathbf{0} \\ r_k > 0 \end{cases} \quad (1)$$

with $\mathbf{N} = \{n_{ij}\}$ a $m \times q$ stoichiometric matrix, $\mathbf{r} = \{r_j\}$ the vector of q metabolic fluxes, r_j denoting the net specific rate of reaction j and k denoting the irreversible reactions in the metabolic network. The universe of solutions of system (1) forms a convex polyhedral cone in the solution space (Rockafellar 1970). It is a property of this system that the infinite set of solutions may be expressed as nonnegative linear combinations of a finite set of n fundamental vectors $\mathbf{e}_i$ called elementary modes (EMs):

$$\mathbf{r} = \sum_{i=1}^{nem} \lambda_i \mathbf{e}_i \qquad \forall \mathbf{r} \in \Re^q \quad (2)$$

The non-null elements in each EM, $\mathbf{e}_i$, define a subset of active reactions of the overall metabolic network **N**, which are essentially pathways for the conversion of substrates into end-products. The complete set of EMs can be organized in the columns of a matrix $\mathbf{K}_{EM}$ to obtain an expression relating the measured macroscopic fluxes ($\mathbf{R}_{obs}$) with the fluxes of the EMs ($\mathbf{R}_{EM}$):

$$\mathbf{R}_{obs} = \mathbf{K}_{EM} \,.\, \mathbf{R}_{EM} \quad (3)$$

2.2. The PLSEM Algorithm

The goal of the PLSEM algorithm is to maximise the covariance between measured environmental factors (**X**) and measured extracellular fluxes ($\mathbf{R}_{obs}$) (see Figure 1).

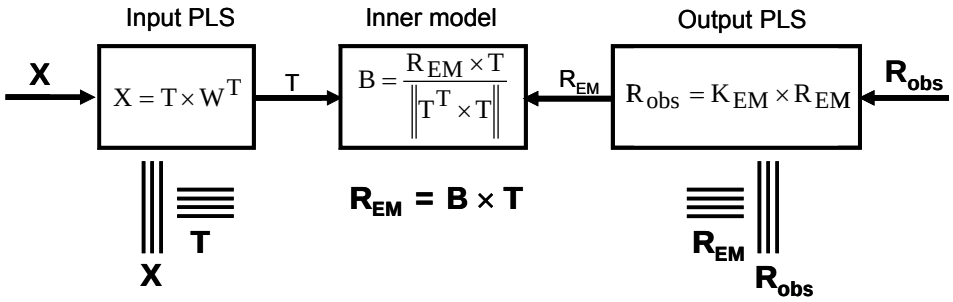

Figure 1 – The PLSEM algorithm.

The core of the PLSEM is identical to the classical PLS. PLS finds latent variables (LVs) of both the predictor and target matrices. The interesting feature of PLS is that these latent structures obey to the principle of orthogonality in relation to the original data. This operation eliminates redundant information of the inputs and outputs. The calculation of the predictor LVs in the PLSEM algorithm is done exactly in the same way as in PLS. The main difference lies in the calculation of the target output LVs. In the PLSEM, the EMs analysis is applied with the loadings matrix replaced by the EMs stoichiometry ($\mathbf{K}_{EM}$). Every flux vector in the solution space can be represented by linear combinations of the unique set of elementary modes. Therefore, the complete set of EMs contains all the orthogonal vectors that constitute the convex basis of the solution space, corresponding to the latent variables of the target output.

3. Materials and Methods

3.1. Culture conditions

A BHK21A cell line expressing the fusion glycoprotein IgG1-IL2 (antibody type one linked to Interleukin two) is the biological system under study. The culture medium used, SFM4CHO (Hyclone), is a serum-free and protein-free medium. The bioreactions were carried out in 2 L vessels. The starting volume was 950 ml, dissolved oxygen was kept at 30% of air saturation through sparging with an aeration rate of 0.02 vvm; the agitation rate was kept at 70 rpm. pH was allowed to vary between 7 and 7.25; the addition of NaOH (0.2 mM) or CO_2 occur only when pH lied outside this range. A set of six experiments were performed, one batch and five fed-batch cultures, using different initial concentrations of glucose, glutamine, glutamate, serine and aspartate and different feeding strategies. The quantification of viable cells, glucose, lactate, ammonia, recombinant protein, amino acids and osmolality is described elsewhere (Teixeira et al.,).

3.3. Metabolic Network

The biochemical network considered in this work is depicted in Figure 2. These reactions represent the major fluxes of carbon and nitrogen through the metabolism of BHK cells. The main metabolic pathways considered include glycolysis, glutaminolysis, TCA cycle, pentose phosphate pathway, recombinant product synthesis and biosynthesis of cellular components (nucleotides, carbohydrates, lipids, and proteins). The network contemplates also the catabolism of all amino acids except tryptophan.

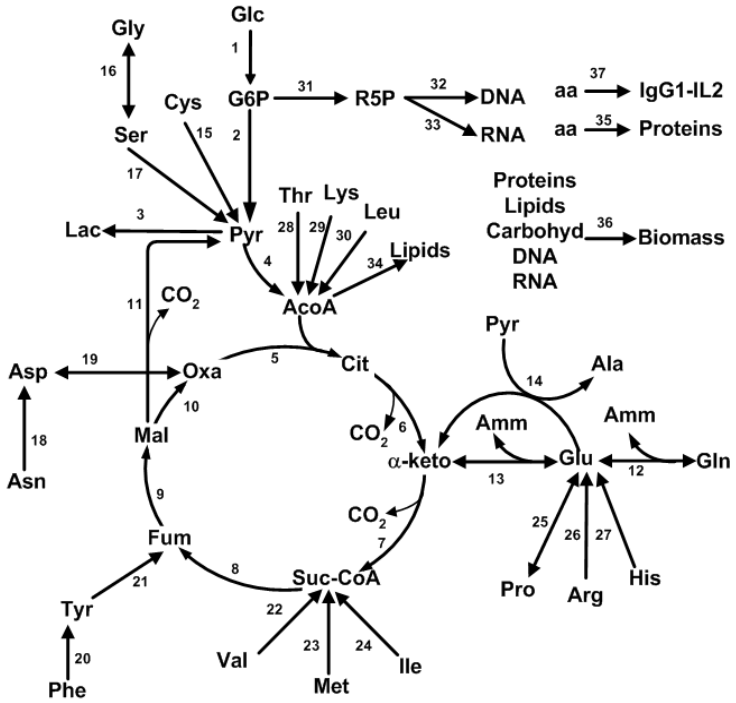

Figure 2 – Metabolic Network of the BHK cells.

4. Results and Discussion

4.1. Elementary Modes of the BHK metabolic network

The Elementary modes of the metabolic network represented in Figure 2 were determined using FluxAnalyzer software (Klamt et al. 2003), giving a total of 251 pathways connecting substrates with end-products. Within the set of EMs, there are 139 for biomass synthesis,

meaning that cells have many alternative routes to produce the biomass building blocks. This denotes the high degree of redundancy of the cellular metabolic network.

4.2. Typical active Elementary Modes during BHK cultures

The PLSEM algorithm was applied to data from the growth phase of six different experiments, in order to disclose the main trends in the operation of the metabolic network of BHK cells. The environmental factors comprising the input predictor of the algorithm are the pH and osmolality of the culture bulk, viable cells density, together with the concentrations of 23 measured compounds, namely glucose, lactate, ammonia, glycoprotein and 19 amino acids. The output matrix consists of 24 measured extracellular rates. Figure 3 shows the correlations obtained between the measured rates and the rates calculated through the fluxes of the active elementary modes; there is a high degree of correlation for the majority of extracellular rates. It should be emphasized that the EMs fluxes describing the observed rates were selected in the sense of maximising the correlation with the envirome factors; thus, these results evidenced the potential for macroscopic control of the intracellular fluxes. Fig. 3b presents the selected EMs together with the variance of the measured rates explained by each one. It can be observed that 20 EMs captured over 92% of the data variance.

80	92.74

Figure 3 – (a) Correlations between the measured rates and the rates calculated through the fluxes of the active EMs. (b) Rank of EMs obtained with data from the growth phase of six BHK cultures.

The first selected EM is one of the 139 EMs for biomass synthesis, describing more than 60% of the variance of the data. This result was expected since almost all specific extracellular rates can be partially described by an EM for biomass synthesis, as the majority of compounds is consumed or produced in such metabolic pathways. For the same reason, the unique EM for product formation (EM1) is in the rank, since it contributes to describe not

only the specific product formation but also part of the specific rate consumption of every amino acid.
The EM corresponding to the anaerobic conversion of glucose into lactate was selected in third place (EM11: Glc → 2 Lac). This EM is known to be very active in mammalian cell cultures when extracellular glucose concentration is higher than a defined concentration, normally a very low value. Glucose is taken up at high rates and the excess inside the cells enters in overflow metabolism being transformed into the waste and toxic by-product lactate.
Serine transamination into two molecules of glycine was the fourth selected EM (EM6: Ser + Amm → 2 Gly). One molecule of ammonia, the main toxic by-product for mammalian cells, is consumed during this pathway. Thus, this reaction may represent a strategy that cells found for ammonia detoxification.
Finally, it is worth to mention that the complete oxidation of glucose through the TCA cycle (EM43: Glc → 6 CO_2), the main source of energy for mammalian cells, is also present in the rank. After this overview, it can be stated that the PLSEM algorithm allowed the identification of typical pathways which are known to be active in mammalian cells. Thus, a very important structural insight into the operation of metabolic networks can be provided with this algorithm.

4.3. Assessment of the effect of the envirome on fluxome

The most relevant feature of the PLSEM algorithm is the possibility of using its regression coefficients to identify the environmental factors which correlate with the active EMs fluxes. This information can be potentially used to direct the fluxome to a desired state through manipulation of the envirome. There are many envirome factors which positively correlate with the flux of the EM20 corresponding to biomass synthesis, namely the concentration of glucose and lactate and also the concentration of nine amino acids, including glutamine. On the other hand, the pH of the culture bulk and the concentrations of product and histidine correlate negatively with the flux of this EM. Although BHK cells are capable of glutamine synthesis from glutamate (Neermann and Wagner 1996), higher growth rates were achieved in culture media with high levels of glutamine. The remaining amino acids correlate positively with this EM because normally they are more concentrated in the initial stage of the exponential growth phase when the biomass formation is higher. Then, their concentration decreases as they are consumed and cellular growth decreases as well. Therefore, this information may not necessarily mean that high levels of those amino acids promote higher biomass growth.
In terms of product synthesis, the envirome factors that correlate negatively with the flux of EM1 are the pH and the glucose concentration, while the osmolality and the concentrations of valine, isoleucine, leucine and lysine correlate positively with this EM. The high negative correlation with glucose concentration is expectable because in all experiments glucose concentration decreases from the beginning to the end of the batch, whereas the opposite trend is observed for product formation. However, this correlation is explained by reactor operation factors rather than a possible glucose inhibition mechanism on product synthesis. The effect of the pH deserves further attention, since it correlates negatively with both EMs of biomass formation and product synthesis. There are some reports agreeing that maximum growth rates (Yoon et al. 2005) and maximum productivities of recombinant proteins are obtained at pH = 7 (Osman et al. 2001). Regarding the osmolality effect, it has been reported in literature that the specific productivity of mammalian cells increases when the osmolality of the culture medium increases (Ozturk and Palsson 1990; Lin et al. 1999). Our PLSEM results support this observation. Altogether, these results demonstrate that the algorithm provides a basis for the macroscopic control of the intracellular fluxes. Nevertheless, the identification of the envirome factors which correlate with the flux of EMs would profit from a richer data set, obtained from a higher number of perturbations of the system. Although we have data from six experiments, some environmental factors (namely the concentration of essential amino acids) have similar profiles which may not be sufficient to disclose all the relevant information.

Conclusions

The PLSEM algorithm was developed merging two compatible concepts: the projection to latent structures and the elementary modes (EMs) methodologies. As in metabolic flux analysis, the PLSEM algorithm allows to calculate a set of unknown fluxes from a set of measured fluxes under the constraint of the metabolic network stoichiometry. The main difference lies in that the PLSEM uses the additional information contained in the envirome for structural analysis of the metabolic network in the sense of minimising pathway redundancy, by selecting the active EMs.

The method was evaluated by using data obtained from BHK cultures performed under different batch and fed-batch conditions.The algorithm provides two important pieces of information: the set of active EMs (the ones that correlate with the envirome) and the regression coefficients between EM fluxes and envirome factors. From a bioprocess engineering viewpoint, the PLSEM constitutes a powerful tool for process optimisation and control since it links the envirome, which can be manipulated macroscopically, with the fluxome under the constraint of the known network stoichiometry and thermodynamics.

Topic: Systematic methods and tools for managing the complexity

Abstract

Two advanced techniques have been compared to enhance bioprocess monitoring and control by online reconstruction of biomass and specific growth rate for feedback control: a software sensor based on standard measurements of the oxygen uptake rate and inline near infrared spectroscopy. An automatic search method for wavelength selection was proposed to enhance the prection ability of the near infrared method. Both techniques perform well, however when it comes to feedback control, the software sensor is preferred, because it is more robust against variations in the operating conditions and noise. The results are shown on real cultivations of *Bordetella pertussis.*

Introduction

Bioprocesses are characterised by natural variability in the raw materials, initial conditions, human intervention, and varying properties of the micro-organism. By setting fixed protocols the current GMP regulations do not encompass reduction of these deviations. This leads to products that have a variable quality, and are even out of specs. The FDA's guidance (2004) on Process Analytical Technology (PAT) finds more and more applications in the biopharmaceutical industry. It involves a shift from testing quality in finished drug products to building quality into products by introducing timely measurement and control of quality variables during the production process.

Wold et al. (2006) defined five levels of chemometrics analysis for PAT and states that the fifth level "PAT process control" in the sense of feedback control based on online monitored variables is still a challenge of the future. The use of spectroscopic instrumentation, although, is often seen as promising for PAT, however in the frame of feedback control it is less well developed. This work describes a step towards real-time feedback control for PAT by comparing two technologies for online monitoring of biomass growth (Soons, 2008). The ensuing controller design is based on the preferred technique. The dual substrate cultivation of *Bordetella pertussis* for the production of whole cell whooping cough vaccine was chosen as a test case.

Materials and methods

Bioprocess monitoring

Data of the near infrared sensor and data from other sensors (dissolved oxygen, pH, etc.) together with offline measurements of biomass concentration were taken from eight batch cultivations with *Bordetella pertussis*. The nutrient and biomass profiles were similar for all experiments. In four batches periods of deviations from the intended

* Corresponding author. Tel + 31-317-484955. E-mail:zita.soons@gmail.com or ton.vanboxtel@wur.nl

profiles, like oxygen limitation or poor pH control, were introduced to enhance the model robustness in counteracting the natural deviations of bioprocesses and to test PLS prediction performance. Every minute a spectrum was recorded consisting of 2074 wavelengths between 833 and 2500 nm. The noise was filtered by Savtisky-Golay smoothing with a 45-point window and a second order polynomial. Out of eight batches, six were assigned for the training dataset, two for the validation set. We refer to Soons (2008) for the more details on the measurement methods, the bioreactor conditions, and the spectral data pre-treatment.

Bioprocess control

The batch cultivations were extended with a fed-batch phase to obtain a higher biomass concentration in a controlled way. The fed-batch phase and the specific growth rate controller automatically started when the limiting substrates were almost depleted and the specific growth rate dropped to the set-point. We refer to Soons et al. (2006) for the more details on measurement methods and bioreactor conditions.

Bioprocess monitoring

The specific growth rate and biomass formation are important variables that we would like to control during the cultivation of bacteria for vaccine production. This is particularly important when the produced bacteria form the basis of a whole cell vaccine like whooping cough. Biomass growth, however, can not be measured online, because there are no suitable sensors.

Software sensor for biomass growth

A software sensor based on an Extended Kalman Filter (EKF) was developed to reconstruct biomass (C_X) and specific growth rate (μ) from standard measurements of the oxygen uptake rate (*OUR*) (Soons et al., 2008). The application of the EKF in biotechnological applications is amongst others discussed by Stephanopoulos and San (1984). The EKF calculates new estimates every minute using the model, the *OUR* measurement, the previous estimation, and the variance. The software sensor is based on a generic model with only two parameters (m_O and Y_O) that are required to be known accurately:

$$\begin{aligned} \frac{dC_X}{dt} &= \left(\mu - \frac{F}{V}\right) C_X \\ \frac{d\mu}{dt} &= 0 \\ OUR &= \left(\frac{\mu}{Y_O} + m_O\right) C_X \end{aligned} \qquad 1$$

Biomass estimation using near infrared sensor

It has also been investigated how nIR spectra can be used to yield an alternative measurement of biomass. Scarff et al. (2006) provide an overview on calibration of near infrared models for cultivation of micro-organisms. The evolvement of the spectra in time contains information on the course of the cultivation process. The interpretation of the spectra is challenging due to the large number of wavelengths and due to the overlapping absorbance bands of specific components. Partial least squares (PLS) is commonly used to regress a response variable (component concentrations) on a set of predictor spectra (near infrared measurements) (Van Sprang et al, 2007). Not all wavelengths in the spectrum, however, contain information relevant to the component of interest. To counteract these effects, wavelength selection is a common tool to

gather wavelengths that do contain relevant information. The complexity of the near infrared spectrum, however, precludes to some extend the use of the classical wavelength selection approach. Most works select spectral regions on the basis of prior knowledge on the absorbance of specific chemical components (amongst others Van Sprang et al., 2007 and Vaidyanathan et al., 1999). As an alternative, automated search methods were suggested by amongst others Triadaphillou et al. (2007). The currently available wavelength search methods are not effective in finding global minima. To overcome this problem, in this paper, the controlled random search procedure presented by Price (1977) is applied to obtain the most informative wavelengths by selecting the center and width of a spectral window and the number of latent variables for the PLS calibration. The window of wavelengths may vary in size, ranging from a single wavelength to 241 wavelengths.

The controlled random search first generates a set of *NT* trial points from the search domain *V*, specified by *n* parameters (center and width of the spectral window and the number of latent variables). The goal function (root mean squared error *RMSE*) is evaluated for all trial points and stored in a matrix *A*. Then the search starts by generating each iteration a new trial point and calculating the goal function for this point (*RMSE*). The new trial point *TP* is generated by choosing *n+1* random distinct points from the set *A* and calculating the next trial point form the centroid of the *n* random points minus the last point. When *RMSE* is smaller than the stored trial point with the greatest *RSS* (*M*), *TP* replaces *M* in *A*. This process continuous until the set in *A* has converged.

Bioprocess control

Control of bioprocesses is a difficult task due to the time-varying characteristics of cultivation processes. The control purpose is to regulate the specific growth rate (μ) to a desired value by adding a feed with limiting substrates. By combining a dual substrate model for biomass growth with a reference model, a controller was derived that adapts its settings in response to time-varying conditions (Soons et al., 2006):

$$F_{G+L} = \frac{ac + bd}{aC_G^{in} + bC_L^{in}} \hat{C}_X V + K_P \cdot (\mu_{set} - \hat{\mu}) + \int_0^t K_I \cdot (\mu_{set} - \hat{\mu})\, dt \qquad 2$$

where the controller gains K_P and K_I are adjusted online to the changing volume:

$$K_P = \frac{V}{\gamma_1 (aC_G^{in} + bC_L^{in})}, K_I = \frac{V}{\gamma_2 (aC_G^{in} + bC_L^{in})} \qquad 3$$

γ_1 and γ_2 are the tuning parameters for the controller and *a*, *b*, *c*, and *d* are constants depending on the micro-organism (in the work *B. pertussis*) and the set-point for specific growth rate.

Results and discussion

Wavelength selection

The controlled random search procedure was applied several to the training dataset and converged to the same spectral window and number of latent variables during each run. Figure 1 indicates that a window of 850-910 nm gives the best prediction of the biomass concentration. The selection of a wide window consisting of 199 wavelengths makes that the model is not too specific for the training dataset and is able to predict biomass concentrations on other batches.

Figure 2 shows the measured (C_X^m) versus the predicted biomass concentrations (C_X^{nIR}). The results show good correspondence for the low and medium values of biomass in the training set. In the high biomass range the biomass concentrations were

slightly overestimated. Out of six batches in the training dataset three contained “natural” deviations in pH and/or dissolved oxygen (PAB0003, PAB0004, and PAB0007). Despite of these hick-ups the near infrared model is capable to estimate biomass properly.

The performance of the PLS model obtained from the controlled random search procedure was compared with the PLS model built on the full spectrum (2074 wavelenths) by comparing *RMSE* of the full spectrum (*FS*) with *RMSE* of the selected wavelengths (*WS*) using Eq. 4. An improvement in PLS modelling accuracy of 62% was obtained.

$$I = \frac{RMSE_{FS} - RMSE_{WS}}{RMSE_{FS}} \cdot 100\% \qquad 4$$

The training set is shown in open symbols, the validation set in filled symbols (PAB0005 and PAB0009-1); the batches in red and indicated with an asterix (*) contain temporary deviations in pH and dissolved oxygen; the batches in black do not contain deviations.

Bioprocess monitoring

The performance of monitoring based on the software and on the near infrared sensor is compared during eight batch cultivations and illustrated on one batch. The biomass estimations for the near infrared sensor were also used for online estimation of the specific growth rate, which is useful in situations where the specific growth rate is

controlled. In fig. 3A it can be seen that the software sensor accurately observes the exponential increasing biomass concentrations. The software sensor was hardly affected by the presence of hick-ups, and performed well over the entire range from start to end. Also the normally distributed noise in *OUR* (shown in Fig. 4A) was effectively filtered out by the software sensor.

In the same figure it can also be seen that the near infrared estimations also predict well the exponential increasing pattern of the biomass concentration. The estimations, however, were relatively noisy over the whole range of the cultivation (Fig. 3C). The software sensor was less sensitive for such disturbances.

The erratic and noisy biomass estimations from the near infrared sensor have important consequences for specific growth rate estimation and control. The variations were not normally distributed and therefore more difficult to filter out, resulting in a delayed reconstruction of the specific growth rate (Fig. 3B). These erratic properties of the spectroscopic biomass growth monitoring may deteriorate performance in feedback control.

Overall, in the cultivations that were consistent with the cultivations of the training dataset the PLS model predicted the biomass growth fairly well. If however variations occurred, which were unseen in the training set, the prediction power deteriorated. For future calibration of PLS models, it is important to assure that the training dataset comprises all sources of natural variation that might be expected during production runs; for instance by performing “design of experiment” batches.

Whilst the accuracy of the PLS model has improved by application of wavelength selection, the online prediction of biomass is not that robust against noise and unseen disturbances. So, if near infrared estimations are intended for feedback control, special care must be taken. It is suggested to check whether the behaviour of the current batch is consistent with the training dataset to detect deviating behaviour, e.g. by performing a principal component analysis on the online process data. In the current state of development the software sensor is the preferred choice when it comes to feed-back control.

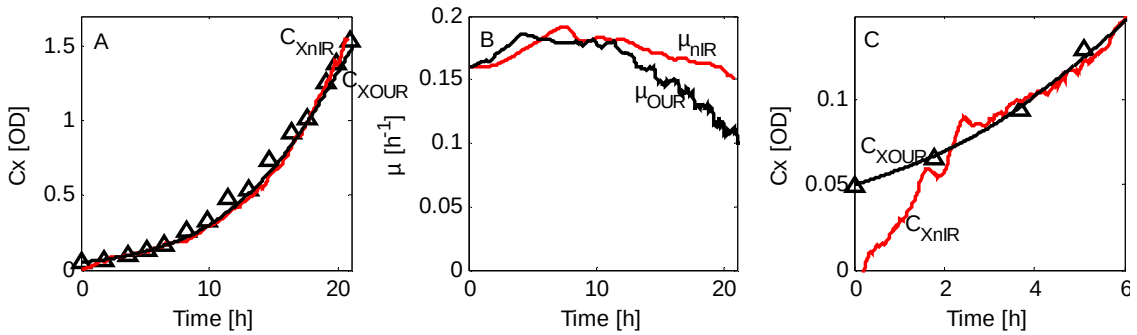

Fig. 3. Bioprocess estimations based on the near infrared and on the software sensor during batch cultivation. **A.** Biomass **B.** Specific growth rate. **C.** Detail of Fig. 1A: biomass estimations in the initial phase of the batch.

Bioprocess control

The next step was to extend the standard batch cultivation with a fed-batch phase by adding a feed with limiting substrates to control the specific growth rate, estimated by the software sensor. This way three times higher biomass concentrations were obtained in laboratory cultivations (Fig. 4) in a controlled way. The controller, therefore, contributes to enhanced batch-to-batch consistency and quality.

Wold et al. (2006) state that “PAT process control” is still a challenge of the future. This work is intended to be a step towards real-time feedback control for PAT by implementing two technologies for online monitoring and control of biomass growth during the cultivation step in vaccine production for *B. pertussis*.

Keywords: Process analytical technology (PAT), Near-infrared spectroscopy, pharmaceutical industry, identification, qualification, quantification.
Topic: Systematic methods and tools for managing the complexity.

Abstract

The FDA's Process Analytical Technology regulatory framework was born to support innovation and efficiency in pharmaceutical development, manufacturing, and quality assurance. PAT is a "system for designing, analyzing, and controlling manufacturing through timely measurements (i.e., during processing) of critical quality and performance attributes of raw and in-process materials and processes, with the goal of ensuring final product quality".

Several PAT tools are described in the FDA guideline for monitoring, process supervision, diagnostics, and control. Among monitoring techniques near-infrared (NIR) spectroscopy, is one of the most powerful and well know since it is intrinsically a PAT tool due to its multi-parametric capabilities (measures different in nature quality attributes) and also fingerprinting capabilities of whole process samples. NIR therefore has the potential to enhance process understanding and control of many pharmaceutical manufacturing processes, at also to replace advantageously quality control by in-process measurements validated and in accordance to regulatory requirements.

Here we describe the use of near-infrared diffuse reflectance spectroscopy as a Process Analytical Tool (PAT) used in a Pharmaceutical industry. NIR has been used for identification and qualification of raw-materials and intermediate manufacturing products, and for quantification purposes, likewise the determination of moisture and active pharmaceutical ingredients (API's), in intermediates and final products.

1 Introduction

The pharmaceutical industry is a highly regulated industry and in many cases innovation is first initiated when there are external requirements. Today's quality systems in pharmaceutical industries are gigantic organizations that are operated under the requirements of Good Manufacturing Practice (GMP), which can be a 'straight jacket' for innovation. To facilitate innovation and encourage the adoption of the PAT approach, FDA has supported the idea that technology innovation does not necessary require a heavy regulatory and bureaucratic process. The FDA PAT initiative is the key driver when it comes to innovation and introduction of PAT in the pharmaceutical industry.

The American FDA published a final PAT Guidance in September 2004. This guidance is a regulatory framework to encourage the voluntary development and implementation of

* bsel@ist.utl.pt

innovative pharmaceutical development, manufacturing, and quality assurance. This guidance does not intend to force the pharmaceutical industries to adopt the PAT concept; it just describes the current opinion of the FDA about this issue. By reading the guidance, we can anticipate that in the future, inspections of companies will be based on risk assessment. This means that if a company uses PAT and proves a high level of process understanding, their products are considered of less risk to the public safety compared to pharmaceutical products manufactured in the traditional way.

Companies that do not prove to have enough process understanding will then be of more concern to the FDA.

According to FDA, PAT is "*a system for designing, analysing, and controlling manufacturing through timely measurements (i.e., during processing) of critical quality and performance attributes of raw and in-process materials and processes, with the goal of ensuring final product quality*" (FDA, 2004).

The goal of PAT framework is to enhance understanding and control of the manufacturing processes, in order to be consistent with the sentence that reflects the ideal drug quality system: "*quality cannot be tested into products; it should be built-in or should be by design*".

PAT aims for the combination of the most recent scientific and technologically advanced resources in an integrated systems approach, in order to reach the desired state of pharmaceutical manufacturing and regulation (FDA, 2004).

Besides the regulatory aspect of PAT other benefits include improved process understanding, improved quality control, less batch rejections and higher throughput which all adds in favour of more competitive processes. Though PAT is not mandatory, the situation could certainly change when a large number of successful applications have been approved by the authorities. PAT is the road to higher quality more affordable drugs, which is both a benefit for pharma companies, patients and public healthcare systems.

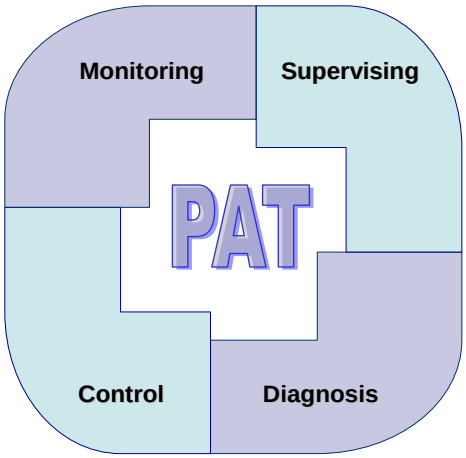

Figure 1 – PAT building blocks

In the last years, a favourable environment has been created around the PAT concept. Beyond any doubt, it is possible to said that the FDA's guidance gave the best contribution to the divulgation and discussion of PAT concept in the scientific world and consequently to its acceptance increase.

Several PAT tools are described in the FDA guideline, but near-infrared (NIR) spectroscopy is those who developed a strait relation with the PAT concept, since it is nowadays, a very well known and advantageous analytical technique, to which doesn't remain much to prove.

NIR has been used as a PAT tool in a pharmaceutical industry, for identification and qualification of raw-materials and intermediate manufacturing products, and for quantification purposes, likewise the determination of moisture and active pharmaceutical ingredients (API's), in intermediates and final pharmaceutical products.

2 Experimental

2.1 Equipment and software

NIR reflectance spectra were collected at-line, with a MPA™ (Multiple Purpose Analyzer) FT-NIR Bruker Optics spectrometer equipped with a reflectance fiber-optic probe. All methods were developed with OPUS software, version 4.2, with QUANT and IDENT packages, from Bruker Optics.

2.2 Identification and qualification of raw material

All the raw-materials used in the manufacturing of pharmaceutical products must be reliable identified. NIR has been used for this purpose for several years, and here we describe the overall strategy used for the development of a NIR identification method for daily use in a pharmaceutical industry.

For the identification process of incoming raw material, two independent spectral libraries were constructed: one for Active Pharmaceutical Ingredients (API's) and another one for excipients, in order to by-pass eventual overlaid problems in the spectra within these groups. During the methods development several chemometric techniques and multivariate data analysis were used for the development of an appropriate model that allow identification of new batches that reach the quality control, which was done for both libraries.

Several qualification methods were also developed, in order to complement the identification process and give a result as reliable as possible not only about the incoming raw material identity but also about its application. The qualification can be required after the identification step, because the same product can have different physical (e.g. particle size, density, compactation), or chemical properties (e.g. polymorphism, hidratation degree) related with different applications.

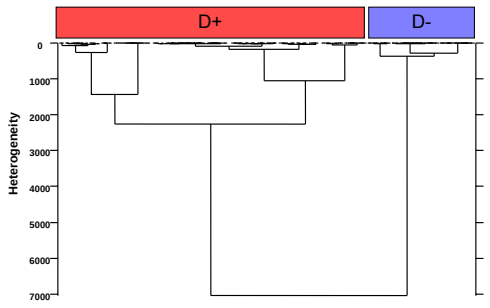

Figure 2 - Dendogram from a qualification cluster method

The global process passes through the identification of new incoming batches, which is positive if the result matches the previously defined threshold for the respective class group in the method. Qualification can be required if we are in presence of a raw-material that shows different properties as said before. Figure 2 is an example of qualification, which represents a dendogram from a cluster model which can qualify correctly several batches of the same API with different dispersability properties in water according to these properties.

The proven advantages of this identification technique include: reduced use of technician time; elimination of the consumption and exposure of noxious solvents used in some sample preparation procedures; faster raw-material approval in the receiving area and more information about it (e.g. chemical and physical properties).

This kind of NIR application could be considered as a PAT initiative, since it is an efficient and innovative approach for the control of critical quality attributes of a raw material to a pharmaceutical manufacturing process. Although this application is used in the first step of the process (raw material analysis), it will enable process control, thus reducing the vulnerability of the process and manufacturing time cycles, to use in the incoming raw material with a positive impact in productivity and final product quality assurance.

2.2 Quantification methods

NIR is being used for quantitative purposes. Several quantitative methods (multivariate calibrations) were developed. Most of all were developed to determine moisture content in process intermediates (i.e. In-Process analysis), and some of them for the content determination of active ingredients (API) in intermediates and end-products simultaneously.

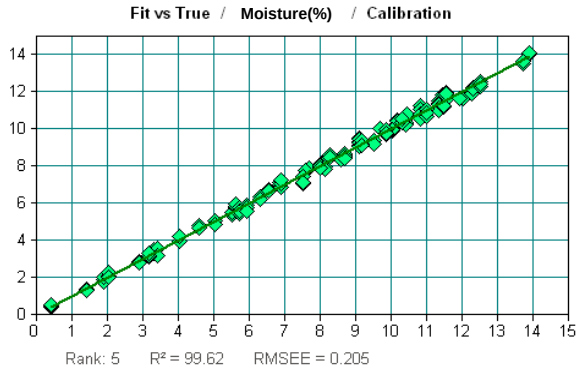

Figure 3 – Calibration for moisture determination

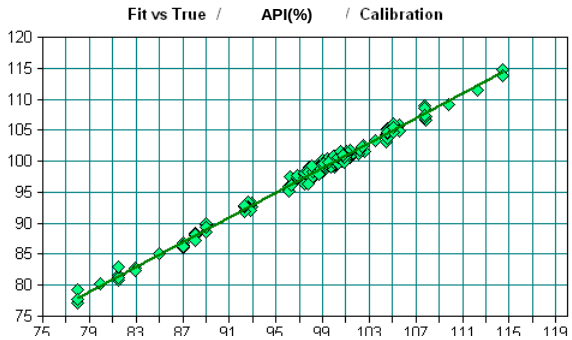

Figure 4 – Calibration for API determination

Figure 3 represents a calibration for moisture determination in an intermediate granulate analysed during manufacturing process (in-process), and figure 4 represents a calibration for an API determination in a final solid dosage form.

Moisture or API content is monitored and controlled during the manufacturing process, which allows to check if the product meets the specification criteria and also to assure its final quality. This could be considered a PAT application, as multiple quality attributes of different nature are included in the NIR evaluation and can be seen as the first step to establish a multi-parametric release system, since it allows the real-time measurement, monitoring, and control of critical quality parameters as it is the moisture or API content in pharmaceutical products.

All calibrations were validated for specificity, linearity, range, accuracy, and precision (repeatability and intermediate precision) parameters, and proved to be suitable for its intended use.

3 Conclusions

The use of NIR spectroscopy for qualitative and quantitative purposes in a pharmaceutical industry has proved its usefulness over conventional analytical techniques. NIR applications could be considered PAT applications, since they represent an efficient and innovative approach for the control of critical to quality attributes of pharmaceutical products over all the manufacturing process (viz. raw materials, intermediates, and final products).

The NIR applications described here enable process control, thus reducing the vulnerability of the process and manufacturing time cycles, with a positive impact in productivity and final product quality assurance

NIR implementations have the potential to enhance process understanding and control of existing and running manufacturing processes, at the same time they provide very valuable quality control analytical results in-process in accordance to regulatory requirements.

Keywords: Chemical Processes, E-learning, Virtual Laboratories, Web Platform

Abstract

This work describes the development of a Virtual Platform with a wide scope, directed to the learning of Chemical Processes. The platform is organized in five different sections: Separations and Unit Operations, Reaction Engineering, Process Systems Engineering, Biological Processes and Virtual Experiments. The first four sections deal with the chemical/biochemical processes and include simulators, applications and case studies aimed at leading the students to understand those processes. The fifth section, Virtual Experiments, deals both with the laboratory visualization of the basic phenomena related to the processes in the other four sections, and with the remote monitoring of laboratory experiments. Moreover, this platform, which has been constructed as a dynamic Web Portal, will allow discussion forums and is aimed at sharing experiences with other schools. This paper describes the different applications included in the web platform, as well as the simulation strategies and web methodologies used for its construction, presenting also one example of application in the classroom.

1 Introduction

Recent advances on information and communication technologies (ICT) have facilitated the development of educational and laboratorial systems based on distributed multimedia technologies, namely virtual reality, under relatively low costs. The traditional methodology of education conducted only in the classroom does have a number of inherent limitations that include passive learning attitudes, difficulties in applying the concepts introduced to real life problems, and little responsibility on the side of students regarding self-learning. New educational tools, based on virtual learning environments, can contribute to stimulate each student, in order to develop competencies of autonomous and critical thinking, in accordance namely with the Bologna process.

The Chemical Engineering Departments of both the Universities of Coimbra and Porto have been experimenting, on their own, for quite sometime, new teaching methodologies (Rafael et al., 2007, Mendes, 2002) taking into consideration the concerns referred above, and also taking advantage of the information technology skills available in the new students' populations. Recently, these departments got engaged in a broader project, directed towards the development of a virtual platform with a wider scope, aimed at the teaching/learning of Chemical Processes, at the graduation level in Chemical Engineering, for Portuguese-speaking students including those from African countries. A large group of academics (13 Chemical Engineering Faculty members and 5 research students), with complementary competencies and expertise were involved in this project.

This paper describes the different sections included in the web platform built, as well as the simulation strategies and web methodologies used for its construction. The web platform structure adopted is illustrated in Figure 1. The functional areas of the platform are as follows: Separations and Unit Operations, Reaction Engineering, Process Systems

Engineering, Biological Processes and Virtual Experiments. Moreover, our teaching platform also includes an area directed towards secondary school students interested in chemical engineering, where, besides general information on “What Chemical Engineering is all about”, fundamentals of physics and chemistry, in relationship with engineering applications, are covered.

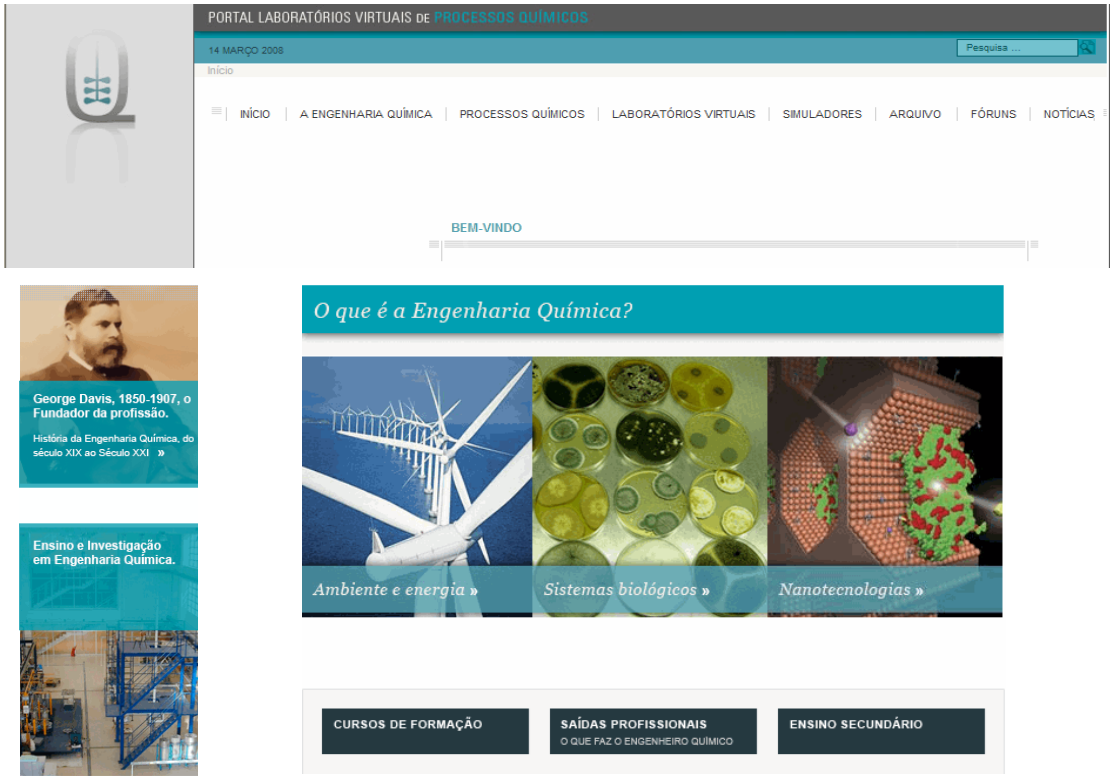

Figure 1 – Structure of our Teaching Web Platform.

2 Development of the virtual platform

The Web infrastructure of the Virtual Laboratories of Chemical Processes Platform is an information platform based on standard open-source and freely available software - *CMS Joomla*!, free software under the GPL license. This approach allows similar functionalities provided by other commercial software, with the flexibility to better adapt code to the specific needs of this Portal. In addition to these functionalities, the use of *Joomla!* allows the installation of additional components and modules, to support other functionalities of the portal such as discussion forums, search boxes, online surveys, lists of documents available for downloading, etc.

One of the key components of the web platform is process simulation. The study of the different chemical processes is supported by twenty interactive simulation modules, covering both fundamental topics as well as more practical and complex applications. Figure 2 depicts the basic architecture of the simulation system, comprehending two main blocks: the *web interface*, which helps the user in entering the data required for simulation and supports the visualization of the corresponding results, and the *computational platform*, where the mathematical model of the chemical process is solved. The exchange of information between these two levels is mediated by a simulation gateway, designed in agreement with the CGI (Common Gateway Interface) protocol. The input data set, collected in an input form, supports numerical values as well as discrete options (chemicals to be processed, type of model to be used or different modes of simulation). The simulation output may include graphics and in some cases several sets of results for different input conditions and also dynamic profiles drawn in real time. Matlab was chosen as the preferential computational

platform, although other tools are also used, such as Octave and FORTRAN, for greater flexibility and faster execution, or to use previously developed codes.

Regarding the mathematical process models embedded in the simulators, they may be sets of algebraic and/or differential equations, depending if the process operation is continuous or batch and if the model has or has not variables distributed on space. These sets of equations are solved using standard numerical methods and in some more complex problems a decomposition strategy and/or iterative procedure may also be needed.

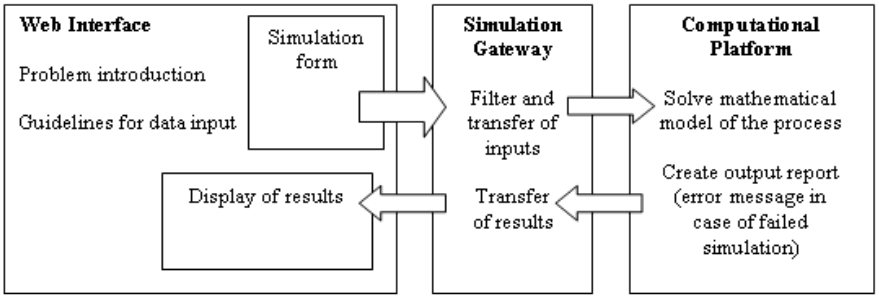

Figure 2 - Flowchart with the simulation Components.

3 The Chemical Processes area

Next, the main features of the different blocks in the Chemical Processes area are presented. Each block includes a library of fundaments, models and applications, simulators and case studies to lead the students through the study of the process concerned. Moreover, some processes in the four main areas previously mentioned are also illustrated through web visualizations of laboratory experiments, in the “Virtual Experiments” section, which interacts with all the other modules.

3.1 Unit Operations and Separation Processes

This section is directed to the study of Unit Operations, especially equilibrium and rate based processes applied to Chemical Processes. Five different separation processes have been considered so far: Distillation, Liquid/liquid extraction, Absorption, Adsorption and ion-exchange and Crystallization. Thermodynamics and Heat and Mass Transfer Fundaments were considered as autonomous modules and have been developed as well in this section, preceding the Separation Processes modules. For the design of distillation equipment both short-cut and the rigorous Wang-Henke method have been implemented. As for the design of liquid/liquid extraction equipment a McCabe-Thiele type method has been implemented, which is only valid when both solvents can be considered immiscible. The design of tray absorption towers, for both Absorption and Stripping, is also being based on the McCabe-Thiele method for the determination of the theoretical number of trays, for concentrated solutions, and on the Kremser equation when the user introduces a linear equilibrium equation (valid, in general, for diluted solutions). The rate-based processes considered in the platform are Gas/Liquid Absorption in packed towers and Adsorption and Ion-exchange in solid/liquid systems. With the simulator “Absorption in packed columns” the user can choose calculating one or all the design parameters: packing height, column diameter, pressure-drop and flooding mass flux. The simulator “Adsorption” consists of two major parts. In the first part, the user gets information on the equilibrium parameters by testing four different isotherms. In the second part, the user can choose models for studying the kinetic behaviour of batch, continuous stirred tank and fixed-bed adsorbers.

3.2 Chemical Reaction Processes

At the Chemical Reaction Engineering level our main goal is focused on the development of e-learning tools in the field of kinetic studies, design and operation of reactors to be used in homogeneous and heterogeneous processes. In what regards reaction kinetics, experimental data can be used to determine kinetic parameters, reaction orders and activation energies in order to obtain reaction rates equations that reflect the influence of

temperature and reactants concentration. The simulator allows using both integral and differential methods. In the context of reactor analysis the platform addresses ideal chemical reactors, stirred tanks under continuous, batch and semi-batch operation as well as plug flow reactors. Catalytic reactors are also addressed with particular emphasis on fixed-bed reactors largely used in the industry. In this domain, pseudo-homogeneous and heterogeneous mathematical models were developed in steady state regime, requiring different numerical techniques for computer simulation of the resulting ordinary differential equations, ODEs, or algebraic and ordinary differential equations, DAEs. Moreover, in the Residence Time Distribution (RTD) section, the students can calculate and plot the response to pulse or step inputs of tracer, which are the experimental techniques used to evaluate the RTD in open systems. The experimental procedure is also illustrated in one of the virtual experiments.

3.3 Process Systems Engineering

The main objective of the PSE section is to introduce the student to a variety of problems and methodologies that can be typically associated to the development and manufacture of chemical related products (pharmaceuticals, novel material, commodities and specialties) and process operating modes (batch or continuous). One basic module of the virtual platform includes a set of examples covering key concepts in the domain of instrumentation, by linking to a multimedia library, and process control. Moreover, a data acquisition system was implemented to monitor outdoor air quality (SO_2, NO_2 and CO emissions) using electrochemical sensors, temperature and relative humidity, in real time.

Students are also introduced to additional concepts related to dynamic systems. The physical examples considered are built starting from simple examples (like hydraulic systems), where most of the basic concepts of instrumentation and single-loop control laws can be illustrated, to more advanced processes, through the gradual introduction of additional chemical and physical phenomena, once the concepts described in other sections of the portal are mastered. Using this approach, both important practical aspects such as the effects of the choice of the sampling rate for discrete control, or the effects of errors introduced by linearizing models at various operating points, to the use of more advanced concepts such as alternative control strategies (adaptive and predictive), and the setup of parameter estimation and system identification schemes can be covered. One additional module in this section addresses the use of process integration and optimization methodologies in the context of rationalization of energy and utility usage in the process industries. Finally, this section includes also a subsection focused on Product Engineering, which links to a more detailed web page developed by the University of Cambridge (Moggridge , 2008).

3.4 Biological Processes

Modelling biological processes using theory, empirical correlations and mathematical tools contributes to the understanding of biological phenomena, to determine process parameters, to predict the performance of the equipment under different working conditions, etc., always considering the properties of the biological entities. This section includes the quantitative analysis of biological kinetic data to evaluate simple or more complex fermentations as affected by process conditions such as cell density and growth rate, substrate concentration, air flow rate, dissolved oxygen concentration, stirrer speed, etc. The recovery of bioactive products is more constrained in comparison with the unit operations that are more traditional in chemical engineering, in order to avoid loss of activity and contamination by other products. At this stage only the basic principles of membrane and chromatographic processes are covered. The simulation of the ultrafiltration process, in batch or continuous mode, can be tested as an example for illustrating the potentialities of the membrane technology in separating macromolecules. Regarding the chromatography, the partition of two components between a mobile and a stationary phase (adsorbent) has been simulated by using the technique of the elution chromatography, in which the sample is injected into the column as a pulse. The students, in both cases, have the opportunity of testing key concepts

involved in these operations and evaluating different operating approaches to achieve the best separation efficiency.

3.5 Virtual Experiments

Experimentation is as fundamental for students' learning process as the theoretical knowledge. The inclusion of a section named "Virtual Experiments" aims to cope with this objective. *Virtual Experiments* is meant to be an independent section, with links to other relevant areas of the site, as reaction, separation, biological systems and processes control. In this way different approaches for facilitating the learning and teaching processes in Chemical Engineering laboratories, will be coupled. Four experiments are included here: Determination of the Kinetic Constant and Activation Energy for the Liquid Phase Homogeneous Reaction between Ethyl Acetate and Sodium Hydroxide; Flow Pattern Characterisation in a Tubular Reactor Packed with Glass Beads; Study of the Sucrose Inversion and Study of a Cation-Exchange Resin. In addition to the description of the experimental setups and procedures and the theoretical background for each lab work, multimedia support is provided in the form of a video, illustrating each setup's components and the major steps in the operation procedures and experimental occurrences. In the section of process control, the students may carry out remotely one feedback control experiment, whose setup is located at the Chemical Engineering Department of the Faculty of Engineering - University of Porto.

4 Using the virtual platform in the teaching of chemical processes

According to the philosophy behind the construction of the platform, the site can be used in the classroom to illustrate the design and operation of process equipment, as for instance to show the influence of operating conditions, feed characteristics, etc. on the design outcome, or still to evaluate the validity of different models to do the design.

In this section of the paper we will next describe one example of the use of the platform to determine kinetic parameters of a reaction (reaction orders and activation energy). The estimation of the kinetic parameters is often addressed in the curricula of chemical engineering based on the liquid phase homogeneous reaction between ethyl acetate (EAc) and sodium hydroxide (NaOH). The reaction rate, r, is given by: $r = k\left(C_{NaOH}\right)^{n}\left(C_{EAc}\right)^{m}$, where k is the kinetic constant, n and m are the partial orders for sodium hydroxide and ethyl acetate, respectively; C_{NaOH} is the sodium hydroxide concentration and C_{EAc} is the ethyl acetate concentration. This reaction was carried out in a batch stirred reactor at 15, 20 and 25 ºC, and the students may determine, using the simulator in the Chemical Reaction Processes section, the partial orders (n, m) based on the integral or differential method. In order to fit the known concentration profile of NaOH, the conversion of this reagent, x_{NaOH}, was used to relate the concentrations of the two reagents and to allow integration and linearization. The students are expected to understand the consequences of admitting different values for n and m. For example, considering $n = m = 1$, the following equation is fitted by the simulator ($r = \mathrm{d}C_{NaOH}/\mathrm{d}t$)

$$\ln\left(\frac{M - x_{NaOH}}{M\left(1 - M - x_{NaOH}\right)}\right) = kC_{NaOH,0}\left(M - 1\right)t \qquad (1)$$

where M corresponds to $C_{EAc,0}/C_{NaOH,0}$, $C_{NaOH,0}$ is the initial concentration of NaOH, t is the time. By plotting the experimental data as indicated in Figure 3 (a) when the temperature of the system is set at 15 ºC, the linear fitting is the one indicated through the solid line, with a coefficient of correlation, $R^2 = 0.999$. The students shall conclude that the orders n=m=1 are adequate trials, and that the kinetic constant is 5.28×10^{-5} $m^3 \cdot mol^{-1}.s^{-1}$. For each case, the user may also validate the model by comparing the predicted values with the experimental ones. Since none experiment was performed at the conditions of excess of one reagent, the differential method is limited to the case of $n = m$; otherwise the linearization is not possible.

For this particular case ($n = m$), students may compare the fitting obtained with this method with the one obtained through the integral method.
Another important analysis that may be performed in the platform concerns the calculation of the activation energy, E , and the pre-exponential factor, k_0 , by using the Arrhenius equation. After knowing the kinetic constant calculated at 15, 20 and 25 ºC, the students may obtain a similar fitting to the one represented in Figure 3 (b). In this case, one may conclude that the system is characterized by $E = 4.79 \times 10^4$ J·mol^{-1} and $k_0 = 2.58 \times 10^4$ m^3·mol^{-1}·s^{-1}.

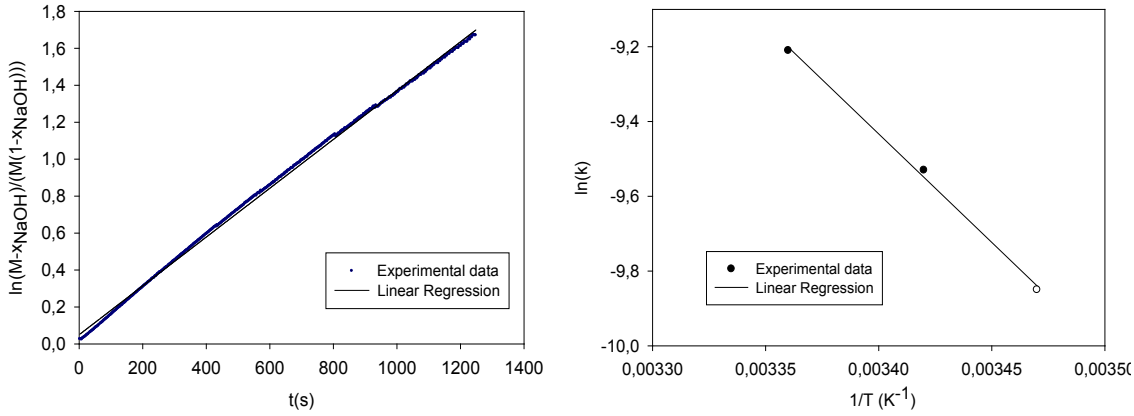

Fig. 3 - (a) - Fitting of the experimental values for the hydrolysis of ethyl acetate using the integral method, when $n = m = 1$; (b) - Fitting of the Arrhenius equation.

5 Conclusions

The Portal LABVIRTUAL (http://labvirtual.eq.uc.pt) showed to be a valuable tool for the teaching of Chemical Processes because of the several features which are usually not combined in a single platform: i) Broad collection of chemical processes being addressed in the same platform, in the different areas of Chemical Engineering; ii) Simulators (twenty in total) which enable designing and dimensioning the different processes addressed, iii) Applications and case studies to help the students in the use of the simulators and give them a practical perspective of the basic concepts; iv) Virtual experiments which enable the students to visualize some basic phenomena on which the design of chemical processes is based, and also help the students to get better prepared to carry out experiments in the real laboratory. These features give to the student an integrated approach to Chemical Processes, and lead to an easier integration of knowledge which is addressed in different courses Moreover, the portal has also been built to disseminate information about Chemical Engineering to the general public, and mainly to students in the basic and secondary education levels. Finally, and because the language of the portal is Portuguese, it is expected that it can be used to strengthen the relations between universities in Portugal and their counterparts in the Portuguese speaking countries, involved in the teaching of Chemical Engineering.

Keywords: Distillation, Shortcut Methods, Design, Column Sizing, Add-ins, Spreadsheet

Topic: Educating chemical and biological engineers for coming challenges

Abstract

A computer program, in Visual Basic for Applications, was developed for design and sizing of binary and multicomponent distillation columns using shortcut methods. The program is in the form of two add-ins for Microsoft Excel, one for binary and the other for multicomponent distillation.

These two add-ins are easy to use and to incorporate in Microsoft Excel, a widespread working tool for engineers, and can be helpful as a teaching aid, or as a tool for operator training or preliminary design and sizing of distillation columns.

1. Introduction

Distillation continues to be one of the most used separation techniques in the chemical industry, in sipte of its energy intensive character. This unit operation uses heat as the separating agent, and the difference in relative volatilities as the separation principle. The design of distillation columns is greatly influenced by the type of mixture to be separated, in particular, its ideal or non-ideal behaviour. In spite of its widespread used, distillation cannot be applied to the separation of all kinds of liquid mixture, more specifically, distillation should not be a first choice for the separation of azeotropic, closed boiling or thermodegradable mixtures.

Due to its generalized use, which is not restricted to the chemical industry, the design of distillation columns is well understood, and many reliable mathematical models for performing distillation calculations are available in the literature. These models can be divided in two main classes: i) shortcut models and ii) rigourous models. The shortcut models are easier to use and can be considered rigorous enough for preliminary design and process evaluation, or for qualitative studies.

This work presents two software tools, in the form of Microsoft Excel add-ins, for the application of shortcut models to the design and sizing of binary and multicomponent distillation columns.

2. The software tools

The add-in for binary distillation uses the McCabe-Thiele method for column design, allowing the user to interact with the program by means of self-explanatory user-forms. The software is able to design and size binary or pseudo-binary distillation columns, with multiple feeds and sidestreams, having different feed entalpic conditions, for ideal vapour and non-ideal

* Corresponding author. Tel + 351-22-5081974. E-mail:fgm@fe.up.pt

liquid mixtures. The design of steam distillation columns is also considered. The vapour-liquid equilibrium can be described by assuming constant relative volatility, ideal mixtures, or by using the Margules, van Laar, Wilson, NRTL, UNIQUAC and UNIFAC models to describe the non-ideality of the liquid phase (Smith et al., 2001). Figure 1 shows the screenshots of the add-in for binary distillation. The calculations are illustrated by means of a graphical interface, and the results summarized in a spreadsheet. The program allows the calculation of the minimum reflux ratio, minimum number of stages, operating reflux ratio, number of ideal trays, and can also be used to perform estimates of the number of real trays, the height, and diameter of the column. The sizing of the column is based on the shortcut method purposed by Douglas (1988). The value of the actual reflux rate may be given as input or estimated by specifying the value of the ratio R/Rmin. This computer program does not only offer to the process engineer a good first estimate for the design and size of binary distillation columns, but is also an important teaching aid for students and operator training, showing graphically the influence of the different design variables in the final project.

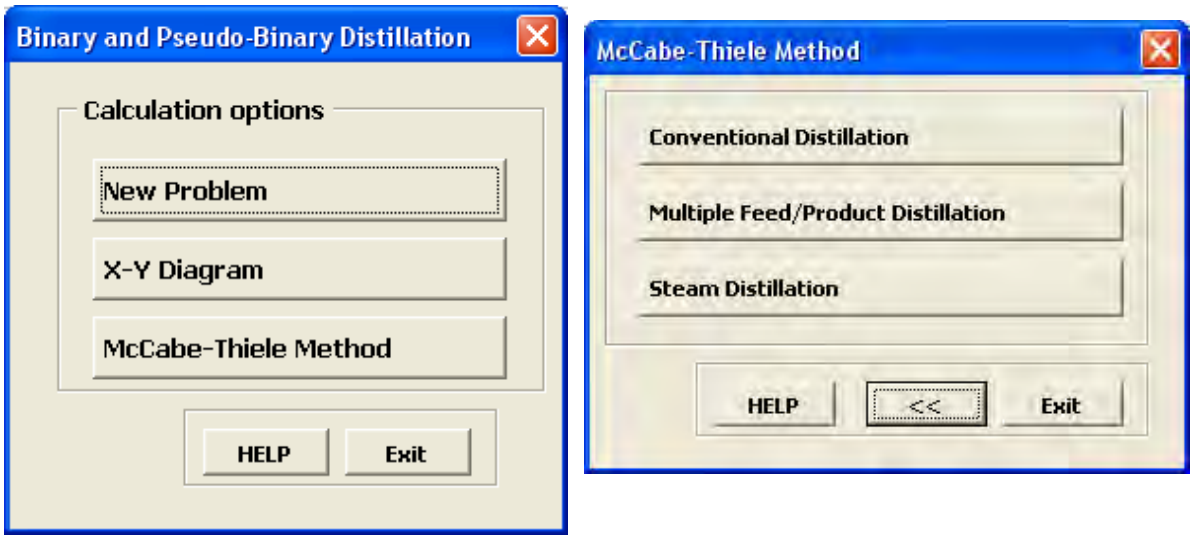

Figure 1 – Screenshots for binary distillation.

The add-in for multicomponent distillation uses the Fenske-Underwood-Gilliland-Kirkbride shortcut method. This method assumes constant internal flows in each section of the column, and constant relative volatility. For systems of variable relative volatility, the equilibrium constants or the parameters for the Antoine equation must be given, in order for the program to calculate an average value for the relative volatility. Two alternative equations are used to fit the Gilliland correlation, the Martins (1999) and Molokanov et al. (1972) equations. For application of the Gilliland correlation either the value of R/Rmin or N/Nmin must be specified. As output, the program gives the following information: minimum number of stages, minimum reflux ratio, composition and flows of both products at total and at minimum reflux ratio, number of ideal stages, operating reflux ratio and feed tray. The software is able of autonomously analyze the possibility of the distribution of non-key components.

3. Examples

This section gives an overview of the potentialities of the developed software, by showing how the two add-ins can be used to design distillation columns for a closely ideal mixture (i.e., benzene/toluene), a highly non-ideal mixtures (i.e., ethanol/water) and a multicomponent mixture.

Example 1: Binary distillation – Separation of the mixture benzene/toluene.

The first example corresponds to the separation of an equimolar saturated liquid mixture of benzene/toluene at 100 kPa. The behaviour of this mixture is closed to ideal, and therefore the phase equilibrium can be described by assuming the relative volatility constant, and equal to 2.456. The recovery of benzene was set equal to 90%, its purity equal to 90 %, and the reflux ratio equal to 2.61. Figure 2 shows the input form with the data used to design this conventional distillation column.

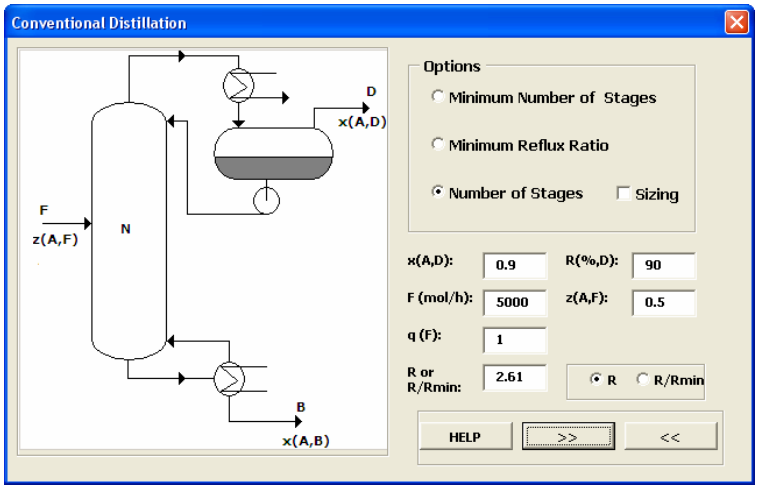

Figure 2 – Input form for the design of a binary conventional distillation column.

Running the add-in, the McCabe-Thiele diagram is created, and the minimum reflux ratio, the operating reflux ratio, and the ideal number of plates shown in the diagram (Figure 3). If the operator chooses the sizing option, the number of real stages and the column diameter and height will also appear in the generated McCabe-Thiele diagram.To further exemplify the capabilities of the software, the same example is now run using a column with 2 feeds and 1 sidestream, and assuming non-ideal liquid phase. The input form for this example is given in Figure 4, and the corresponding McCabe-Thiele diagram shown in Figure 5.

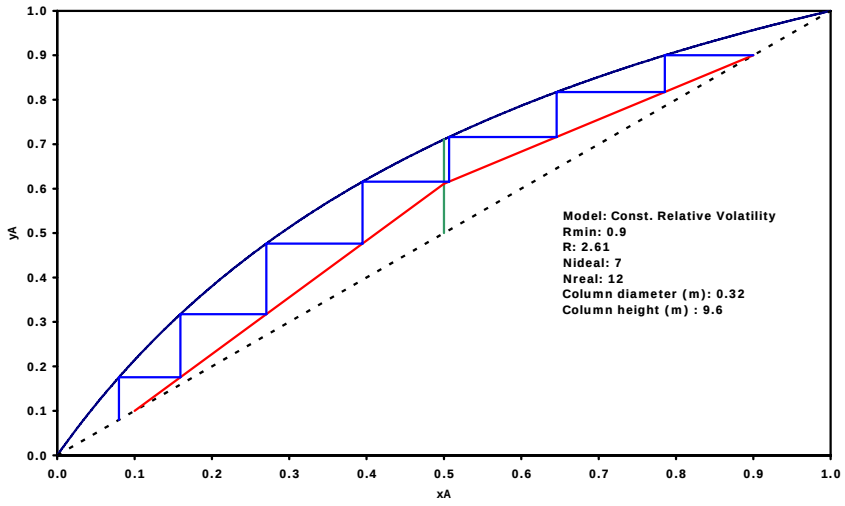

Figure 3 – McCabe-Thiele diagram for the system benzene(A)/toluene(B).

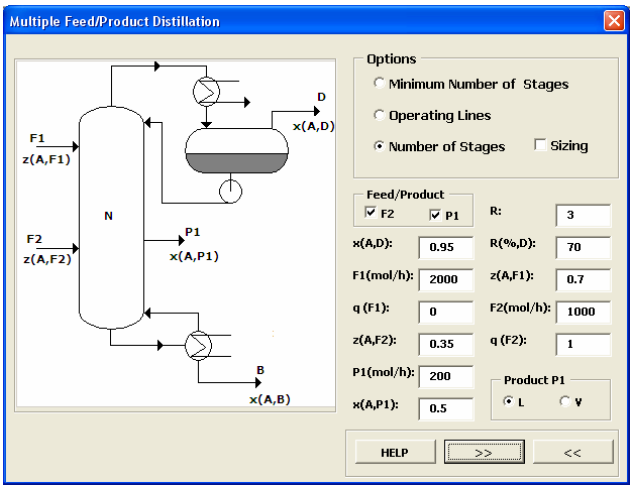

Figure 4 – Input form for a binary distillation column with 2 feeds and 1 sidestream.

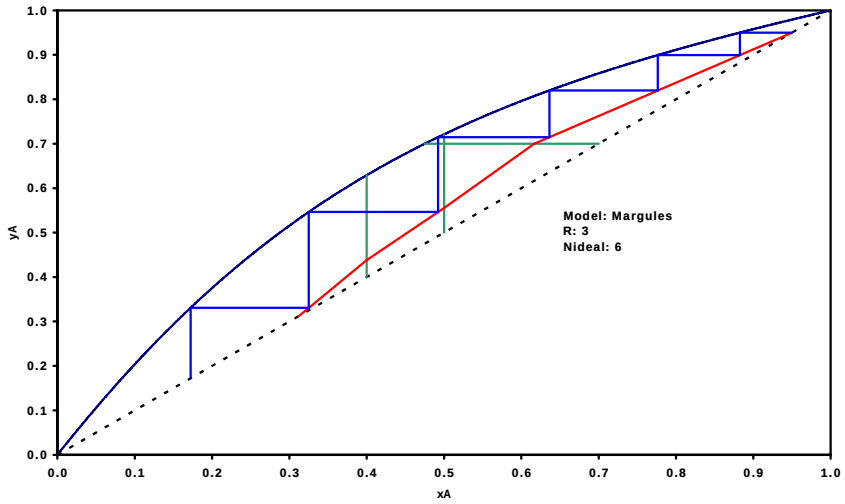

Figure 5 – McCabe-Thiele diagram for the system benzene(A)/toluene(B) in a column with 2 feeds and 1 sidestream

Example 2: Binary distillation – Separation of the mixture ethanol/water.

Figure 6 shows the McCabe-Thiele diagram for the mixture ethanol/water, assuming an ethanol recovery of 90%, and a distillate purity of 89% in ethanol. The feed was considered saturated liquid with 35% ethanol (molar percentage), and the R/Rmin ratio was set equal to 1.3. The vapour/liquid equilibrium was predicted by using the UNIQUAC model.

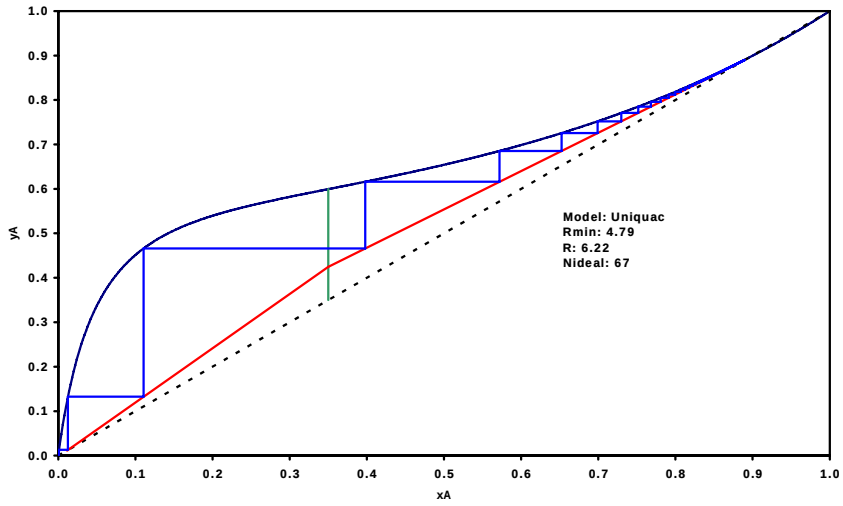

Figure 6 – McCabe-Thiele diagram for the system ethanol(A)/water(B).

As can be seen, for this highly non-ideal system, a large number of stages is necessary to attain the required separation, being most of the stages located in the rectifying section.

This add-in also allows the design of steam distillation columns, a capability that is not easily found in most of the available software applications.

Figure 7 shows the McCabe-Thiele diagram for the separation of the mixture ethanol(A)/water(B) by steam distillation.

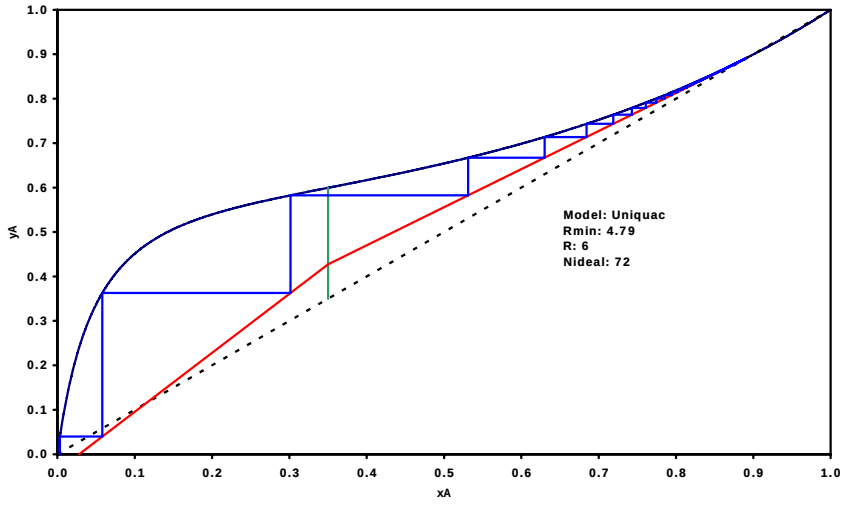

Figure 7 - McCabe-Thiele diagram for the separation of ethanol(A)/water(B) by steam distillation.

Example 3: Multicomponent distillation

The first case to be analyzed for multicomponent distillation deals with the separation of n-butane/n-pentane from a mixture with the following composition (molar percentage): 5% propane, 40% n-butane, 10% i-pentane and 45% n-pentane. The recovery of n-butane in the distillate and n-pentane in the bottom product were both set equal to 95%.

The key components are n-butane (light-key) and n-pentane (heavy-key), the operation pressure is 1000 kPa, and the ratio R/Rmin is 1.3. Table 1 shows the results generated by the add-in.

Table 1 – Results for the Fenske-Underwood-Gilliland-Kirkbride shortcut method.

	Fenske			Underwood			Gilliland (Martins, 1999)	
Components	**xd**	**xb**	**Nmin**	**xd**	**xb**	**Rmin**	**N**	**R**
Propane	0.109	0.000	7	0.108	0.000	1.201	15	1.561
n-Butane	0.830	0.037	**D/F**	0.819	0.037	**D/F**	**Kirkbride**	
i-Pentane	0.032	0.158	0.458	0.044	0.149	0.464	**Nr**	**Ns**
n-Pentane	0.029	0.805		0.029	0.814		8	7

This add-in can be used in alternative to the McCabe-Thiele method for binary systems of constant volatility. Table 2 shows the results of the application of the Fenske-Underwood-Gilliland-Kirkbride shortcut method to the separation of the binary mixture of benzene/toluene studied in example 1. As can be seen, identical results are achieved.

Table 2 – Results of the Fenske-Underwood-Gilliland-Kirkbride shortcut method for the system benzene/toluene.

	Fenske			Underwood			Gilliland (Fernando, 1999)	
Components	**xd**	**xb**	**Nmin**	**xd**	**xb**	**Rmin**	**N**	**R**

			0.500			0.500	**Nr**	**Ns**
							3	4

4. Conclusions

The potencialities of two Microsoft Excel add-ins developed for the design and sizing of binary and multicomponent distillation columns were discussed. These add-ins use shortcut methods, the McCabe-Thiele and Fenke-Underwood-Gilliland-Kirkbride methods, for design of binary and multicomponent distillation columns, and the method of Douglas for column sizing. The developed add-ins also allow the design of steam distillation columns, columns with multiple feeds and sidestreams, and columns used for the separation of non-ideal mixtures.

This software can be sucessfully used as an aid for teaching, or a tool for operator training and preliminary design and sizing of distillation columns.

Keywords: distillation, rectification, McCabe-Thiele, efficiency, Rayleigh

Topic: Educating chemical engineers for coming challenges

Abstract

The importance of distillation in the separation field prompts the inclusion of distillation experiments on chemical engineering curricula. This work describes the performance of an Oldershaw column with 5 sieve trays in the rectification of a cyclohexane/n-heptane mixture. Different modes of column operation are studied, namely continuous rectification, with total and partial reflux, and batch rectification with constant reflux. The effect of internal flows upon the separation and column efficiency is also assessed. With this experimental work students train relevant concepts, including vapour-liquid equilibrium, continuous *versus* batch operation, McCabe-Thiele graphical method, column efficiency, and the generalized Rayleigh equation.

1. Introduction

The distillation is by far the most frequently used separation process. Although not energy-efficient, it has a simple flowsheet and is a low-risk process. It is indeed the benchmark with which all newer processes must be compared. Following Null (1987), distillation should be selected unless $\alpha_{12} < 1.05$, whereas Nath and Motard (1981) and Douglas (1988) indicate $\alpha_{12} < 1.10$, a more conservative critical value. Generally, design heuristics point out that processes using energy separation agents should be favoured.

Previous features justified the inclusion of distillation experiments on the chemical engineering curricula of the Department of Chemistry at University of Aveiro (DCUA). Students start receiving lectures on distillation as part of their course of Separation Processes I, which is essentially devoted to equilibrium-staged unit operations. Afterwards, experiments are carry out in Laboratory EQ, a weekly, six-hour lab course intended to study separation, reaction, and control.

In this paper the lab exercise on continuous and batch rectification developed at DCUA is presented. Experiments are performed in an Oldershaw column with 5 sieve trays to separate cyclohexane/n-heptane under different modes of operation: total reflux, continuous rectification with partial reflux, and batch rectification with constant reflux. The effect of the power supply to the reboiler flask upon the separation and column efficiency is evaluated.

An Oldershaw tray column is a laboratory scale column equipped with perforated trays. Of special importance is the fact it produces separations close to those in large industrial columns (Fair et al., 1983). In fact, experimental results show that commercial towers will

* Corresponding author. Tel + 351 234 401 549. E-mail:carlos.manuel@ua.pt

require a similar number of stages to reach the same separation level obtained in the Oldershaw unit (Humphrey and Keller, 1997).

With this work students train relevant concepts introduced earlier on their curriculum, namely vapour-liquid equilibrium, continuous *versus* batch operation, McCabe-Thiele graphical method, efficiency, and the generalized Rayleigh equation. Examining experimental results students gain insight in this unit operation.

2. Experimental Section

2.1 Experimental set-up

Experiments are performed in an Oldershaw tray column equipped with a dest-star advance controller supplied by Normschliff Gerätebau. The unit is shown in Figure 1 and comprehends five perforated plates, a reboiler, a total top condenser using tap water as cooling fluid, a lateral condenser to remove distillate as liquid, a solenoid valve to divide the vapor stream into reflux and distillate under partial reflux mode. Additional features are: temperature sensors placed between trays; samples of liquid may be withdrawn from each tray to determine its composition by refractive index (RI); temperature sensors immersed in reboiler and located at the top allowing the determination of the bottom and head compositions, respectively.

Figure 1: Oldershaw tray column.

2.2 Experiments at total reflux, $R = \infty$

Continuous rectifications at total reflux were performed at two distinct reboiler powers ($P = 700$ W and 900 W) to evaluate their effect upon separation and column efficiency. The temperature profile of the column was used to detect the stationary state. Top and bottom temperatures (T_D and T_B) were utilized to calculate the corresponding cyclohexane molar compositions, x_D and x_B, by Liquid-Vapor equilibrium relationships.

2.3 Continuous rectification at partial reflux

This equipment is extremely versatile, being possible to devise a continuous rectification under partial reflux. With an adaptation the distillate is directly fed to the reboiler (see Figure 1), allowing us to reach the corresponding stationary state. Such experiment was carried out at $R = 6$ under last power programmed, i.e. $P = 900$ W. Once more, T_D and T_B were utilized to determine x_D and x_B.

2.4 Batch rectification at constant partial reflux

Finally, a semi-continuous or batch distillation was performed with $R = 6$ and $P = 900$ W. Presently, the distillate is not fed to the reboiler, but collected to an independent flask shown in Figure 1. Under this mode of operation, compositions vary along time. T_D and T_B were registered during 1 h approximately, being used yet again to determine the corresponding x_D and x_B. At the end of the batch rectification, the refractive index of distillate was measured.

3. Calculations

3.1 Vapor-Liquid Equilibrium

At low pressures, the vapor-liquid equilibrium may be represented by:

$$y_i P_t = x_i \gamma_i P_i^{\sigma} \quad (1)$$

where y_i and x_i are the molar fractions of component i in the vapor and liquid phases, respectively, P_i^{σ} is its vapor pressure, γ_i is its activity coefficient, and P_t is the total pressure. P_i^{σ} is determined by the Antoine equation, while γ_i is calculated using the Margules equations. The corresponding parameters are listed in Table 1.

Table 1: Antoine (Boublik et al., 1973) and Margules parameters.

	Antoine[a)]			Margules	
	A	**B**	**C**	**A12**	**A21**
Cyclohexane	6.84941	1206.001	223.148	0.0563	-0.0938
n-heptane	6.90253	1267.828	216.823		

a) $\log P^{\sigma} = A - B/(T(^{o}C) + C)$

3.2 Number of equilibrium stages

The number of equilibrium stages is obtained by the well-known McCabe-Thiele method (Seader and Henley, 1998). In this work the column has a rectifying section only. Its operating line is:

$$y = \left(\frac{R}{R+1}\right)x + \left(\frac{1}{R+1}\right)x_D \quad (2)$$

When the column operates at total reflux ($R = \infty$) the rectifying operating line coincides with the diagonal line. The number of equilibrium stages is given by the number of outlined steps between x_D and x_B. One equilibrium stage, corresponding to the reboiler, must be discounted to the total number of stages.

3.3 Overall efficiencies

The experimental overall efficiency is given by:

$$E_{ov}\,(\%) = \frac{N_{ideal}}{N_{act}} \times 100 \quad (3)$$

where N_{ideal} is the ideal number of equilibrium stages and N_{act} is the actual number of trays (in this case $N_{act} = 5$).

The overall efficiency can be predicted by empirical correlations, namely, those by Drickamer and Bradford (1943), and O'Connell (1946). Drickamer and Bradford correlated the overall efficiency in terms of the molar average liquid viscosity, μ, of the column feed at the average tower temperature:

$$E_{ov}\,(\%) = 13.3 - 66.8 \log \mu\,(\mathrm{cP}) \quad (4)$$

O'Connell used viscosity and relative volatility, α, dependence:

$$E_{ov}\,(\%) = 50.3\left[\,\alpha \times \mu\,(\mathrm{cP})\,\right]^{-0.226} \qquad (5)$$

The relative volatility is the geometric average of bottom and top values.

3.4 Generalized Rayleigh equation

The liquid number of moles in the reboiler is related with distillate and residue compositions by the Generalized Rayleigh equation:

$$\ln\frac{B}{F} = \int_{x_{B,0}}^{x_{B,\,ftinal}} \frac{dx_B}{x_D - x_B} \qquad (6)$$

where F and B are the initial and final liquid number of moles in the reboiler, respectively. By knowing experimental (x_D, x_B) pairs, the B/F fraction may be obtained by numerical integration.

4. Results and Discussion

Table 2 presents the results obtained by total reflux experiments at 700 W and 900 W. For illustration, the McCabe-Thiele diagrams at total reflux and 900 W is plotted in Figure 2a. The minimum number of equilibrium stages were 4.76 and 4.61 for $P = 700$ W and 900 W, respectively, giving rise to overall efficiencies of 95.1% and 92.1%. These results indicate the column is more efficient when operated at 700 W, which is usually unexpected for the students. Actually, higher reboiler powers generate higher internal flows. Although such effect leads to a foreseen increase of the mass transfer coefficients, it also decreases the mean residence times of both phases in each tray which has a larger impact in the whole.

Table 2: Experimental conditions and results for total reflux experiments.

$P\,(W)$	T_D(ºC)	T_B(ºC)	x_D	x_B	E_{ov}(%)		
					Exp.	Eq. 4	Eq. 5
700	83.9	92.6	0.878	0.281	95.1	53.1	64.8
900	84.2	92.7	0.864	0.273	92.1	53.2	64.9

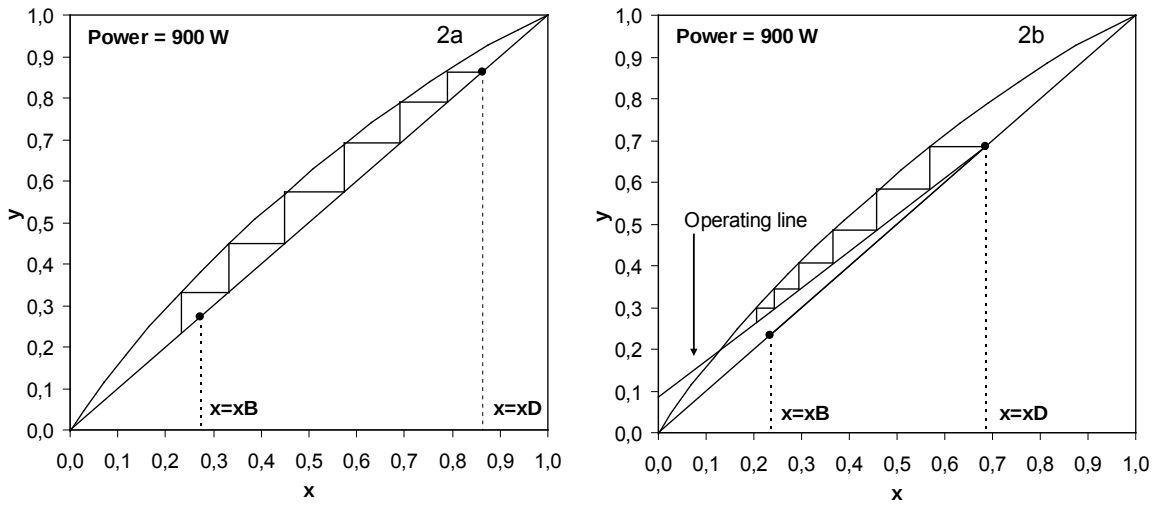

Figure 2: McCabe-Thiele diagram for a) total and b) partial reflux rectifications.

The experimental and predicted overall efficiencies for $P = 700$ W and 900 W are included in Table 2. Obtained results show that the predicted E_{ov} are significantly inferior to the experimental ones. Overall column efficiency is known to be a complex function of the system properties, operating conditions and column geometry; however, empirical correlations used only takes some system properties into account. Moreover, other results from literature (Seader and Henley, 1998) indicate that similar systems exhibit efficiencies 10% to 20% higher than the obtained by O'Connell correlation.

The results obtained for the partial reflux rectification ($P = 900\,W$ and $R = 6$) are given in Table 3. The corresponding McCabe-Thiele diagram is plotted in Figure 2b. As may be observed, the overall efficiency achieved was about the same of that obtained at total reflux for the same reboiler power.

Table 3: Results for partial reflux experiment.

T_D(ºC)	T_B(ºC)	x_D	x_B	E_o(%)
88.2	93.5	0.660	0.234	92.0

Figure 3 shows the evolution of distillate and residue compositions during the batch rectification ($P = 900\,W$ and $R = 6$). As expected, the column was exhausted in cyclohexane along time, because it is the light component.

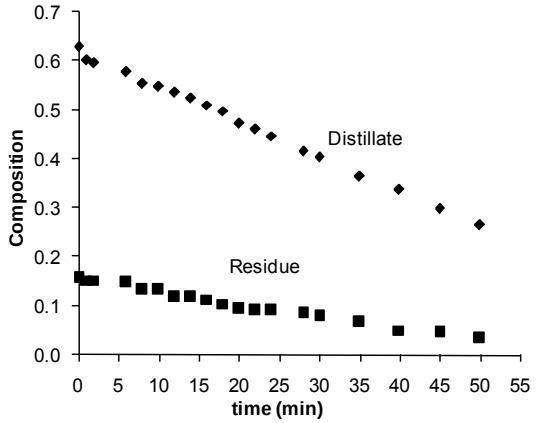

Figure 3: Distillate and residue compositions during the batch rectification.

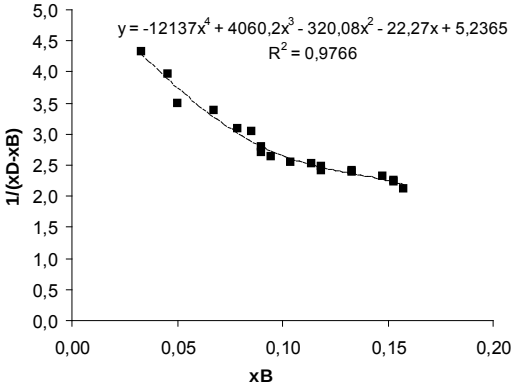

Figure 4: Graphical integration of Rayleigh equation.

The undistillated liquid fraction, B/F, was determined by numerical integration of the Rayleigh equation, using the polynomial fitted to experimental data (see Figure 4). Furthermore, B/F was also calculated by a mass balance using the initial ($x_{B,0}$) and final ($x_{B,final}$) residue compositions, and the composition of final distillate obtained by refractive index. As may be observed, B/F fractions obtained by both methods are very similar (see Table 3).

Table 3: B/F fraction obtained by Rayleigh equation and mass balance.

x_D **(RI)**	B/F **(Rayleigh Eq.)**	B/F **(mass balance)**
0.410	0.696	0.667

5. Conclusions

This work describes an experimental procedure where students have the opportunity to study distillation, using an Oldershaw tray column, under three different modes of operation: total reflux, partial reflux, and batch. The reboiler power (and so the internal flows) effect on column performance was investigated at total reflux. Results show the efficiency decreases slightly with increasing power. Column efficiency measured at partial reflux is analogous to that obtained at total reflux. In batch distillation the evolution of distillate and residue compositions was followed along time. Undistillated liquid fraction was calculated by numerical integration of the generalized Rayleigh equation and global material balance, giving rise to similar results.

With this work students train relevant concepts, including vapour-liquid equilibrium, continuous *versus* batch operation, McCabe-Thiele graphical method, column efficiency, and data analysis with the generalized Rayleigh equation.

Regeneration of sulfur poisoned nickel based catalysts for steam-methane reforming

S. Meysam Hashemnejad[1], Matin Parvari[1]*
[1] Chemical Engineering Department, Iran University of Science and Technology, Farjam Str., Tehran, Iran.

Keywords: Methane Steam Reforming; Nickel Catalysts; Sulfur Poisoning; Regeneration.
Topic: Regeneration of Spent Nickel Catalyst.

Abstract

This paper reports the result of regeneration of Razi petrochemical catalyst used for steam methane reforming. Nickel catalyst was poisoned by sulfur component from abnormally available in natural gas. A remarkable loss of sulfur was observed and the catalyst gains its activity. No changes of crystal structure were detected by XRD analyses. The first part leads to the identification of the catalyst by X-ray diffraction (XRD), Scanning Electron Microscope (SEM), carbon and sulfur analyzer. It clearly shows that sulfur and carbon deposition was the main problem in deactivation of catalyst. The catalyst activity of the catalyst contaminated with sulfur before and after regeneration was measured on methane steam reforming at a CH4:H2O ratio of 1:3 at 850Ċ. The result shows that approximately, main quantity of sulfur is removed and the regenerated catalyst gained 80% of its catalyst activity.

1 Introduction

Hydrogen gas or mixtures of hydrogen, carbon monoxide and carbon dioxide (synthesis gas) are used extensively in a wide range of industrial processes [1]. Hydrogen is predicted to become a major source of energy in the future. It is an important raw material in the chemical and petroleum industries; large quantities are used in the manufacture of ammonia and methanol and in a variety of petroleum hydro treatment processes [2, 3]. Methane can be converted into synthesis gas by steam reforming, CO_2 (dry) reforming or by conversion with O_2 through secondary reforming and partial oxidation [4]. Three main methane steam reforming reactions are always carried out as presented in the following equations:

$$CH_4+H_2O \leftrightarrow 3H_2+CO \quad (1)$$

$$CO+H_2O \leftrightarrow CO_2+H_2 \quad (2)$$

$$CH_4+2H_2O \leftrightarrow CO_2+4H_2 \quad (3)$$

Both water–gas shift reaction (Eq. (2)) and reverse methanation (Eq. (3)) are associated with the steam reforming over a catalyst at elevated temperatures [5]. Steam reforming reactions are usually carried out on supported nickel catalysts. Nickel is cheap, sufficiently active, and allows suitable catalysts to be economically produced.

One of the major problems in the application of these catalysts is sulfur poisoning. Even after a thorough desulfurization of the feedstock, sulfur-containing compounds in the feed may reach

* Corresponding author. Tel +98(21)73912755, Email: Parvari@iust.ac.ir

the nickel catalyst at a ppb level. Sulfur is a strong poison for nickel catalysts and blocks the active nickel sites. The sulfur adsorption capacity of steam-reforming catalysts is therefore an important catalyst parameter [6].

2 Sulfur poisoning

The most common cause of poisoning involves strong chemisorptions of gas phase species on the active sites. If the chemisorptions are weak, desorption and reactivation may occur, if it is strong deactivation results. The effectiveness of a poison depends on the equilibrium constant for the poisoning reaction and on the catalysts activity of the product formed. Sulfur is the good case in point.

Sulfur is a severe and common poison for nickel steam reforming catalysts as a sulfur-poisoned nickel catalyst has essentially no activity below 700Ċ. All sulfur -containing compounds in the feed are converted into hydrogen sulfide at reforming conditions [6]. The sulfur atom in hydrogen sulfide adsorbs strongly at the nickel surface by following reaction:

$$H_2S + Ni_{Surface} \leftrightarrow Ni_{Surface}\text{-}S + H_2 \qquad (4)$$

Process (4) is a fast, reversible process in a large range of concentration. Feedstock with S contents lower than 10 ppb are recommended to avoid appreciable deactivation of the Ni catalytic surface [7]. Process (4) is carry out with the adsorption of water in active site

$$H_2O + Ni_{Surface} \leftrightarrow Ni_{Surface}\text{-}O + H_2 \qquad (5)$$

This is to compete with sulfur binding for high water steam contents in the feed.

Concept that contributes to the sulfur poisoning is sulphating of support, which may change the crystalline structure and nature of support [8-10], so we can find out that the type of support may affect on reversible of sulfur poisoning.

3 Experimental Section

3.1. Catalyst preparation and reaction tests

The commercial catalyst was supplied by Razi petrochemical complex (Iran). Ni (14wt %) supported on $CaAl_4O_7$ is an industrial steam methane reforming catalyst. The catalyst was crushed and sieved to the appropriate size (30–50 mesh).

The experimental setup used for these experiments was operated at atmospheric pressure with ratio of methane to steam (CH_4/H_2O = 1/3). High purity methane (not less than 99.99%) was used as the reactant. Runs were carried out in a fixed bed quartz micro reactor (6.6 mm ID). Experiments were performed with 200 mg of the catalyst. After catalyst loading, because XRD study shown that a part of the Ni in the fresh catalysts is found as NiO so catalyst was reduced in situ for 2 h in a 50 mol% H_2/N_2 mixture (60 ml/min), while the temperature was raised from ambient to 600Ċ at a rate of 10Ċ/min. The catalyst was heated to 850 Ċ under the nitrogen flow with the rate of temperature increase of 10 Ċ /min. water and methane were then introduced to the reactor respectively. The composition of the gas stream leaving the reactor was determined by gas chromatography that is able to simultaneously analyze the remaining CH_4 and produced CO, CO_2 and H_2. The remaining water vapor exiting the reactor was removed from the product stream by use of a condenser.

3.2. Catalyst characterization

X-ray diffraction studies were performed in a PW-1800 Philips diffractometer with Cu Kα radiation (λ = 1.5406 Å) at 40 kV, 30 mA for determining crystalline phases.

Chemical analysis of all samples was carried out using a scanning electron microscope (SEM) coupled with an energy dispersive spectroscopy (EDS) analysis for the determination of chemical composition of samples. SEM images were taken on a Philips XL30 microscope.

The amount of deposited carbon and sulfur on species after reaction was quantified by Carbon Analysis (CA) which was performed on a thermal analysis Leco CS-444 from ambient to burned sample temperature. The samples burned on excited oven and amount of gas outlet was determined by a quadruple mass spectrometer.

3.3. Regeneration treatments

The regeneration process was performed in an attempt to remove both sulfur and carbon from the Ni catalyst, using the steam treatment in 700Ċ, higher temperature may increase the risk of sintering of nickel particles. The treatments were carried out in 2 hour. In all cases we added hydrogen to steam to prevent fully oxidation atmosphere, one of the reason of that is help us not to do repetitious reduction of catalyst before reforming reaction. After each satisfactory treatment the catalyst was cooled under nitrogen to room temperature and analyzed the sulfur and carbon content.

4 Results and Discussion

4.1. Catalyst characterization

In this case we have nickel catalyst used for production of synthesis gas with H_2/CO=3/1 ratio. There are three deactivated catalyst from top, middle and bottom of tower, which are compared with each others. As we know, one of the unexpected problems is excess existence of sulfur and sulfur derivations as poison of nickel catalyst in feed. The reaction conditions employed here are rather severe in terms of sulfur and also carbon deposition. Sulfur content in three deactivated catalysts is summarized in table 1. It clearly shows the huge amount of sulfur and carbon in catalyst at top that we do not have this severe condition for catalysts in middle and bottom so we can conclude the operations are take place out of control.

Table 1 sulfur and carbon weight percentage of nickel catalyst at top, middle and bottom of tower in Razi petrochemical complex.

Wt%	Top	Middle	Bottom
Carbon	0.17	0.04	0.03
Sulfur	0.2	0.03	0.03

The powder X-ray diffraction patterns of the deactivated samples in top, middle and bottom of the tower are shown in Fig. 1. NiO give peak at 37.249°, and no indication of $NiAl_2O_4$ is observed for this catalyst. Figure 1 clearly point out that calcium aluminate was used as support. The results demonstrate that there are no considerable changes of nickel crystallite sizes in three deactivated catalysts with each other and also compare with fresh one has been occurred. Sharpen up for support phase at top of the tower, indicating that particles of calcium aluminate became larger; this is consistent with the SEM micrographs of these samples as shown in fig. 2.

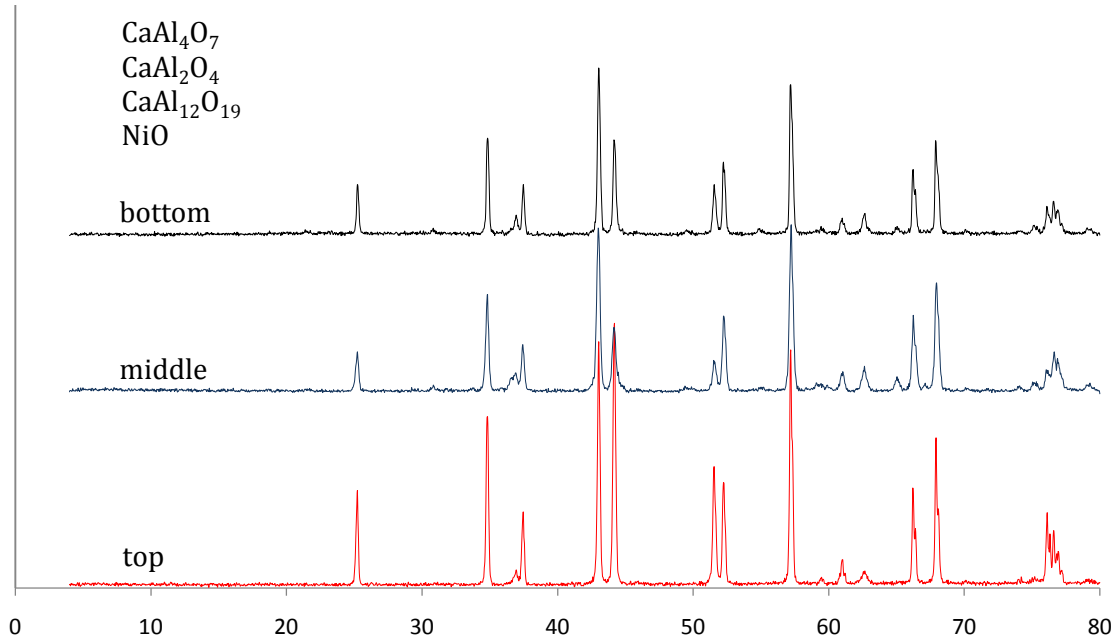

Fig. 1. XRD pattern of active and support phases for top, middle and bottom of tower catalyst sample in Razi petrochemical complex.

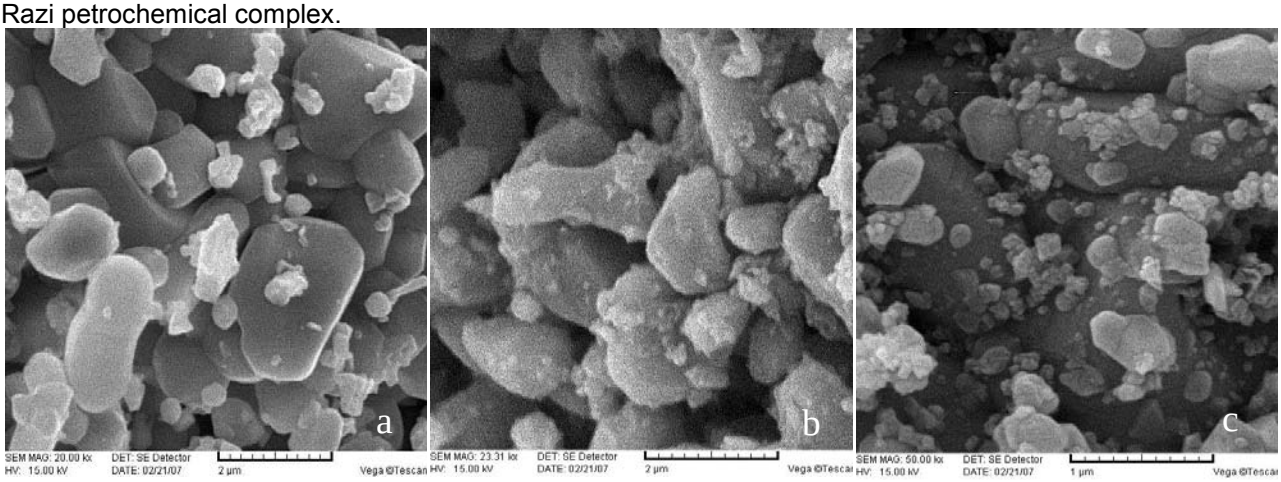

Fig. 2. SEM micrograph of bottom (a), middle (b) and top (c) used catalyst sample, in Razi petrochemical complex.

4.2. Catalyst regeneration

Regeneration of nickel catalyst was shown to be effective upon injection of steam stream at 700Ċ:

$Ni_{Surface}$-S + H_2O ↔ NiO + H_2S (6)

H_2S + 2H_2O ↔ SO_2 + 3H_2 (7)

One of the other reasons for adding hydrogen to the steam stream is to lead forward reaction (7) to prohibit hydrogen sulphide remaining in system and change it to SO_2.

The data in figure 1 show the impressive results in sulfur removal from Ni base catalyst. The degree of regeneration is declared with the ratio S/S_0, S and S_0 are the sulfur contents after

regeneration treatment and in initial deactivated catalyst, we have the same situation for carbon content. We can see the profound changes in sulfur content in regenerated catalyst.

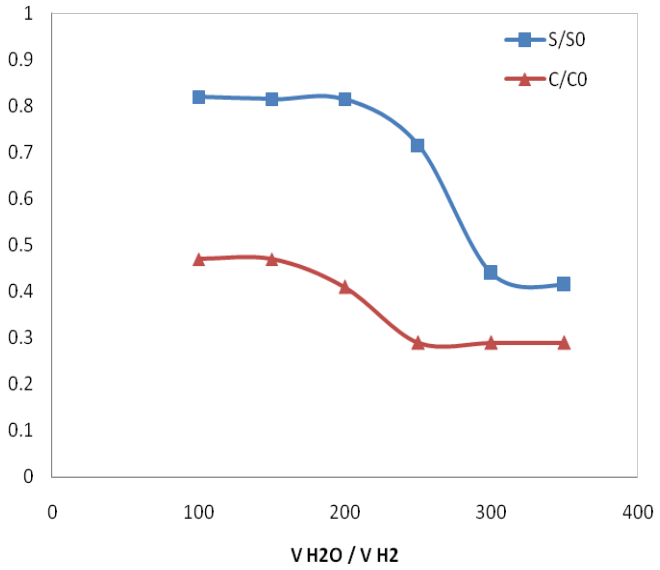

Figure3. Results in regeneration treatment with V_{H_2O}/ V_{H_2} for taking out sulfur and carbon in contaminated Ni based catalyst.

When the ratio VH_2O/ VH_2 was increased no improvement was observed as expected from the chemisorptions experiment. However, at VH_2O/ VH_2 above 200 a significant decrease of sulfur content in regenerated catalyst was observed (fig.1); surprisingly there is the same condition for removal of carbon deposition as shown figure 1. One of the characteristics of this treatment is that the catalyst structure does not change during the regeneration, as we shown in fig. 2.

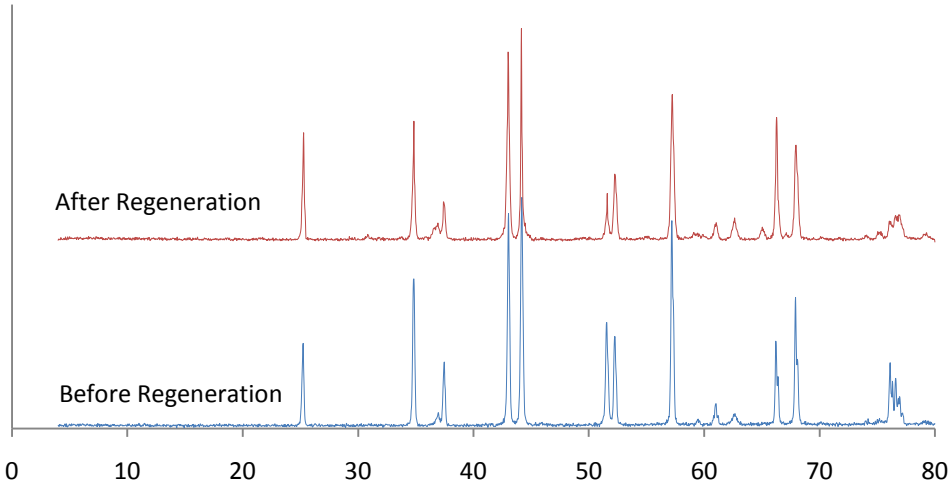

Figure4. XRD pattern of Ni catalysts where denote catalysts structure before and after treatment with steam.

The observed methane conversions for the catalyst before and after regeneration are summarized in figure 3. The catalyst regained more than 80% of its activity at VH_2O/ VH_2 = 350.

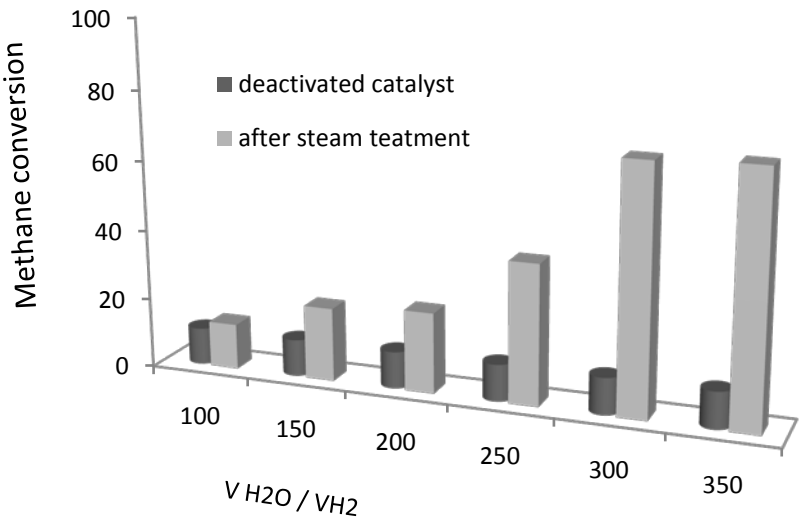

Figure5.methane reforming conversion in deactivated nickel catalyst before and after treatment with steam.

5 Conclusions

Sulfur poisoning is critical subject for steam reforming catalysts. Regeneration experiments have been performed on conventional Ni catalyst ($NiO\text{-}CaAl_4O_7$). The regeneration process is based on an oxidative removal of sulfur and carbon from the deactivated catalyst with steam treatment in 700Ċ. The steam reforming of methane at a CH_4:H_2O ratio of 1:3 was employed to test the catalytic activity of the catalyst. Since most of the sulfur and carbon is thereby removed, catalyst regained its activity more than 80%. One of important thing is no changes of the crystal structure were detected by XRD diagram.

Acknowledgment
The authors would like to thank Razi petrochemical complex for providing Ni catalyst.

Keywords: catalytic oxidation, VOC, ethyl acetate, platinum, palladium, titania
Topic: Advancing the chemical and biological engineering fundamentals.

Abstract

The catalytic oxidation of ethyl acetate in low concentration (2,000 ppmv) was investigated over noble metal catalysts (palladium or platinum) supported on titania. The influence of several parameters was investigated, such as the crystalline phase of the support, the type and amount of noble metal, the metal dispersion and the activation conditions. Platinum was found to be more active and selective into CO_2 than the corresponding palladium catalyst. The activation conditions influence the activity of the Pt/TiO_2 catalyst. The highest activities were obtained when the catalyst was activated under hydrogen atmosphere. The presence of water vapour in the feed enhances the global conversion and decreases the CO_2 selectivity.

1 Introduction

Volatile organic compounds (VOC) are considered an important class of air pollutants, not only due to their toxic nature but also because they are precursors of ground level ozone and smog. VOC are emitted from a variety of sources such as industrial processes (stationary sources ≈ 40 %) and vehicle exhaust (mobile sources ≈ 60 %). Among the different techniques that can be applied to efficiently control the emissions of VOC, catalytic oxidation seems to be the most efficient and cost-effective technology for emissions containing low concentrations (Everaert and Baeyens, 2004). In this process, high elimination efficiency can be achieved at relatively low temperatures, although the performance of the process critically depends on the type of the catalyst used, operating temperature, VOC type and concentration, space velocity and O_2 concentration.

The optimization of the catalyst formulation is not usually an easy task, due to the large variety of VOC molecules and the complex nature of VOC mixtures. Extensive studies have been done in recent years in order to develop more active catalysts and to understand the factors that determine VOC reactivity over oxidation catalysts (Papaefthimiou et al., 1998a; O'Malley and Hodnett, 1999; Tsou et al., 2004). In general, platinum and palladium supported catalysts are considered more active than metal oxides in the oxidation of several VOC (mainly in the oxidation of non-oxygenated VOC) (Papaefthimiou et al., 1998b; Tsoncheva et al., 2006). As a result, the majority of commercial catalysts consists of either platinum or palladium or both supported on alumina carriers, in pellet or monolith forms.

The main goal of the present work is to study the oxidation of ethyl acetate catalysed by noble metals supported on titania. Several parameters were investigated, such as the structure of the support and type of noble metal (platinum and palladium). The best catalytic system was chosen for further studies, namely the load of noble metal, pre-treatment

conditions, stability and the influence of the presence of other species in the performance of the catalyst.

Among VOC, ethyl acetate is a common solvent, widely used in the printing industry and is one of the most difficult gaseous pollutants to oxidise completely. Several studies have been reported choosing ethyl acetate as a model for volatile organic compounds (Papaefthimiou et al., 1998a; Papaefthimiou et al., 1998b; Sawyer and Abraham, 1994; Papaefthimiou et al., 1997; Yang et al., 2007).

2 Experimental

2.1 Preparation and characterization of the catalysts

TiO_2 with different amounts of anatase and rutile phases were used in this work. The first sample consists of 100% anatase and was synthesized by a sol-gel process, via hydrolysis of titanium alkoxides, in acidic medium. The second sample is a commercial product (Degussa P-25) containing 80% anatase. The third sample was obtained by submitting P-25 to a thermal treatment at 700 ºC under air, in order to reduce the content of anatase to 47% (Grzechulska-Damszel et al., 2006)

Platinum and palladium supported catalysts were prepared by incipient wetness impregnation on Degussa P-25 using as metal precursors, H_2PtCl_6 and $PdCl_2$, respectively (metal load: 1% or 2%). The resulting materials were dried at 110 ºC overnight and calcined at 500 ºC for 2 hours.

The crystalline structure was identified by X-ray diffraction (XRD) measurement. The metal dispersion was obtained by hydrogen chemisorption at room temperature. The characterization results are shown in Table 1.

Table 1- Properties of the catalysts (crystalline phase and metal dispersion).

Catalyst	Phases	Metal dispersion, D_M (%)
TiO_2 (sol-gel)	100% anatase	-
TiO_2 (P25)	80% anatase	-
TiO_2 (P25, air, 700 ºC)	47 % anatase	-
1% Pt/TiO_2	80% anatase	15
2% Pt/TiO_2	80% anatase	18
1% Pd/TiO_2	80% anatase	14
1% Pt/TiO_2 (air/steam, 500 ºC)	80% anatase	1

2.2. Kinetic study

The reaction was carried out in a BTRS Jr Autoclave Enginners fixed bed reactor at atmospheric pressure and in the temperature range of 150-400 ºC. The reactor was maintained at each temperature for 30 minutes in order to obtain experimental values at steady state. The ethyl acetate conversion (X) and the conversion into CO_2 (X_{CO_2}) were respectively calculated as $X = 1 - \frac{F_{VOC}}{F_{VOC,in}}$ and $X_{CO_2} = \frac{F_{CO_2}}{\nu F_{VOC,in}}$, where F_{VOC} is the outlet molar flow rate of VOC at steady state, $F_{VOC,in}$ is the inlet molar flow rate of VOC, F_{CO_2} is the outlet molar flow rate of CO_2 at steady state and ν is the number of carbon atoms in the VOC molecule (for ethyl acetate, ν = 4). A concentration of ethyl acetate in the feed stream of 2,000 ppmv and a space velocity of 16,000 h^{-1} were used as standard conditions. The catalyst sample (0.05 g) was diluted with glass spheres of the same size as the catalyst particles ($0.2<\phi<0.5$ mm), in order to minimize the thermal effects (catalyst bed length: 2 cm). The temperature was evaluated by a K-type thermocouple placed in the middle of the catalyst bed. Prior the reaction, the best catalytic system was pre-treated in situ according to three different protocols: a) air at 400 ºC for 1 hour; b) hydrogen at 350 ºC for 2 hours; c) mixture of steam and air at 500 ºC for 2 hours.

The analytical system consisted of a gas chromatograph equipped with a flame ionization detector (FID) for the analysis of the organic compounds, and two non-dispersive infrared (NDIR) analyzers for detection and quantification of CO (Analytical Development Company) and CO_2 (NOVA Analytical Systems Inc.).

3. Results and discussion

3.1 Catalyst screening

The oxidation of ethyl acetate was studied over the TiO_2 samples and the noble metal/TiO_2 catalysts. This study was made in order to obtain the best catalyst for this reaction with respect to: a) crystalline phase of the support, comparing three samples with different amounts of anatase; b) type of noble metal (palladium or platinum). The results are presented in Figure 1.

The influence of the TiO_2 crystalline phase was studied in the temperature range of 150-400 ºC. As can be seen, this parameter does not have a major effect on the catalytic activity of TiO_2, although the anatase structure is a little more active than the rutile phase. In the presence of the support, ethyl acetate is completely oxidized at about 340 ºC, but the CO_2 yields are very low at this temperature (XCO_2 values between 47% and 67%, respectively for the 47% and 100% anatase samples). High amounts of by-products were formed, such as acetic acid, acetaldehyde and acetone, due to the large number of acidic sites on titania. This is in agreement with the information reported by other authors (Papaefthimiou et al., 1998a).

Supporting palladium or platinum on TiO_2 considerably reduces the amount of by-products formed and enhances the activity, decreasing the temperature at which ethyl acetate is completely converted into CO_2 to 330 and 280 ºC, respectively. This effect is less pronounced for palladium catalysts, where at high temperatures large amounts of ethylene were formed. Thus, Pt/TiO_2 catalyst was selected for further studies.

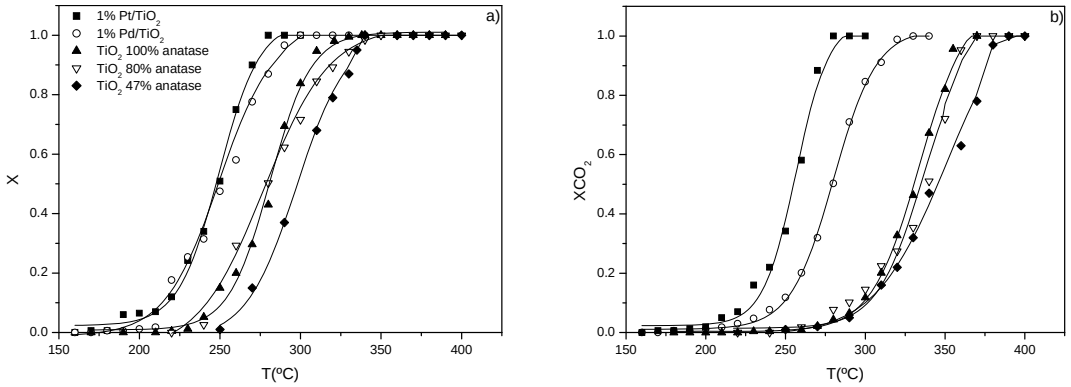

Figure 1- Catalytic activity of 1% Pt/TiO_2, 1% Pd/TiO_2 and TiO_2 (100%, 80% and 47% of anatase), for the oxidation of ethyl acetate: a) Ethyl acetate conversion (X) b) Conversion into CO_2 (XCO_2).

3.2. Influence of the pre-treatment conditions

The effect of the electronic state of platinum was studied in this reaction by comparing the activities of the Pt/TiO_2 catalyst pre-reduced under hydrogen at 350 ºC and pre-calcined under air at 400 ºC. The behaviour of both catalysts is shown in Figure 2. As can be seen, the pre-reduced catalyst is more active in the oxidation than the calcined one. For instance, at 250 ºC the conversion into CO_2 is about 57% with the pre-reduced catalyst, while with the pre-calcined catalysts can only achieve this conversion at 260 ºC. This behaviour is in agreement with reports by other authors, where metallic platinum was also found to be the

most active catalyst, namely in the oxidation of o-xylene and MIBK over Pt/HFAU (Tsou et al., 2005) or n-heptane over Pt/Al_2O_3 (Völter et al., 1987).

Figure 2 also shows the activity of Pt/TiO_2 after a pre-treament in situ with air/steam at 500 ºC. It is well known that a treatment with a mixture of air and steam at high temperatures promotes the sinterization of the platinum particles (Löwendahl and Otterstedt, 1990). In fact, the metal dispersion was found to decrease from 15 to 1% (see Table 1). The results show that the complete oxidation of ethyl acetate into CO_2 over the steamed catalyst occurs at higher temperatures (290 ºC). However, the intrinsic activity of the catalyst was found to increase with increasing particle size of Pt, which makes this reaction structure-sensitive.

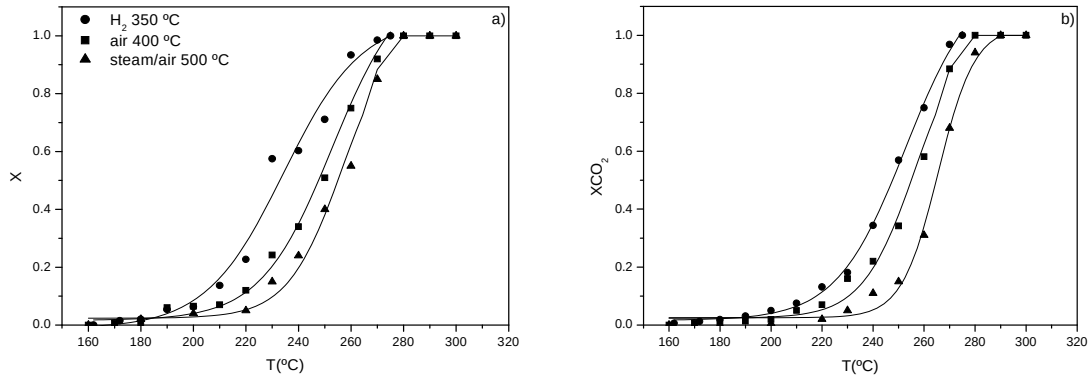

Figure 2- Effect of the activation conditions on the catalytic activity of Pt/TiO_2 catalyst: a) Ethyl acetate conversion (X); b) Conversion into CO_2 (XCO_2).

3.3. Influence of platinum content

The influence of platinum load on the catalytic activity was investigated varying the platinum level from 1 to 2%. The results are presented in Figure 3. For a similar metallic dispersion (see Table 1), the higher the platinum content, the higher the global conversion and the CO_2 yield. For instance, complete oxidation of ethyl acetate into CO_2 is obtained at 290 ºC for a Pt content of 1% and at 280 ºC for 2%.

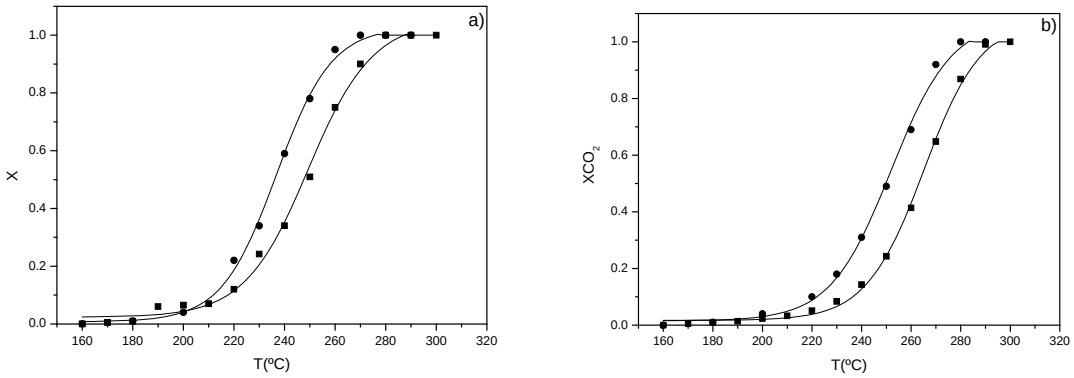

Figure 3- Ethyl acetate conversion (X) and conversion into CO_2 (XCO_2) as a function of temperature over Pt/TiO_2 with different platinum loads: 2%(●) and 1% (■).

3.4 Stability of the catalyst

In order to analyze the stability of the materials, light-off experiments were made with a fresh catalyst and with a sample previously used in a long duration experiment at 450 ºC for 24 hours. It was concluded (data not shown) that the platinum supported catalyst is very stable and does not present any kind of deactivation.

3.5 Effect of the presence of water vapour, CO_2 and ethanol in the feed

In practical situations, the conditions for the oxidation of VOC will not be the same as the standard conditions used in this work. Moisture, CO_2 and other VOC will be present in the feed to be treated. In order to study the effect of these parameters on the performance of the catalyst, kinetic studies were carried out introducing CO_2, water or ethanol in the feed.

It was observed (results not shown) that CO_2 does not have a major effect in the performance of the catalyst, suggesting that CO_2 has a little affinity towards the support.

The presence of water vapour enhances the conversion of ethyl acetate, but decreases the CO_2 selectivity (results not shown). Larger amounts of by-products are formed such as acetaldehyde, ethylene, acetone, acetic acid and ethanol. Water promotes the decomposition of ethyl acetate into ethanol and acetic acid, which are further converted into acetaldehyde and acetone, or oxidized completely into CO_2 and H_2O (Sawyer and Abraham, 1994).

In addition to the results obtained above, the behaviour of Pt/TiO_2 in the oxidation of ethyl acetate and ethanol mixtures was investigated. Kinetic experiments were carried out at different temperatures in the standard conditions described previously (2,000 ppmv of each VOC).

The conversion of ethyl acetate alone and in the presence of 2,000 ppmv of ethanol over Pt/TiO_2 is shown in Figure 4 as a function of the reaction temperature. It was found that the oxidation of ethyl acetate is not affected by the presence of ethanol.

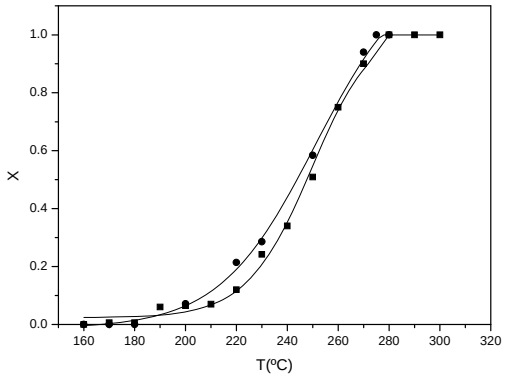

Figure 4- Conversion of ethyl acetate as a function of temperature on 1%Pt/TiO_2: ethyl acetate alone (2,000 ppmv) (■) and with ethanol (2,000 ppmv + 2,000 ppmv) (●).

4 Conclusions

The following conclusions can be drawn from this study:

- The TiO_2 phase does not play a major role on the catalytic activity, in spite of the anatase structure being a little more active than the rutile phase.
- The presence of a noble metal is essential to increase both activity and selectivity into CO_2.
- The platinum catalyst is more active and selective than the corresponding palladium catalyst.
- The pre-reduced catalyst is more active than the pre-calcined one.
- The performance of the Pt/TiO_2 catalyst in the oxidation of ethyl acetate is not very sensitive to the metal dispersion.
- The higher the platinum content, the lower the temperature necessary to convert all ethyl acetate into CO_2.

- Long duration experiments show that the platinum supported catalyst is very stable during the catalytic oxidation.
- The presence of water vapour in the feed stream increases the global conversion but decreases the CO_2 selectivity. On the contrary, CO_2 has no influence on the catalytic activity.
- The presence of ethanol in the feed has no effect on the catalyst performance for the oxidation of ethyl acetate.

Incidence of the preparation method of the support on the behavior in n-butane dehydorgenation of $Pt/MgAl_2O_4$, $PtSn/MgAl_2O_4$ y $PtPb/MgAl_2O_4$ catalysts

Sonia Bocanegra*, Alberto Castro, Osvaldo Scelza, Sergio de Miguel
Instituto de Investigaciones en Catálisis y Petroquímica (INCAPE)/Facultad de Ingeniería Química-Univ. Nac. del Litoral- CONICET, Santiago del Estero 2654, Santa Fe, 3000, Argentina..

Keywords: Synthesis of $MgAl_2O_4$, Dehydrogenation, Bimetallic catalysts
Topic: Advancing the chemical engineering fundamentals

Abstract

Two preparation methods of $MgAl_2O_4$ have been used: ceramic and co-precipitation. The supports were characterized by measurements of the textural properties (BET isotherms), XRD and 2-propanol dehydration. The XRD characterization shows the formation of $MgAl_2O_4$ spinel for both materials.The textural properties indicated that the specific surface of $MgAl_2O_4$ obtained by co-precipitacion was much higher than that obtained by the ceramic method. The results of 2-propanol dehydration reaction show a scarce activity for both $MgAl_2O_4$, mainly for $MgAl_2O_4^{co\text{-}precipitation}$. This means that these materials have very low acidity.
The monometallic catalysts were prepared by impregnation of both supports with solution of H_2PtCl_6 such as to obtain a Pt loading of 0.3 wt%. The bimetallic catalysts (PtSn and PtPb) were obtained by impregnation of the corresponding monometallic ones with an aqueous solution of $SnCl_2$ or $Pb(NO_3)_2$. The Sn contents were 0.3 and 0.5 wt%. The Pb contents were 0.52 and 0.87 wt%. These catalysts were characterized by H_2 chemisorption, TEM, TPR, XPS, test reactions of the metallic phase (cyclohexane dehydrogenation and cyclopentane hydrogenolysis) and evaluated in the n-butane dehydrogenation reaction at 530 ºC. The H_2 chemisorption and TEM results show that $Pt/MgAl_2O_4^{co\text{-}precipitation}$ displays a lower metallic dispersion than the Pt supported on $MgAl_2O_4^{ceramic}$. The characterizations carried out by TPR, XPS and test reactions show good interaction for bimetallic catalysts, except for $PtPb/MgAl_2O_4^{co\text{-}precipitation}$. The evaluation of catalysts in n-butane dehydrogenation displays a lower activity of $Pt(0,3)/MgAl_2O_4^{co\text{-}precipitation}$ than $Pt(0,3)/MgAl_2O_4^{ceramic}$ and a similar selectivity to all butenes. The bimetallic catalysts that contain Sn showed better activities and selectivities with regard to the monometallic ones, but the PtPb catalysts did not show the above mentioned behavior. Likewise, the $PtSn(0.3)/MgAl_2O_4^{ceramic}$ shows the best catalytic performance.

1 Introduction

$MgAl_2O_4$ is a material with interesting properties to be used as a support of metallic catalysts for dehydrogenation. This material has a high thermal stability, low acidic character and good interaction with the metallic phase (Armendariz et al, 2001). The traditional method to obtain this material is the ceramic one (reaction in solid phase at high temperature). This preparation method has certain disadvantages such as the low specific surface area and chemical heterogeneity. In order to avoid these problems others preparation methods have been used: mechanochemical, sol gel and co-precipitation (Li et al., 2001) . With respect to the nature of the metallic phase, it must be indicated that Pt has been intensively used as the active metal. Pt has a high activity of alcanes dehydrogenation and low hydrogenolytic capacity. In spite of these properties, the performance of the metallic phase can be enhanced by addition of metals of the 14 group as Sn, Pb and Ge (Pakhomov et al., 1980).

2 Materials and methods

Synthesis of $MgAl_2O_4$

i) Ceramic method (***$MgAl_2O_4^{cer}$***)

$MgAl_2O_4$ was prepared by a solid phase reaction between MgO (Alfa Aesar, purity 99.99%) and γ-Al_2O_3 (CK 300 from Cyanamid Ketjen, purity 99.9%). The stoichometric ratio was 1 mol of MgO/1mol γ-Al_2O_3. The mixed solids were grounded and then calcinated in an electric furnace at 900 ºC for 24 h.

ii) Co-precipitation method (***$MgAl_2O_4^{cop}$***)

$Mg(NO_3)_2$.6 H_2O (Merck, 99.0% purity), $Al(NO_3)_3$.9 H_2O (Merck, 98.5% purity) and ammonia solution (Merck, 28%, analytical grade) were used as reagents. A solution of the nitrates was prepared, with a Al/Mg molar ratio = 2. The precursor was prepared by adding the ammonia solution into the mixed salt solution under stirring, until reaching pH 11 at 40ºC. The resulting gel was aged and then washed. The dried gel was calcinated in flow air at 800ºC for 4 h.

Catalysts Preparation

The Pt(0.3 wt%)/$MgAl_2O_4$ catalysts were prepared by incipient impregnation of both supports with an aqueous solution of H_2PtCl_6 for 6 h. Then the samples were dried at 100º C.

The bimetallic catalysts (PtSn and PtPb) were obtained by impregnation of the corresponding monometallic ones with an aqueous solution of $SnCl_2$ in HCl medium or $Pb(NO_3)_2$ for 6 h. The Sn contents were 0.3 and 0.5 wt%. The contents of Pb went equimolares to those of Sn (equivalent to 0.52 and 0.87 wt% Pb). After impregnation the catalysts were dried at 100 ºC. After the preparation all catalysts were calcined at 500ºC.

Characterization of $MgAl_2O_4$ supports and catalysts

The different stages of preparation of the supports were characterized by XRD which were performed in a Shimadzu model XD3A instrument using CuK_α radiation (λ =1542 Å).

The specific surface area and pore volume of both supports were determined through the BET isotherm in a Quantachrome Corporation NOVA-1000 equipment.

In order to characterize the acid properties of supports, isopropanol dehydration experiments at atmospheric pressure were carried out in a flow reactor. H_2/isopropanol molar ratio=19. The space velocity of feed was 0.52 mol alcohol h^{-1} g cat^{-1} and the temperature was 200ºC.

The characteristics of the metallic catalysts were determined by different techniques:

H_2 chemisorption measurements were made in volumetric equipment at room temperature and performed in the range of 25-100 torr. The isotherms were lineal in the range of used pressures. From the data of chemisorbed H_2 the metallic dispersion was calculated.

TEM measurements were carried out on a JEOL 100CX microscope with a nominal resolution of 6 Å, operated with an acceleration voltage of 100KV.

TPR experiments were performed in a quartz flow reactor. The samples were heated at 6ºC min^{-1}. The reductive mixture (5 v/v % H_2-N_2) was fed to the reactor with a flow rate of 10 ml min^{-1}. Catalysts were previously calcined “in situ” at 500ºC in air flow for 3 h.

XPS measurements were carried out in a VG-Microtech Multilab spectrometer, which operates with an energy power of 50 eV (radiation $MgK\alpha$, $h\nu$ = 1253.6 eV). Samples were previously reduced “in situ”. Binding energies were referred to the C1s peak at 284.9 eV.

Cyclohexane dehydrogenation (CHD) and cyclopentane hydrogenolysis (CPH) were carried out in a differential flow reactor. Prior to these reactions, samples were reduced “in situ”. In both reactions the H_2/hydrocarbon molar ratio was 26. The reaction temperatures in CHD were 300ºC, whereas in CPH the temperature was 500ºC.

n-butane dehydrogenation reaction

The n-butane dehydrogenation test was carried out in a continuous flow reactor at 530 ºC. The reactor was fed with 18 ml min^{-1} of the reactive mixture (n-butane + hydrogen, H_2/n-C_4H_{10} molar ratio= 1.25). Prior to the reaction, catalysts were reduced "in situ" at 530ºC. The reactor effluent was analyzed in a GC-FID equipment. With this analytical device, the amounts of methane, ethane, ethylene, propane, propylene, n-butane, 1-butene, cis-2-butene, trans-2-butene and 1,3 butadiene were measured.

3 Discussion of results

Figure 1 shows XRD results corresponding to the synthesis of $MgAl_2O_4^{cer}$. Figure 1a displays the diffractograms corresponding to the mixture of the reactives (MgO and γ-Al_2O_3). In Figure 1 b it can be observed that the main product of the solid phase reaction was the $MgAl_2O_4$ spinel thus remaining traces of MgO and γ-Al_2O_3. After purifying the solid with a aqueous solution of $(NH_4)_2CO_3$ (1M), the XRD shows the complete elimination of the MgO (Figure 1c).

Figures 2 shows XRD results that correspond to the synthesis of $MgAl_2O_4$ by the coprecipitation method. Figure 2a displays the diffractogram corresponding to the coprecipitated precursor, thus showing that the main phase is a $MgAl_2(OH)_8$, together with meixnerite and bayerite (Armendariz et al., 2001). After the calcination at 800ºC, the characteristic peaks of the $MgAl_2O_4$ spinel are clearly observed in the X-ray diffractogram (Figure 2c).

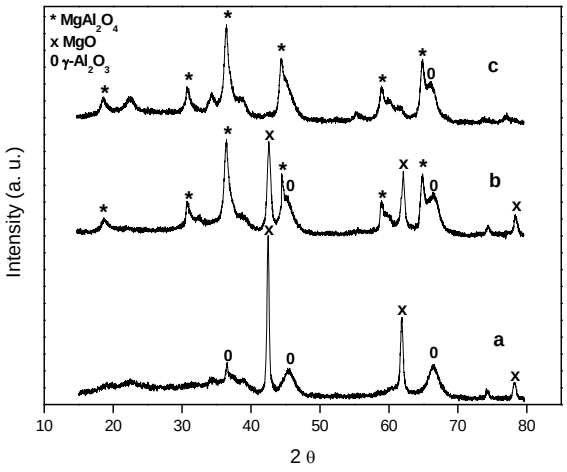

Figure 1: XRD of $MgAl_2O_4^{ceramic}$, impurified (b) y purified (c), and mixture MgO whit γ-Al_2O_3 before reaction (a).

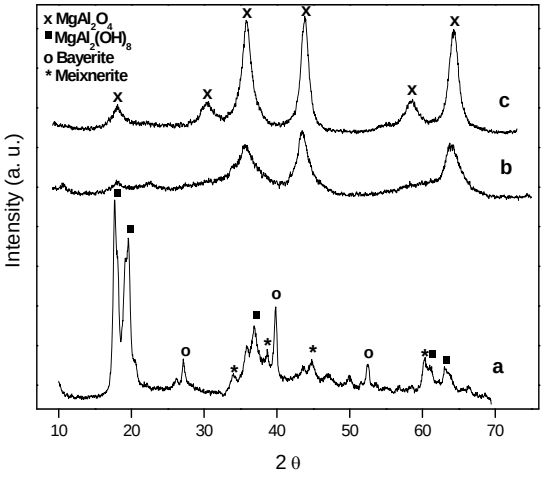

Figure 2: XRD of $MgAl_2O_4^{co\text{-}preicpitation}$, precursor (a), precursor calcinated at 500ºC (b) and calcinated at 800ºC (c).

The results of specific surface area and pore volume, reported in Table 1, indicate that the support obtained by co-precipitation have higher specific surface area and pore volume that the $MgAl_2O_4^{cer}$, which are more suitable characteristics for the deposition of the metallic precursor. However, the metal dispersion also depends on other factors such as the interaction strength between the metallic precursor and the support.

In order to determine the acid properties of the supports, the 2-propanol dehydration reaction was carried out. Results are shown in Table 1. It can be observed that γ-Al_2O_3 (reference material), which has Lewis acid centers, shows an important activity in this reaction. On the other hand, both $MgAl_2O_4$ display a very low dehydration activity, mainly for $MgAl_2O_4^{cop}$.

Table 2 displays the H_2 chemisorption results for the different catalysts. It can be observed that the Pt/$MgAl_2O_4^{cop}$ catalyst displays a lower metallic dispersion than Pt/$MgAl_2O_4^{cer}$. In the case of bimetallic catalysts it is observed that the H_2 chemisortion capacities are clearly lower than the corresponding of the monometallic ones. This effect can be attributed to a blocking and/or dilution of the Pt by Sn or Pb, besides, a probable formation of alloys.

The distribution of Pt particle sizes (by TEM) shows a mean particle diameter of 1.83 nm for $Pt/MgAl_2O_4^{cop}$ catalyst and a mean particle diameter of 1.32 nm for the $Pt/MgAl_2O_4^{cer}$ catalyst. These results are in agreement with the H_2 chemisorption results, and with acid properties of supports. Hence during the metallic impregnation, the $MgAl_2O_4^{cer}$ would be able to adsorb $PtCl_6^{2-}$ with a higher interaction, thus leading probably to a higher metallic dispersion.

Table 1: Textural properties of supports and conversion in 2-propanol dehydration

Support	Specific surface ($m^2\ g^{-1}$)	Pore Volume ($cm^3\ g^{-1}$)	$X_{initial}$ (%) (2-propanol)	X_{final} (%) (2-propanol)
$MgAl_2O_4^{cer}$	37	0.11	1.8	1.3
$MgAl_2O_4^{cop}$	108.2	0.33	0.2	0.2

Table 2 shows the results obtained in the reaction tests of the metallic phase for different catalysts supported on both $MgAl_2O_4$. In the cyclohexane dehydrogenation (CHD) reaction can be observed that $Pt/MgAl_2O_4^{cop}$ and $Pt/MgAl_2O_4^{cer}$ catalysts show similar values of the initial CHD rate. The addition of Sn or Pb to Pt decreases the initial reaction rate in CHD, though the addition of Pb appears to have a more marked effect on the reaction rate. This fact would be in agreement with results obtained in the literature [15,21], which indicate that both lead and tin produce blockage of the superficial platinum atoms, but the first one produces a larger effect than the second one. Respect to the activation energy in this reaction, it is mesured an increase of the values only when Sn is added to $Pt/MgAl_2O_{4\ cer}$, which would indicate a certain electronic effect in these bimetallic catalysts.

Table 2 also shows the results of cyclopentane hydrogenolysis (CPH). It can be observed that when Pb and Sn are added to Pt supported in the $MgAl_2O_4^{cop}$, there is a small decrease of the CPH rate values, being this effect more pronounced for PtPb catalysts. This means that Sn or Pb are intercalated between Pt atoms, but in a low extension. On the other hand when Sn or Pb are added to $Pt/MgAl_2O_4^{cer}$, the initial reaction rates of CPH are lower than those found for bimetallic catalysts supported on $MgAl_2O_4^{cop}$. These results would indicate higher dilution and blocking effects than in the other catalyst series.

Table 2: hydrogen chemisorption, initial rate of CH dehydrogenation reaction (R^o_{CH}) and initial rate of CP hydrogenolisis (R^o_{CP}) of Pt, PtSn and PtPb catalysts.

Catalyst	H_2 ($\mu mol\ g_{cat}^{-1}$)	Dispersion (%)	R^o_{CH} ($mol\ h^{-1} g_{Pt}^{-1}$)	R^o_{CP} ($mol\ h^{-1} g_{Pt}^{-1}$)
$Pt/MgAl_2O_4^{cer}$	3.75	49	52,1	7.6
$Pt/MgAl_2O_4^{cop}$	2.35	31	68.1	6.0
$PtSn(0.3)/MgAl_2O_4^{cer}$	1.52	-	20.8	2.0
$PtSn(0.5)/MgAl_2O_4^{cer}$	1.52	-	0.2	2.0
$PtSn(0.3)/MgAl_2O_4^{cop}$	1.63	-	52.7	4.4
$PtSn(0.5)/MgAl_2O_4^{cop}$	1.00	-	40.0	3.6
$PtPb(0.52)/MgAl_2O_4^{cer}$	0.62	-	10.9	1.0
$PtPb(0.87)/MgAl_2O_4^{cer}$	0.28	-	7.0	0.8
$PtPb(0.52)/MgAl_2O_4^{cop}$	1.75	-	40.4	3.5
$PtPb(0.87)/MgAl_2O_4^{cop}$	1.96	-	34.0	2.8

Figures 3 and 4 show the results obtained by TPR on mono and bimetallic catalysts supported on both $MgAl_2O_4$. It can be observed in Figure 3 for catalysts supported on $MgAl_2O_4^{cer}$ that the $Pt/MgAl_2O_4^{cer}$ has a main reduction peak located at about 270 ºC and a secondary peak at about 425 ºC. This fact was explained by the existence of two different oxychlorinated Pt species (Lietz et al., 1983). When Sn or Pb are added to Pt, the main reduction peaks are broader and are shifted to higher temperatures, which can indicate a Pt-Sn (or Pt-Pb) co-reduction and a good interaction of Pt with the second metal. For the Pt catalysts supported on $MgAl_2O_4^{cop}$ (Figure 4), two reduction peaks can be observed, the main one, placed at 254 ºC, and the secondary one located at about 450 ºC. The appearance of two reduction peaks was previously explained. The main peak is shifted to higher

temperatures when increasing Sn amounts are added to the monometallic catalyst. This behaviour indicates a good interaction between both metals. In the case of PtPb catalysts supported on $MgAl_2O_4^{cop}$, the main reduction peak is shifted to slightly lower temperatures and it is not observed a broadening of this peak. Besides, for these catalysts, two reduction zones are found at about 250-350 ºC and 350-500 ºC. These broad reduction zones are associated to the reduction of free Pb species. These facts would indicate both a Pt-Pb segregation and a low interaction between Pt and Pb.

XPS results of PtSn catalysts supported on both $MgAl_2O_4$ indicate that a small fraction of Sn (10-15%) is in the zerovalent state and probably alloyed with Pt, while the remainder are attributed to oxidized species of Sn. The presence of Sn(0) in bimetallic catalysts and the absence of this species in the Sn monometallic one, would indicate a higher Sn reducibility in PtSn catalysts, these results agreeing with TPR ones. Considering the TPR and cyclohexane dehydrogenation results for $PtPb/MgAl_2O_4^{cop}$, although an important fraction of the lead is like Pb(0), it would not be forming alloy with Pt, but isolated.

The n-butane dehydrogenation results are displayed in Figures 5 and 6. The n-butane conversion (Figure 5) shows that the initial activity of $Pt/MgAl_2O_4^{cer}$ is higher than that of $Pt/MgAl_2O_4^{cop}$, thus agreeing with TEM and dispersion measurements. Besides, the addition of Sn to both monometallic catalysts increases the conversion. However, the Pb addition to Pt supported in both $MgAl_2O_4$ decreases the n-butane conversion with respect to the corresponding monometallic ones. With respect to the selectivity to all butenes (Figure 6), $Pt/MgAl_2O_4^{cop}$ catalyst show a slightly higher selectivity than that of $Pt/MgAl_2O_4^{cer}$. The Sn addition to Pt clearly increases the selectivity to butenes reaching values near 98%. On the other hand, the Pb addition to Pt does not produce an increase of the selectivity to all butenes, except for PtPb(0.52 wt%)/ $MgAl_2O_4^{cop}$. It must be noted that the best catalytic performance is obtained by the PtSn(0.3 wt%)/$MgAl_2O_4^{cer}$. In general it can be seen in Figures 5 and 6 that the ceramic method for the support preparation and the lower Sn content added to Pt lead to better dehydrogenation catalysts.

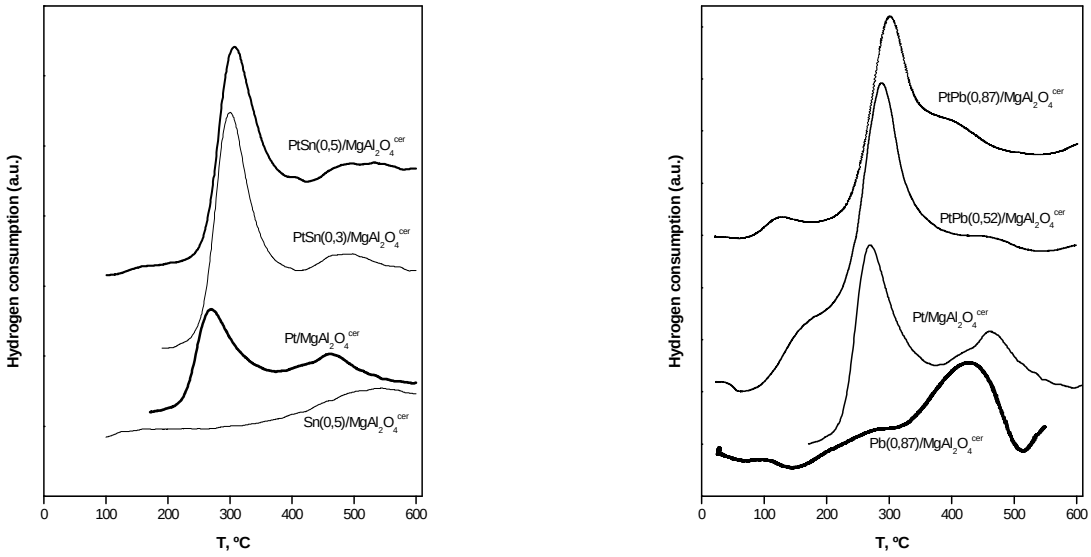

Figura 3: TPR experiencies of Pt, Sn, Pb, PtSn y PtPb catalysts supported on $MgAl_2O_4^{cer}$.

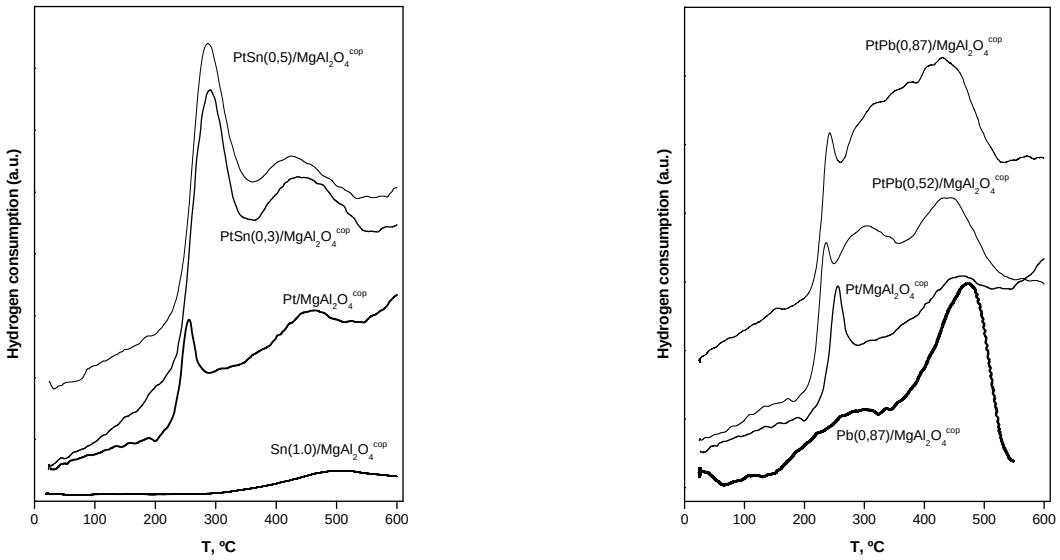

Figura 4: TPR experiencies of Pt, Sn, Pb, PtSn y PtPb catalysts supported on $MgAl_2O_4^{cop}$.

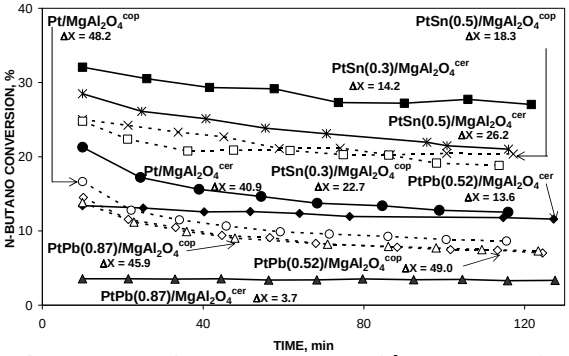

Figure 5: n-butane conversión vs reaction time for Pt, PtSn and PtPb catalysts.

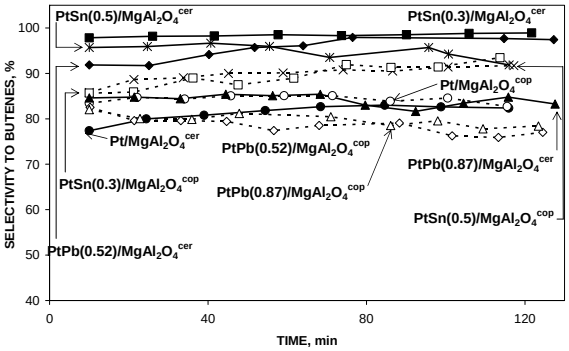

Figure 6: Selectivity to butenes vs reaction time for Pt, PtSn and PtPb catalysts.

4 Conclusions

The $MgAl_2O_4$ spinels show very low acidity and good interaction with the metallic phase. However, the $MgAl_2O_4^{cop}$ displays lower acidity than the $MgAl_2O_4^{cer}$, which seems to influence in the metal-support interaction, since that $Pt/MgAl_2O_4^{cer}$ catalyst shows higher metallic dispersion and better catalytic behavior than the $Pt/MgAl_2O_4^{cop}$ one. The Sn addition to Pt catalysts improves its performance in the dehydrogenation. This behavior is according to catalysts characterization results, where good Pt-Sn interaction is observed, mainly for bimetallic catalysts supported in $MgAl_2O_4^{cer}$. Oppositely, the Pb addition to Pt catalysts does not enhance its catalytic behavior in dehydrogenation. This conduct is in agreement with the characterization results of metallic phase that indicate low interaction Pt-Pb, especially for $PtPb/MgAl_2O_4^{cop}$ catalysts. In conclusion, the synthesis of ceramic method and the Sn addition to Pt lead to better dehydrogenation catalysts, being the $PtSn(0.3)/MgAl_2O_4^{cer}$ catalyst that showed the better performance.

Keywords: Methane reforming, hydrogen, chemical equilibrium, scilab software.
Topic: Advancing the chemical engineering fundamentals.

Abstract

The main contributions of this study are to conduct a comparative thermodynamic analysis of methane reforming reactions and to asses the influence of key operational variables on chemical equilibrium using an in-house code, developed in the open-source software Scilab (www.scilab.org). Equilibrium compositions are calculated by two distinct methods: (1) evaluation of equilibrium constants; (2) Lagrange multipliers. Both methods result in systems of non-linear algebraic equations, solved numerically using the Scilab function "fsolve". Comparison between experimental and simulated equilibrium data, published in the literature, was used to validate the simulated results. Effects of temperature, pressure, initial H_2O/CH_4 ratio (steam reforming), initial CH_4:CO_2:N_2 ratio (dry reforming) and initial O_2/CH_4 (partial oxidation) ratio on the reaction products were evaluated.

1 Introduction

Hydrogen can be produced using several routes. At the present moment, the main route is the catalytic reforming of methane, which includes steam-methane reforming (SMR), partial oxidation (POX), autothermal reforming (ATR) and dry-methane reforming (DMR).

Steam-Methane Reforming produces a H_2/CO ratio equals to three, which is high, when compared to other reforming processes (Seo et al., 2002). Xu and Froment (1989) demonstrated that besides steam reforming of methane (Equation 1), there is another important reaction which takes place in these systems: the water-gas shift reaction (Equation 2). The sum of both reactions results in the Equation 3.

$$CH_4 + H_2O \rightarrow CO + 3H_2 \qquad \Delta H^{\circ}_{298} = 206.0 kJ/mol \tag{1}$$

$$CO + H_2O \rightarrow CO_2 + H_2 \qquad \Delta H^{\circ}_{298} = -41.0 kJ/mol \tag{2}$$

$$CH_4 + 2H_2O \rightarrow CO_2 + 4H_2 \qquad \Delta H^{\circ}_{298} = 165.0 kJ/mol \tag{3}$$

Nevertheless, steam reforming has the disadvantage of intensive energy requirements due to the overall endothermic nature. In order to reduce energy costs, partial or stoichiometric oxidation (Equation 4) of methane has been investigated as an alternative (Corbo and Migliardini, 2006).

$$CH_4 + 1/2\,O_2 \rightarrow CO + 2H_2 \qquad \Delta H^{\circ}_{298} = -35.7 kJ/mol \tag{4}$$

The autothermal reforming process combines the endothermic reforming with the exothermic oxidation. In the reaction process, it is assumed that the heat required for the endothermic reforming can be supplied by the heat released from the oxidation reaction. (Li et al. *In press;* Tomishige et al., 2007).

Finally, dry-methane reforming (Equation 5) produces a synthesis-gas with a H_2/CO ratio near one, which can be used for adjusting H_2/CO ratio in steam reforming, suitable for

[1]Corresponding author. Tel + 55 34 3239-4292, Ramal: 233 – E-mail: ajassis@ufu.br

Fischer–Tropsch reactions and methanol production (Schuurman et al., 2006).

$$CH_4 + CO_2 \leftrightarrow 2CO + 2H_2 \quad \Delta H^{\circ}_{298} = 247.4kJ/mol \tag{5}$$

Although the thermodynamics equilibrium is widely discussed in the literature, it has a scarce systematization and the available programs are usually proprietary, except the CANTERA's software. Therefore, the main objectives of this study are to conduct a comparative thermodynamic analysis for methane reforming reactions and to asses the influence of key operational variables on chemical equilibrium using an in-house code, developed in the open-source software Scilab (www.scilab.org).

2 Simulation methods

Equilibrium compositions are calculated by two distinct methods: (1) evaluation of equilibrium constants; (2) Lagrange multipliers. Both methods result in systems of non-linear algebraic equations, solved numerically.

2.1 Evaluation of Equilibrium Constants method (EEC)

An independent multi-reaction system was organized and each reaction is associated with a reaction coordinate (ξ) and with a distinct equilibrium constant (K_j). The equilibrium constant for each reaction is described by Smith et al. (2000). In this work, the fugacity coefficient for each species in the mixture, $\hat{\phi}_i$, is calculated using the virial's equation considering that there are interactions between the gases (Equations 6). The cross virial's coefficient, used in the Equation 7, follow the correlation proposed by Tsonopoulos and Reidman (1990).

$$\ln \hat{\phi}_i = \frac{P}{RT}\left[B_{ii} + \frac{1}{2} M_{ijk} \right] \tag{6}$$

$$M_{ijk} = \sum_k \sum_j y_k y_j \left(2\delta_{ki} - \delta_{kj} \right) \tag{7}$$

This method is interesting to evaluate when a determined operational condition (T, P, composition) favours a certain reaction, through the analysis of the value of the equilibrium constant of this reaction compared to another one present in the system (Smith et al., 2000).

2.2 Lagrange Multipliers method (LM)

In agreement with Smith et al. 2000, the system composition in the equilibrium can be found solving *N* equilibrium equations, *w* mass balance equations and a restriction equation, represented by Equations 8-10, respectively:

$$\Delta G_{fi} + RT \ln\left(y_i \hat{\phi}_i \frac{P}{P_0} \right) + \sum_k \lambda_k a_{ik} = 0 \tag{8}$$

$$\left(i = 1, 2, ..., N\right)$$

$$\sum_i n_i a_{ik} = A_k \quad \left(k = 1, 2, ..., w\right) \tag{9}$$

$$\sum_i y_i = 1 \quad \left(i = 1, 2, ..., N\right) \tag{10}$$

Where ΔG_{fi} is the standard Gibbs function of the formation of species *i*, *R* is the universal

gas constant, y_i is the molar fraction of species *i* in the mixture, $\hat{\phi}_i$ is the fugacity coefficient of species *i* in the mixture, λ_k is the Lagrange's multipliers oh each element *k*, a_{ik} is the number of atoms of each *k* element of molecule *i* and A_k is the total number of atomic mass of the *k* element. The advantage of this method is to be independent of the reaction system because the choice of a group of molecules is equivalent to choice a system of independent reactions between the species (Smith et al., 2000).

2.3 Simulation method

In both cases, the variation of standard enthalpy and Gibbs free energy of the reaction system ($\Delta H°_j$ e $\Delta G°_j$, respectively) are functions of the temperature and must be corrected with the heat capacities of the gas, *Cp*. The input parameters of the simulator are: molar fraction of the reactants, temperature and pressure in the reactor input and operational temperature and pressure. The resolution of the equations is made through implemented computational codes in the free platform of calculation Scilab © INRIA-ENPC. The numeric calculation uses a function "fsolve", which one utilizes a modification of the hybrid Powell method with a tolerance of 10^{-10}.

3 Results and discussion

3.1 Steam-Methane Reforming

Accordingly to Seo et al. (2002), in the equilibrium, the species of the steam-methane reforming are CH_4, H_2O, CO, CO_2 and H_2, C(solid) and the radicals H, O, OH, HO_2, HCO, CH e CH_2. However, the simulations indicate that the radicals concentrations are neglected when compared to the concentrations of the other products. Therefore, they will be disrespected in this work.

Applying the Denbigh method with the products considered by Seo et al. (2002), one concludes that only Equations 1 and 2 are necessary for the calculation of the thermodynamic balance through the analysis of the balance constants.

The H_2 yield and the H_2/CO selectivity are defined by Fogler (1999) as:

$$Y_{H_2} = \frac{N_{H_2}^{Out}}{N_{CH_4}^{In} - N_{CH_4}^{Out}} \tag{11}$$

$$S_{H_2/CO} = \frac{N_{H_2}^{Out}}{N_{CO}^{Out}} \tag{12}$$

As the reactor temperature is raised from 600 to 800 ℃, CH_4 conversion increases from 44 to 90 %. In agreement with the Figure 1 (a), for temperatures around 800 ℃, the raise of initial H_2O/CH_4 ratio from one to two increases H_2 yield in 4.67%. For temperatures around 430 ℃, this yield is practically the same for all conditions.

Table 1 shows the comparison between the simulated results and literature data for the steam-methane reforming. Lutz et al. (2003) used the software CHEMKIN with the program for chemical equilibrium calculations Stanjan, with a ratio H_2O/CH_4 = 2 and *P* = 10 atm. The average relative error between the results of this work (EEC method) and those one of Lutz et al. (2003) is 7.21% and the average relative error for the LM method is 7.68%. The same analysis is done for the results reported by Seo et al. (2002), but they use the software Aspen Plus™ for the equilibrium compositions with a ratio H_2O/CH_4 = 1 and *P* = 1 bar. This time, the average relative error between the simulated results of this work (EEC method) and

those of Seo et al. (2002) is 24.85%, while for the LM method the average relative error is 24.89%. The discrepancy of the errors between the two author's data can be a function of the consideration of carbon solid in the reforming products by Seo et al. (2002). It's important to note that both softwares used by the authors, use the LM method for the calculation of the equilibrium composition.

The software ScanIt was used to obtain the data of Table 1-3 because all the authors showed the results by graphics.

3.2 Dry-Methane Reforming

Dry-methane reforming analysis is carried out considering the same species as in the case of steam-methane reforming, with the addition of N_2 as an inert. As the reactor temperature is raised from 600 to 800 ℃, CH_4 conversion increases from 43 to 91%. Figure 1 (b) shows the H_2 yield simulation for the DMR with CH_4:CO_2:N_2 sensitivity. Table 2 shows the validation of the simulated results by comparison with CH_4 equilibrium conversion data of Akpan et al. (2007). The average relative error between the results of this work (EEC method) and those one of Akpan et al. (2007) is 6.32% and the average relative error for the LM method is 6.40%.

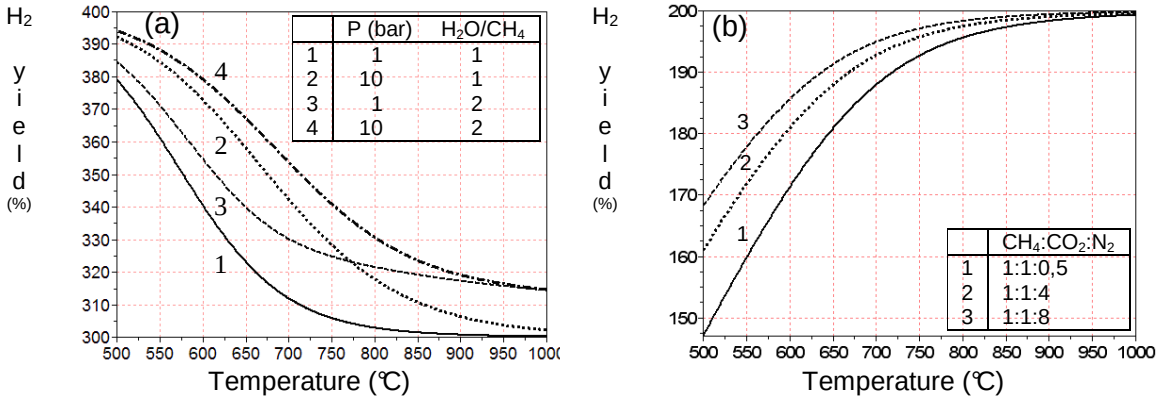

Figure 1. (a) H_2 yield for SMR, pressure and H_2O/CH_4 sensitivity; (b) H_2 yield for DMR, CH_4:CO_2:N_2 sensitivity.

3.3 Partial Oxidation of Methane

For partial oxidation, the following species are considered: CH_4, H_2O, CO, CO_2, H_2 and O_2. Despite of Zhu et al. (2001) consider the formation of others hydrocarbons such as C_2H_6, C_2H_4, C_2H_2, CH_3OH, HCHO and HCOOH, they have a very small yield ($<10^{-7}$%) and, for this reason, they are not consider in this work.

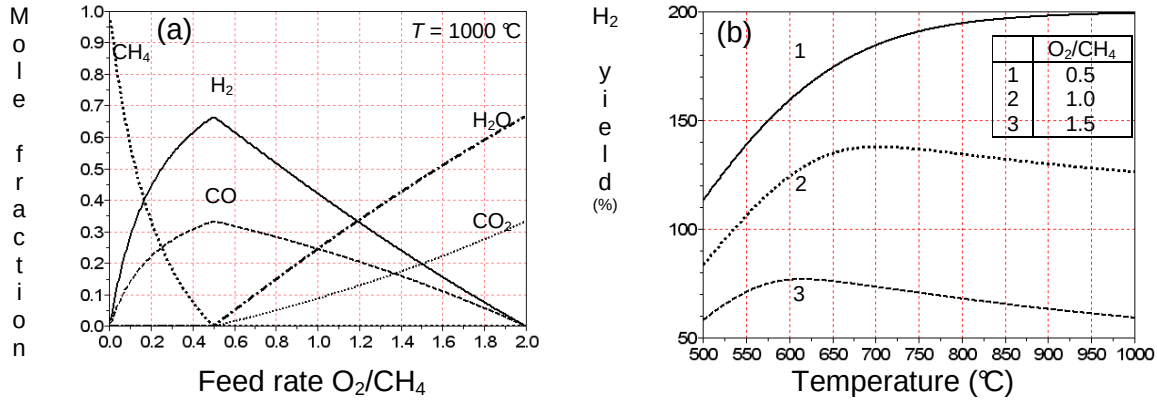

Figure 2. (a) Equilibrium composition of the POX products (P = 1 atm); (b) H_2 yield for POX, O_2/CH_4 sensitivity.

	H_2O	0.107	0.078	0.237	0.198	0.409	0.401
	CO	0.155	0.200	0.118	0.148	0.062	0.063
	CO_2	0.107	0.078	0.195	0.175	0.270	0.268
	H_2	0.417	0.488	0.390	0.456	0.254	0.268

Figure 2 (a) shows the simulated results of the POX equilibrium composition, and it's also possible to note that, at 1000℃, CH_4 is completely consumed when O_2/CH_4= 0.5.

The H_2 yield is strongly influenced by the temperature and by the O_2/CH_4 ratio in the feed. As it is shown in Figure 2 (b), the highest values are achieved for bigger values of temperature and smaller initial O_2/CH_4 ratios. Table 3 shows the validation of the results by comparison with equilibrium composition data of Zhu et al. (2001). The average relative error between the results of this work (LM method) and those of Zhu et al. (2001) is 28.7%.

4 Conclusions

Thermodynamics analysis was carried out for the steam-methane reforming, dry-methane reforming and partial oxidation of the methane. Literature's data were compared with the results of Lagrange's multipliers method and the Equilibrium constants evaluation method. The analyses enabled to validate the simulated results of this work and to verify the best operational conditions for each methane reforming reaction. The developed computer codes in Scilab are available upon request.

Abstract

The goals of this study were to present and to validate a small scale reactor model for the autothermal reforming of methane reaction. In addition, the model should be able to describe the influence of temperature on methane conversion profiles, aiming to maximize hydrogen production. The developed mathematical model considered the mass balance equation for each component, and the set of ordinary differential equations was integrated using the software Scilab^{TM}. The validation was accomplished using experimental data available in the literature. The experimental results and the model presented good agreement with the methane conversion in all studied temperature range. Through simulated data of methane conversions, hydrogen yields and H_2/CO selectivity, it was observed that the best reaction conditions to maximize hydrogen production are around 723 K.

1 Introduction

In recent years, hydrogen has been attracting great interest as a clean fuel for combustion engines and fuel cells (Ayabe *et al*., 2003). Among all the potential sources of hydrogen, the natural gas, which has methane as the main component, has been considered a good option because this gas is very abundant, clean and can easily be converted to hydrogen (Dias and Assaf, 2004).

Nowadays steam reforming of methane is the main route to produce hydrogen in industrial scale. However, this process is highly endothermic, and therefore it requires high temperatures to obtain high equilibrium conversions. This results in a high operational cost. On the other hand, partial oxidation of methane is a slightly exothermic reaction that produces a H_2/CO ratio of approximately 2. This ratio is adequate for Fischer-Tropsoe synthesis. The coupling of steam reforming and partial oxidation of methane main advantage is to use the heat generated from the exothermic reaction as an energy source for the endothermic reaction. This process is called autothermal reforming of methane (ATR). Since this system presents higher energy efficiency and more satisfactory H_2/CO ratio for H_2 production, this reaction can be considered as an important alternative route in the hydrogen production (Dias and Assaf, 2004).

Although the autothermal reforming of methane has a potential interest for industrial application, there is still a limited number of works in literature referring to the reactor design and studies of operational conditions optimization. Therefore, the main objective of this work is to present and to validate a reactor model in small scale for this reaction. In addition, the effect of reactor temperature influence in methane conversions and in the yield and selectivity for H_2 formation were investigated, aiming to maximize the production of H_2.

2 Mathematical model

2.1 Chemical reaction

In this study, ATR is defined as a combination of partial oxidation and steam reforming of methane. In the reactor, several chemical reactions occur, and their rates are strongly dependent of reactions conditions. In order to reduce the number of reactions and to keep the model as simple as possible, only the reactions with significant reaction rates will be considered. According to the literature (Hoang *et al.*, 2006), the reactions that prevail in the autothermal reforming of methane process are represented by Equations 1-4.

R_1: $CH_4 + H_2O \leftrightarrow CO + 3H_2, \qquad \Delta H_1(298K) = 206.2kJ/mol$ (1)

R_2: $CH_4 + 2H_2O \leftrightarrow CO_2 + 4H_2, \qquad \Delta H_2(298K) = 164.9kJ/mol$ (2)

R_3: $CO + H_2O \leftrightarrow CO_2 + H_2, \qquad \Delta H_3(298K) = -41.1kJ/mol$ (3)

R_4: $CH_4 + 2O_2 \leftrightarrow CO_2 + 2H_2O, \qquad \Delta H_1(298K) = -802.7kJ/mol$ (4)

Thus, the model takes into account four reactions and six gas species: methane, oxygen, carbon dioxide, water, carbon monoxide and hydrogen. Nitrogen is present in the inlet air and it is considered as an inert, which affects only the gas properties and the equilibrium conversions.

2.2 Reaction kinetic model

There are a large number of kinetic models for steam reforming and water-gas shift reactions in literature. The model proposed by Xu and Froment (1989) for nickel catalysts is considered to be more general and it has been the most used in literature. For methane total combustion, the rate equation proposed by Trimm and Lam (Trimm e Lam, 1980 apud Smet *et al.*, 2001) will be adopted in this work. This kinetic model was developed for supported platinum catalysts and the corresponding adsorption parameters were adjusted for nickel. Ni catalyst was assumed to be in the reduced state, which implies that total combustion and reforming occur in parallel (Smet *et al.*, 2001).

The rate equations corresponding to the considered reactions are presented in Table 1 (Equations 5-9).

Table 1 – ATR kinetic reaction model

Reaction rate equation	
$R_1 = \frac{k_1}{p_{H_2}^{2,5}}\left(p_{CH_4} p_{H_2O} - \frac{p_{H_2}^3 p_{CO}}{K_I} \right) \times \frac{1}{\Omega^2}$	(5)
$R_2 = \frac{k_2}{p_{H_2}^{3,5}}\left(p_{CH_4} p_{H_2O}^2 - \frac{p_{H_2}^4 p_{CO_2}}{K_{II}} \right) \times \frac{1}{\Omega^2}$	(6)
$R_3 = \frac{k_3}{p_{H_2}}\left(p_{CO} p_{H_2O} - \frac{p_{H_2} p_{CO_2}}{K_{III}} \right) \times \frac{1}{\Omega^2}$	(7)
$R_4 = \frac{k_{4a} p_{CH_4} p_{O_2}}{\left(1 + K_{CH_4}^C p_{CH_4} + K_{O_2}^C p_{O_2}\right)^2} + \frac{k_{4b} p_{CH_4} p_{O_2}}{\left(1 + K_{CH_4}^C p_{CH_4} + K_{O_2}^C p_{O_2}\right)}$	(8)
$\Omega = 1 + K_{CO} p_{CO} + K_{H_2} p_{H_2} + K_{CH_4} p_{CH_4} + K_{H_2O} \frac{p_{H_2O}}{p_{H_2}}$	(9)

The equilibrium constants and the parameters of Arrhenius equation ($k_j = k_{0j} * \exp\left(-E_j / RT\right)$) are presented in Table 2 and the adsorption constants ($K_i = K_{0i} \times \exp\left(-\Delta H_i / RT\right)$) in Table 3.

Table 2 – Equilibrium constants and Arrhenius kinetic parameters

Reaction, j	*Equilibrium constant, K_j*	*k_{0j} (mol/kg$_{cat}$xs)*	*E_j (m^3×bar/mol)*
1	$K_I = \exp\left(\frac{-26830}{T} + 30.114\right)$ (bar^2)	1.17×10^{15} (bar$^{0.5}$)	2.401
2	$K_{II} = K_I . K_{III}$ (bar^2)	2.83×10^{14} (bar$^{0.5}$)	2.439
3	$K_{III} = \exp\left(\frac{4400}{T} - 4.036\right)$	5.43×10^5 (bar^{-1})	0.6713
4		8.11×10^5 (bar^{-2})	0.8600
		6.82×10^5 (bar^{-2})	0.8600

Table 3 – Van't Hoff parameters for adsorption of different species

	K_{0i} (bar^{-1})	*ΔH_i (m^3×bar/mol)*	*K^C_{0i} (bar^{-1})*	*ΔH^c_i (m^3×bar/mol)*
CH_4	6.65×10^{-4}	-0.38280		
CO	8.23×10^{-5}	-0.70650		
H_2	6.12×10^{-9}	-0.82900		
H_2O	1.77×10^5 (bar)	0.88680		
CH_4 (combustion)			1.26×10^{-1}	-0.27300
O_2 (combustion)			7.78×10^{-7}	-0.92800

The rate of consumption or formation of each gas species is determined by summing up the reaction rates of each species in all the reactions, as shown below in Equations 10-15.

$$r_{CH_4} = R_1 - R_2 - R_4 \quad (10)$$

$$r_{O_2} = -2R_4 \quad (11)$$

$$r_{CO_2} = R_2 + R_3 + R_4 \quad (12)$$

$$r_{H_2O} = -R_1 - 2R_2 - R_3 + 2R_4 \quad (13)$$

$$r_{H_2} = 3R_1 + 4R_2 + R_3 \quad (14)$$

$$r_{CO} = R_1 - R_3 \quad (15)$$

2.3 Reactor Model

A one dimensional model was constructed to represent a fixed bed reactor, with nickel-based catalyst, in small scale, in steady state. The reactor considered with 4 mm length is operated with 120 mL/min of inlet flow and 1 cm^3 of catalyst volume. In this condition, is reasonable to adopt the following simplifying assumptions:

i. interfacial mass transfer resistance and intraparticle diffusion limitations were not incorporated;

ii. pressure drop is negligible;

iii. the reactor can be considered as isothermal.

With the assumptions adopted previously, the molar flow along the axial direction, for each component, Fi (mol/s), can be described by the following mass balance equation (Barrio *et al.,* 2007):

$$\frac{dF_i}{dz} = \rho_b * S * \sum_j r_{ij} \quad (16)$$

where i denotes the gas species; j represents reaction index; z is the reactor length (0 to L); density of catalyst bed is ρ_b; with a value of 1.87×10^6 g/m^3; *S* (m^2) is the reactor transversal area and r_{ij} are the reaction rates.

The model is constituted by a set of ordinary differential equations (ODE's), non-linear, of initial value in length. The initial condition is given by $F_i=F_{i0}$, and the inlet composition in molar ratio is 16.7% CH_4: 1.7% O_2: 41.6% H_2O: 40% N_2. The EDO's system was integrated numerically using the function "ode" of free software Scilab™ (www.scilab.org).

2.4 Equilibrium Composition

The chemical equilibrium compositions were calculated using two distinct and classic methods: (1) evaluation of equilibrium constants; (2) Lagrange multipliers. Both methods result in non-linear algebraic equation, solved numerically in Scilab™, through the function "fsolve".

The program developed for the equilibrium composition calculation was validated with data published in the literature and the results are in publication process. The authors are part of same research group, and the results will be published separately.

3 Results and discussions

3.1 Model experimental validation

The model experimental validation was accomplished by comparing the simulated data with experimental data reported by Ayabe *et al.* (2003), in the same operational conditions. Ayabe *et al.* (2003) analyzed the activity of 10%Ni/Al_2O_3 catalyst in ATR reaction, as a function of temperature (light-off curve). The authors observed that there is a large difference in methane conversions when the reaction begins at low temperatures and the temperature is increased gradually, when compared to the inverse procedure, starting the reaction at high temperatures and gradually reducing it. The results show a strong hysteresis of conversion behavior in relation to temperature.

Figure 1 presents a comparison among methane conversions in reactor exit (or in *z* = L), simulated, experimental (Ayabe *et al.,* 2003) and at thermodynamic equilibrium. The agreement between simulated and experimental data is better at higher temperatures, which could be due to poor adjustment of the kinetic parameters or differences between the kinetic model considered and the real one at low temperatures.

3.2 Reaction conditions optimization

It is also possible to observe in Figure 1 that high methane conversions are favored at high temperatures. The experimental results present a strong drop in activity of Ni catalyst at 573 K. In fact the activity experimental value at this temperature is approximately zero, fact that is contemplated in the model.

Figure 2 presents the composition simulated profiles (in molar fraction in dry base) as a function of reaction temperature (light-off curve). The results show at lower temperatures, that methane total oxidation reaction is favored, generating CO_2, while at higher temperatures, methane reforming with CO_2 and steam reforming occur, favoring the formation of synthesis gas (H_2 and CO).

Usually the mechanism for ATR is considered as a coupling of steam reforming of methane with partial oxidation reactions. CO_2 formation at low temperatures, followed by synthesis gas formation at higher temperatures, are indications that the reaction occurs in two stages as described by Mattos *et al.* (2002), for partial oxidation of methane reaction.

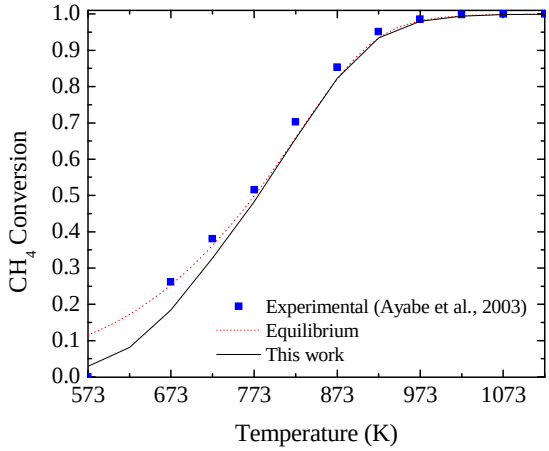

Figure 1 – CH_4 conversion: simulated, equilibrium and experimental (Ayabe *et al.*, 2003), temperature function, in reactor final ($z = L$).

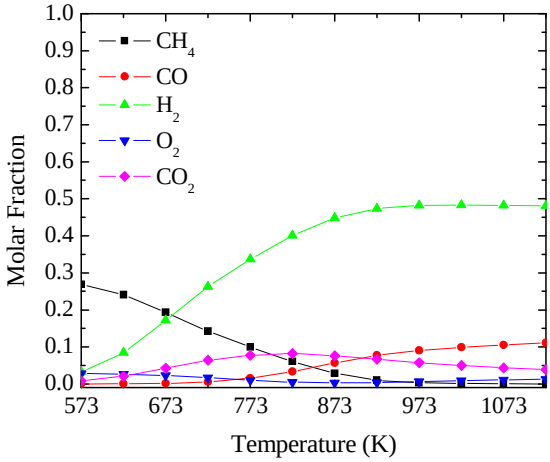

Figure 2 – Molar fraction in dry base of productions of autothermal reforming of methane at different temperatures.

Figure 3 presents the yield for hydrogen production as a function of reaction temperature, as defined by Fogler (1999). The yield was higher than 100%, which shows just that the hydrogen formation does not occur only in steam reforming reaction, but also in water-gas shift reaction. The yield profile decreased with the temperature increase, showing that at low temperatures there is larger hydrogen production in relation to the reacted methane. Starting from 723 K, approximately, the fall in yield value becomes less marked, indicating that the variation of the amount of formed H_2 by reacted CH_4 is small.

Figure 4 presents the profile of selectivity of hydrogen formation to carbon monoxide. There is an exponential decrease in selectivity values with the temperature increase. This result is related to small CO formation at low temperatures, as observed in Figure 2. For temperatures above 773 K, the H_2/CO selectivity is low. These results show that, for larger hydrogen selectivity, the use of lower temperatures is more appropriate.

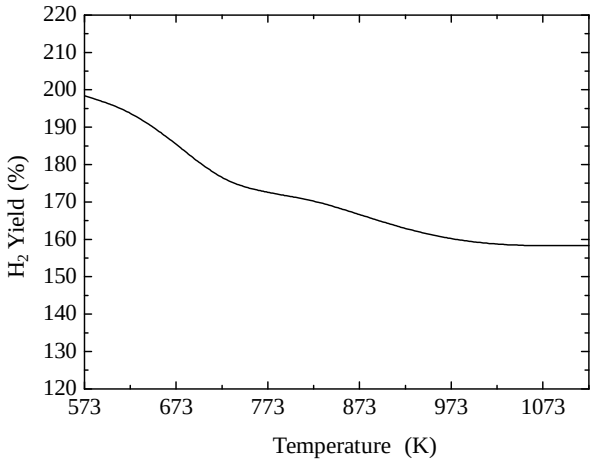

Figure 3 – Yield for H_2 production in autothermal reforming of methane at different temperatures.

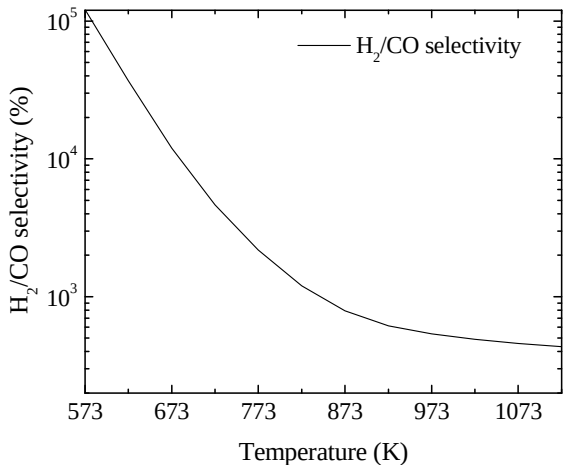

Figure 4 - H_2/CO selectivity in different temperatures for autothermal reforming of methane.

Through the results of methane conversion, yield of hydrogen and H_2/CO selectivity it is

possible to verify coherence among these results. For a maximum in hydrogen production, associated with smaller operational costs, the best reaction conditions are between 723 and 773 K. At these temperatures, there is a high H_2 yield, an elevated selectivity and a methane conversion around 50%. Besides, in these conditions, the catalyst properties are maintained and with smaller chances of sintering. In addition, these conditions have the advantage of smaller energy costs, because the reaction temperature is lower.

4 Conclusions

The proposed mathematical model has a good adjustment to the experimental data of Ayabe *et al*. (2003), presenting a good agreement of methane conversions and H_2 yields in all studied grade. The simulated data showed that the best reaction condition to maximize hydrogen production is around 723 K.

Fluid Dynamics of Fluidized and Vibrofluidized Beds Operating with Flat Particles

Renata de Aquino B. Lima[1] and Maria C. Ferreira[1*]
[1]Drying Center of Pastes, Suspensions and Seeds, Chemical Engineering Department, Federal University of São Carlos, P.O. Box 676, Zip Code:13565-905 – São Carlos – SP, Brazil.

Keywords: Fluidization, Biomass particles, Minimum fluidization velocity, Vibrofluidized beds.
Topic: Advancing the chemical and biological engineering fundamentals – Multiphase flow.

Abstract

Fluid dynamic behaviors of fluidized and vibrofluidized beds operating with flat particles were investigated. Particles made of blank paper sheets cut into different shapes were used to simulate the geometry of actual leaves. Leaf-shaped and square-shaped 'particles', with $\varphi<0.1$ were tested. Curves of pressure drops versus air velocity were obtained in a rectangular column of cross section of 0.20x0.11 m^2, 0.30 m high, at dimensionless vibration parameters of 0; 0.5; 1.0 and 1.5. The flat particles produced poor fluidization patterns and highly non-homogeneous beds. The introduction of vertical vibration contributed to reduce channeling and to decrease the transition velocities from fixed to expanded beds. An additional effect of the vibration was the alignment of the particles into the bed, resulting in a configuration of maximum contact area between particles and fluid.

1. Introduction

Due to the good mixing and high heat and mass transfer rates, fluidized beds are widely applied in industrial operations and many papers have been published on equipment design and testing for a broad range of particulate materials (Hajidavalloo, 1998; Colters and Rivas, 2004). The appealing characteristics of fluidized beds for drying of particulate materials encouraged some authors to investigate their application on the drying of leaves (whole or in pieces) of tea and medicinal plants (Shah and Goyel, 1980; Zanoelo, 2007). Post-harvesting storage of dehydrated plants is an alternative to ensure good-quality products for processing along the whole year, minimizing supplying oscillations due to the seasonal crops. Leaves are particles of irregular and flat shapes, with sphericities (φ) under 0.5, out of the range of the usually fluidized particulate materials. The shape of a particle is one of the parameters that affect their fluid dynamic behavior in fluidized and vibrofluidized beds (Gupta and Mujumdar, 1980). In a recent review, Cui and Grace (2007) pointed out that non-standard particles – such as those large in size and extreme in shape – have flow characteristics not readily predictable; noting that characterization of the multiphase flow aspects of such flat particles is weak. They state about the necessity of additional research to provide a general understanding of how the shape and size of low-sphericity particles affect their fluid dynamic behavior in multiphase flows. It is worth noting that even the definition of which shape factor should be used to characterize irregular and flat particles is not clear and differ from one author to another. According to Taylor (2002), a generalized quantitative definition of shape does not exist and different definitions may be used depending on the application. Few works have been found in the consulted literature reporting the operation of fluidized beds with particles of low φ. Lucas et al. (1986) obtained experimental data and fitted a correlation to predict minimum fluidization velocity (U_{mf}) for particles of $0.1 \leq \varphi \leq 0.5$. Reina et al. (2000) investigated fluidization and segregation patterns of a polydisperse system formed by scrap-wood particles of low mean sphericity ($\varphi=0.35$), and

* M.C. Ferreira, Phone: 55-16-33518442; E-mail: mariaf@ufscar.br

observed that the low particle density and extreme irregular shape presented strong influence on the fluid dynamic behavior during fluidization.

Aiming future applications in the drying of medicinal plants, in this work the fluid dynamic behavior of flat particles in fluidized beds is investigated. Tests will be conducted using particles made of blank paper sheets cut into two different shapes. The use of particles made of paper sheets allows avoiding interfering effects on the bed dynamics caused by surface roughness and segregation due to size distribution. Such effects would necessarily be present if natural particles were used and might difficult the analysis of results on this initial stage of investigation. Vibrofluidized beds will be evaluated as an alternative to fluidization, as the literature suggests that the introduction of a vertical mechanical vibration contributes to reduce U_{mf} and bed pressure drop, and to minimize channeling and dead regions as well, resulting in more homogeneous fluidization patterns and increased heat and mass transfer rates.

2. Materials and Methods

2.1. Particulate Materials

The particles used in the experiments were made of paper sheets (density of 833 $kg.m^{-3}$) cut into the shapes of leaves and squares with previously specified dimensions. The paper used had a gramature of 75 $g.m^{-2}$ and was 90 μm thick. For each shape, ten particles were randomly selected and their main dimensions were measured using a particle analyzer (Galai Macro Viewer) and software Image Pro Plus 3.0. Feret diameters, areas and perimeters of the particles are in Table 1, as well as their sphericity, defined as the relationship between the surface area of a sphere having the same volume of the particle and the surface area of a particle.

Table 1: Properties of particulate materials

Particle	Feret diameters (cm)	Area (cm^2)	Perimeter (cm)	φ
leaf-shaped	maximum – 3.28	4.45	4.98	0.063
	minimum – 1.90			
square-shaped	maximum – 1.49	1.51	8.41	0.090
	minimum – 1.41			

2.2. Equipment and Experimental Procedure

The experimental apparatus is composed of a rectangular column, with a height of 0.30 m, and cross section of 0.20 x 0.11 m^2, made of galvanized iron (a detailed diagram and a full description may be found in Daleffe et al., 2005). The air is provided by a blower and the airflow rate is measured using a previously calibrated orifice plate. Pressures at the orifice plate and at the bottom of the bed were measured by pressure transducers linked to a data acquisition system (acquisition board A/D PCI-6024E from National Instruments). For operation in vibrofluidized mode, an eccentric mechanism was used to adjust the amplitude of vibration and a mechanical controller located at the axle of the electric motor allows for the adjustment of frequency of vibration. Frequency of vibration was measured with an optical tachometer Minipa MDT-2244. Different amplitudes (A) and frequencies (f) of vibration were tested, with vibration parameters Γ of 0.5; 1.0 and 1.5. The vibration parameter is defined as $\Gamma=A(2\pi f)^2/g$. To allow visual inspection of particle's dynamic into the bed, some tests were carried out using an acrylic chamber, with the same dimensions of the original galvanized iron chamber. For the conditions investigated, it was observed neither the presence of electrostatic effects nor significant changes on the behavior of fluidization in comparison to the observed with the galvanized iron chamber.

Experiments were conducted by increasing the gas flow rate step-by-step from zero to the maximum value prior to elutriation of particles. The air flow rate was then gradually decreased, and data of pressure drops versus air flow rates were obtained. Each point was obtained from the mean value of

512 samples, collected during 3 seconds. The air mean temperature was kept at 25 ^{o}C. All the experiments were carried out in triplicates. The voidage at minimum fluidization condition (ε_{mf}) was obtained by filling the fluidization chamber with a known mass of particles (about 128 g) and measuring simultaneously the pressure drops and bed heights as the air flow rate was gradually increased, in tests conducted in the acrylic chamber. The bed height at minimum fluidization condition was then obtained and ε_{mf} was estimated by the classical equation established for fluidization (Reina et al., 2000).

3. Results and Discussion

To check equipment and measurement systems, preliminary tests were carried out using "ballotini" glass spheres (d_p= 925 μm). Data of pressure drop (ΔP) versus the air velocity (U) were obtained and U_{mf} was obtained from the characteristic curve by the classical procedure. The experimental value, U_{mf}=0.47 m.s^{-1}, is in excellent agreement with the estimated from Wen and Yu (1966) correlation, equals to 0.46 m.s^{-1}. This result corroborates the quality of equipment and measuring instruments. In Figure 1(a) are the curves of pressure drops versus air velocity obtained in tests with the square-shaped paper particles.

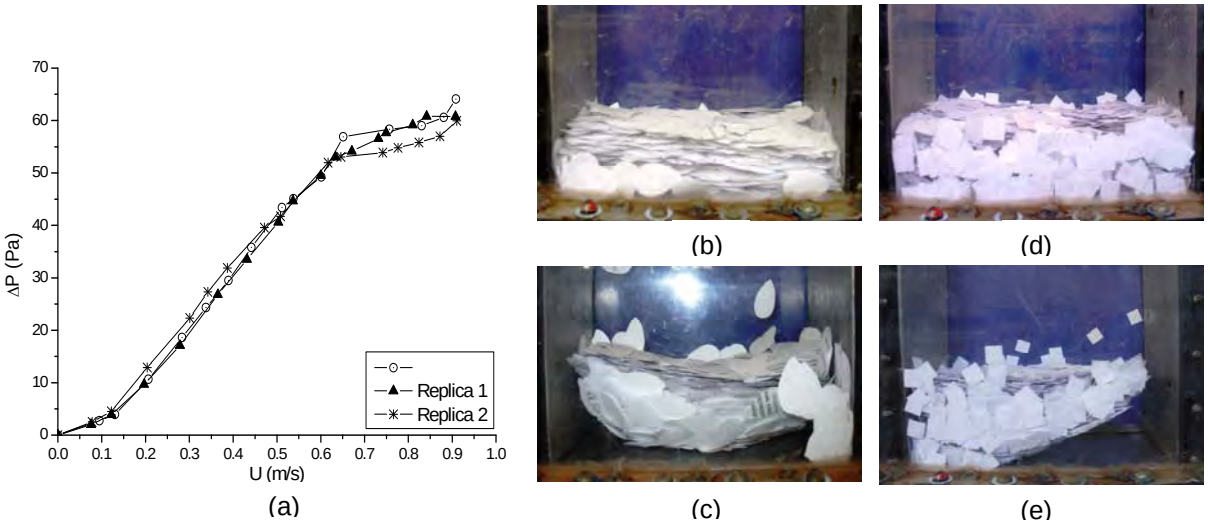

Figure 1: Fluidized bed (Γ=0.0); (a) ΔP vs. U for square-shaped particles; Photos: (b) Leaf-shaped particles; initial static bed (c) U=1.0m.s^{-1}; (d) Square-shaped particles; initial static bed (e) U=1.0m.s^{-1}l.

It is possible to note a region where ΔP increases linearly with the increase of U, a typical behavior for flow through fixed beds. As the air velocity continues to be increased, a change in the slope of the curve is noted, from U≈0.59 m.s^{-1}. In a conventional fluidized bed, this change characterizes the transition to the fluidized regime, in which ΔP is expected to remain constant as U is increased. For the particles tested here though, ΔP does not remain constant as U is raised, but continues to increase at a lower rate, a behavior that may be attributed to the poor quality of fluidization. Visual observation of flow patterns corroborates this evidence, as can be observed in Figures 1(b) and 1(c) for the leaf-shaped particles and in Figures 1(d) and 1(e) for the square-shaped ones, where typical patterns observed during the experiments are depicted. In the 'fluidized' condition, it is possible to note the presence of channeling, with very large voids located preferentially near the chamber walls (see Figures 1c and 1e). The arrangement of particles in the bed, with their surfaces facing the air flow, introduces a great resistance to the flow, preventing a homogeneous percolation of the fluid through the bed. Instead of a bed of particles uniformly percolated by the air, the particles are lifted by the flow as an aggregated bed, almost in a whole block. As channeling has not been observed in the previous tests with glass spheres, it is attributed to the particular characteristics of the particles, which are extremely flat, with φ<0.1. The transition velocity between the fixed bed and expanded regimes was obtained by fitting linear curves to

the points located in the fixed and expanded regions and finding the intercepting point between the lines (in a similar procedure to the one used to finding U_{mf} in classical fluidized beds). In spite of the poor homogeneity of the beds formed, the transition between fixed and expanded regimes is consistently reproducible (Figure 1a). The good reproducibility was also observed for the leaf-shaped particles, (the curves are not presented here for concision). A value of 0.63±0.03 $m.s^{-1}$ for the transition velocity was obtained for the square-shaped particles and of 0.58±0.04 $m.s^{-1}$ for the leaf-shaped ones. The mean voidages of these beds were estimated as 0.84 and 0.86 for the leaves and squares, respectively. These values are not considered representative of real voidages though, due to the large voids caused by channeling. Zanoelo (2007) reported a mean voidage of around 0.92 in a fluidized bed formed by mate leaves, square-shaped and with dimensions very similar to the square-shaped particles used in the present work.

Figure 2(a) shows curves of ΔP versus U for the square-shaped particles in vibrofluidization, with $A=4.0x10^{-3}m$ and $\Gamma=1.0$. These curves were obtained by initially fluidizing the bed and then introducing vibration. After, the bed was defluidized.

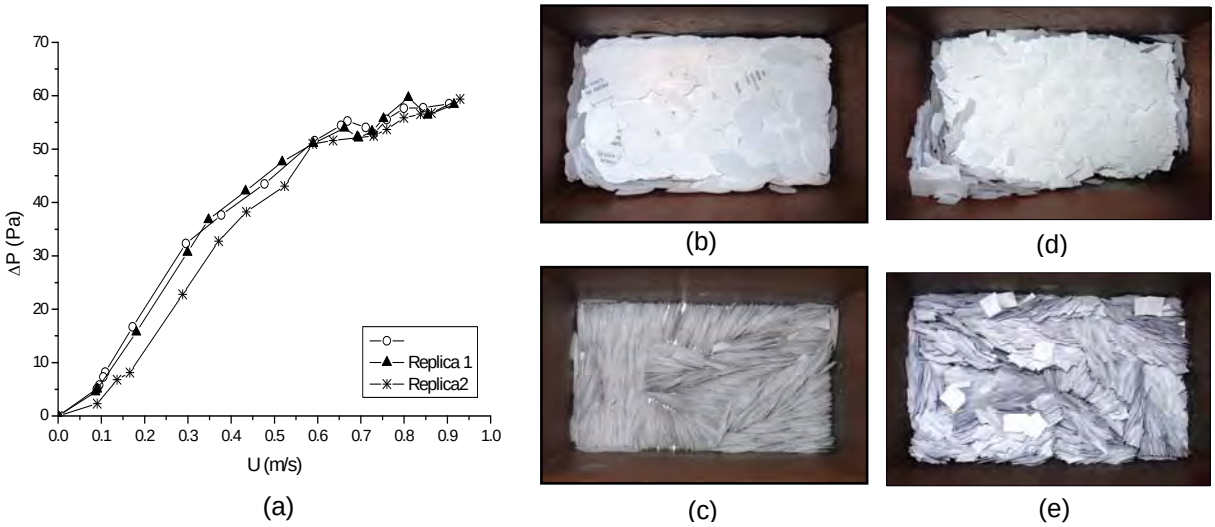

Figure 2 Vibrofluidized bed ($A=4.0x10^{-3}m$; $\Gamma=1.0$). (a) ΔP vs. U (square-shaped particles).Photos (top views): (b) leaf-shaped particles, initial static bed; (c) vibrofluidized bed after a time of 30 min; $U=1.05U_{mf}$ (d) square-shaped particles, initial static bed; (e) vibrofluidized bed after a time of 20 min; $U=1.05U_{mf}$.

By comparing the curves with the ones obtained in fluidization, it is possible to note that the use of vibration extends the range of transition between the fixed and fluidized regimes, a typical behavior of vibrofluidized beds (Daleffe et al., 2005), making the identification of transition velocity more difficult. Reduction of channeling was detected with the use of vibration, because the particles were rearranged and their relative position concerning the direction of air flow rate changed along the essays – the particles gradually become aligned, with their major axis positioned horizontally and their surface area parallel to the direction of air flow (see Figures 2b to 2e). The photos show top views of the beds at the initial static condition and after a period of operation at $A=4.0.10^{-3}m$ and $\Gamma=1.0$ (they illustrate typical patterns observed for practically all the conditions tested). The time for the complete alignment of the particles was a function of the amplitude and frequency of vibration and also of the air velocity. The reproducibility of the characteristic curves in Figure 2a has not been as good as in fluidized beds, which is attributed to the fact that the bed packing structure changed significantly along the process.

The effects of vibration parameters on the fluid dynamic behavior of vibrofluidized beds of square-shaped particles at vibration amplitudes of $4.0x10^{-3}$ and $5.0x10^{-3}m$ may be observed in Figure 3. The extended transition region the fixed to the expanded regimes prevents an accurate identification of the transition velocities. Literature does not present a consensual definition for the transition velocity in vibrofluidized

beds (Daleffe et al, 2005). Here, they were obtained using the same methodology applied for fluidization, and the values are indicated in Figure 3. Although the notation U_{mf} is maintained, it is convenient to note that the transition velocities here are not equivalent to the classical definition applied for conventional fluidized beds, since even for Γ=0 the regime observed may not be considered as really fluidized. According to Gupta and Mujundar (1980), in homogeneous beds the vibration should reduce both U_{mf} and ΔP_{mf}. The results show that the transition velocities in vibrofluidized beds are lower than in the fluidized ones, but the effect of increasing Γ on U_{mf} is not clear. The values of U_{mf} for the leaf-shaped particles (curves not showed here for concision), varied in the range of experimental uncertainty. Concerning the effects of vibration parameters on the fluid dynamics, curves in Figure 3 show that at Γ>0, ΔP in the fixed bed region is always greater than at Γ=0, while in the expanded regime it is not possible to identify significant effects of the vibration on the pressure drops.

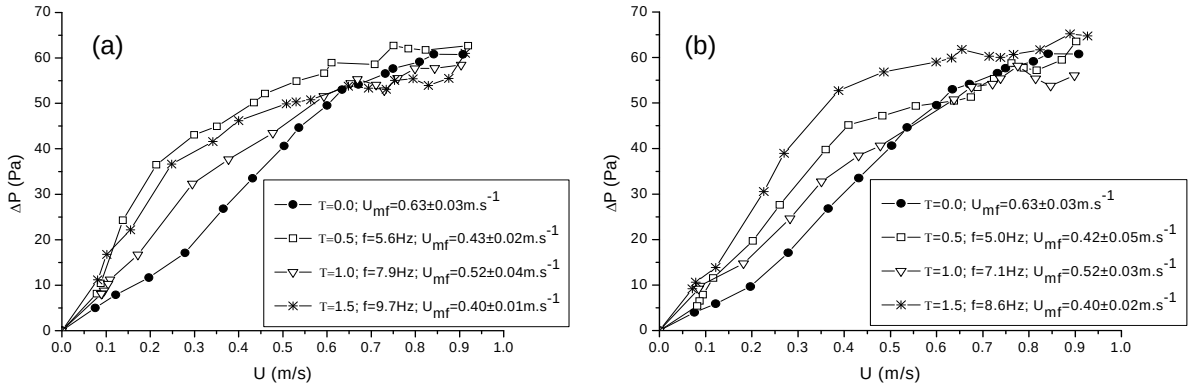

Figure 3: ΔP vs. U; square-shaped particles; (a) A=4.0x10^{-3} m; (b) A=5.0x10^{-3} m.

The shapes tested in the present work have sphericity lower than 0.1, and the superficial area of square-shaped particle is about 30% minor than the leaf-shaped oneparticles. The fluid dynamic behavior for the different shapes are depicted in Figures 4(a) for Γ=0 and 4(b). In fluidization, the increase in the particle dimensions resulted in greater pressure drops at fixed bed region, while opposite behavior is observed for vibrofluidized beds. At values of U>U_{mf}, the pressure drops are similar for the different shapes, because the mass of particles used in the experiments was the same and the particles have the same density, so the pressure drop does not change.

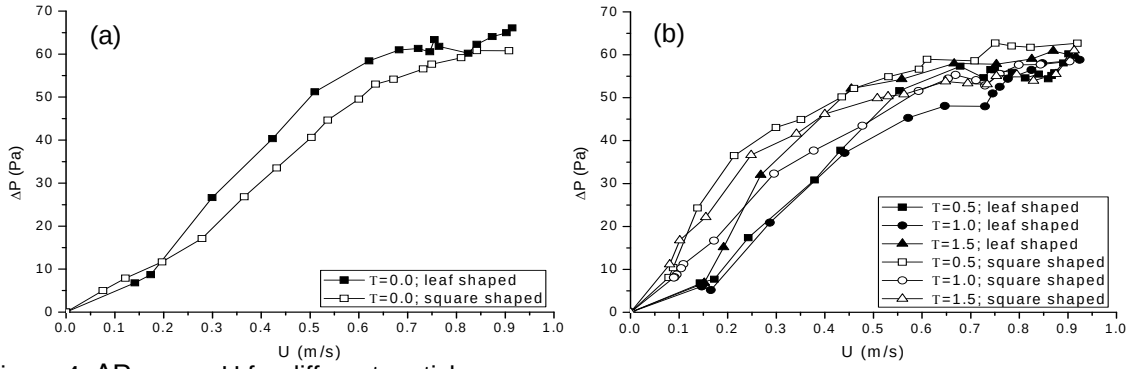

Figure 4: ΔP versus U for different particles.

A correlation developed by Lucas et al. (1986), recommended for particles of 0.1≤ φ ≤0.5 was tested to estimate U_{mf} for our conditions, as well as one suggested by Reina et al. (2000). The deviations were quite large though, exceeding an order of magnitude. The classical correlation from Wen and Yu (1966) was the one which best predicted the experimental results, yielding values of 0.97 and 0.77 m.s^{-1} for the leaf-shaped and square-shaped particles, respectively. Experimental values of ΔP_{mf} in fluidization were compared to the ones predicted by the theoretical relationship. The predicted values

(57 Pa for both particle shapes) agree well with the experimental ones (56±3 e 54±2 Pa for the leaf-shaped and square-shaped particles, respectively).

4. Conclusions

The use of particles made of paper and cut into specified sizes and shapes permitted the measurement of fluid dynamic data in fluidization of particles with very low φ, eliminating variations in size and shape inherent to natural particles. Tests with leaf- and square-shaped particles with $\varphi<0.1$ showed that they produce poor fluidization patterns, very different from the obtained in conventional fluidization of particles with $\varphi>0.5$. The particle beds are expanded by the air flow, but they are strongly non-homogeneous and intense channeling is observed. The results yield to the conclusion that methodologies developed for particles of $\varphi>0.5$ should be applied with caution for flat particles. The use of vertical vibration minimized channeling and reduced U_{mf}. An important effect of vibration was the alignment of the particles, which rest with their major axis positioned horizontally and their surface areas parallel to the air flow. The particle shapes tested presented similar fluid dynamic behaviors in both fluidized and vibrofluidized configurations, with values of U_{mf} and ΔP_{mf} not significantly different for each shape. The correlation developed by Wen and Yu (1966) predicted U_{mf} for the leaf-shaped particles with deviations of 67% (square-shaped particles) and 22% (leaf-shaped particles). Additional experimental data, for other shapes and different ranges of φ, are necessary to the establishment of reliable methodologies for estimating fluidization parameters of low-sphericitiy particles. The results obtained here suggest that the use of fluidized beds for drying of leaves may lead to a non-uniform drying, since the contact between the particles and the percolating fluid along the bed is irregular. Vibration may be used as a preliminary operation before fixed bed drying, since the alignment of the particles may favor heat and mass transfer by maximizing the area of particles in contact with the fluid.

Topic: Advancing the chemical and biological engineering fundamentals.

Abstract

The mass transfer of lignin from the inside of wood chips to the bulk liquor during the kraft pulping of *Eucalyptus globulus* was studied and a kinetic model to describe this process is proposed. The kraft pulping experiments were carried out with target temperatures ranging from 80 to 165 ºC, effective alkali charges from 10 to 45 g Na_2O/L and sulphidities from 15 to 75%. The model is based on extensive experimental data on the dissolved lignin concentration profiles along pulping time, both inside and outside the chips. The lignin concentration in the entrapped liquor was much higher than in the free liquor, and reached a maximum value during the cook. The model follows a lumped parameter estimation approach, where the spatial concentration profile of lignin inside the chip is represented by its spatial average, enabling to estimate the effective diffusion coefficient while taking into account the contribution of the film surrounding the wood chips to the overall mass transfer resistance. The model enabled a good prediction of the dissolved lignin concentration in the free liquor. The effective diffusion coefficient was expressed by an Arrhenius-type equation with an estimated activation energy for diffusion of 29 kJ/mol, being also dependent on the cooking yield raised to 5,07. This exponent high value is explained by the increasing resistance to lignin diffusion along pulping time. The mass transfer resistance in the external film was found to have a significant contribution to the overall resistance (20 to 30% at the beginning of the cook) and should not be neglected.

1 Introduction

The kraft pulping process is strongly dependent on the mass transfer of the reagents and reaction products that occurs between the free (bulk) liquor and the liquor entrapped in the chips. The highly heterogeneous nature of the process comes from the fact that the pulping reactions occur between the reagents in the entrapped liquor and the wood components in the solid matrix of the chips and the chemicals' concentrations in the entrapped liquor are substantially different from those in the free liquor (Egas et al., 2002). The main objective of the pulping process is to remove the lignin from the wood, preserving, as much as possible, the carbohydrates. However, besides promoting the reaction of lignin with the alkaline reagents in the cooking liquor, it is required to withdraw the dissolved lignin from inside the chip to the free liquor, since it can re-precipitate onto the wood after the cook. The mass transfer of the dissolved lignin from the entrapped liquor to the free liquor occurs both during the cook and in the following washing stages.

The majority of the kinetic studies on the kraft pulping of wood are focused on the chemical reactions involving the wood components or the mass transfer of the cooking reagents, and therefore there are very few studies in the literature on the mass transfer of the dissolved organic compounds to the free liquor (Li and MacLeod, 1993; Li and Mui, 1999). Besides, these studies are mostly focused on the mass transfer in the washing stages rather than

* Corresponding author. E-mail:mgc@eq.uc.pt

during the cook. As an example, the model based on experimental studies developed by Li et al. (1997) is one of the few kinetic approaches to describe the diffusion of dissolved lignin within the pulp fibres, during the washing stage. The kinetic model follows Fick's law with cylindrical coordinates in the radial dimension of the fibre walls, being the diffusion coefficient independent of the radial position. According to this model, the diffusion coefficient was found to vary with the pH, leading to a faster diffusion rate at higher pH values.

The dissolved lignin mass transfer kinetics is relevant not only for the washing process that follows the cook, where a deeper knowledge of the mass transfer of organic compounds is needed, but also during the cook. By knowing the dissolved lignin concentration in the free liquor and the mass transfer rate between the free and the entrapped liquors, the lignin concentration in the entrapped liquor can be determined, and consequently the amount of lignin removed from wood at every instant of the cook.

2 Experimental

The proposed model is based on experimental data from laboratory cooking experiments. The experimental procedure is described elsewhere in more detail (Egas et al., 2002; Simão et al., 2008). Pulping of handmade *Eucalyptus globulus* chips (30x30x6 mm) was performed in a six-vessel computer controlled batch-digester system described by Romanenko and Castro (2000). Each cooking experiment consisted of six simultaneous cooks in the same conditions of temperature, pressure and reagents concentration, but with different pulping times. The chips were fully impregnated with water prior to the cooks, which allows disregarding the penetration mechanism. The effective alkali charge, the sulphidity and the target temperature varied among experiments in the ranges 10 to 45 g Na_2O/L, 15 to 75% and 80 to 165 ºC, respectively. The liquid-to-wood ratio remained at 8 L/kg in all experiments (Simão et al., 2008).

After each cook, samples of free and entrapped liquors were withdrawn, being the latter obtained by pressing the cooked chips. The liquor samples were analyzed for dissolved lignin concentration according to the method developed by Trinh (1988): the samples were diluted with NaOH solution at 0.01 N and their absorbance was measured at 280 nm.

3 Model Development

The proposed model is based on a lumped parameter estimation approach, where the spatial lignin concentration profile along the chip thickness is replaced by its spatial average, which corresponds to the lignin concentration in the whole of the entrapped liquor that was measured in the cooking experiments. A similar model for the diffusion of effective alkali was already presented (Simão et al., 2008). This approach is illustrated in figure 1. Therefore, the overall mass transfer coefficient (K_{OL}) relates the lignin concentration in the average of the entrapped liquor with the one in the free liquor. This coefficient can be related to the effective diffusion coefficient (D_{eff}) and the mass transfer coefficient in the external film (k_L).

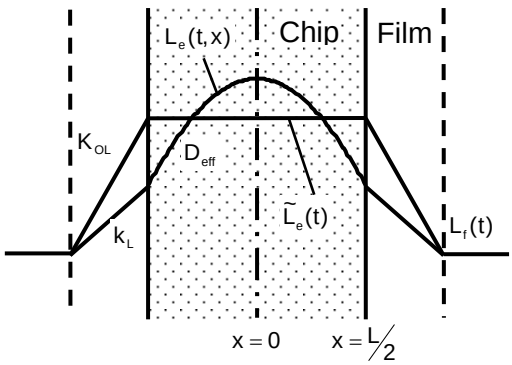

Figure 1. Dissolved lignin profile across the chip and its space average equivalent.

In order to build the lignin mass transfer model, the following assumptions were made:

- The free liquor phase is homogeneous and well agitated;
- The resistances to heat transfer are considered negligible;
- The chip is treated as a infinite slab and its critical dimension is the thickness;
- The convective flux inside the chip is negligible;
- The lignin activity coefficient is the same in the free and entrapped liquors;
- The effective diffusion coefficient is constant along the chip thickness;
- The re-precipitation of lignin on the wood fibres is considered not to occur.

A microscopic mass balance to the dissolved lignin in the entrapped liquor leads to Eq. 1:

$$\frac{\partial(\varepsilon L_e)}{\partial t} = D_{eff}\left(\frac{\partial^2 L_e}{dx^2}\right) + r \tag{1}$$

with the following boundary and initial conditions:

$$x = 0 \quad \Rightarrow \quad \left(\frac{\partial L_e}{\partial x}\right)\Bigg|_{x=0} = 0 \tag{2}$$

$$x = \frac{L}{2} \quad \Rightarrow \quad D_{eff}\left(\frac{\partial L_e}{\partial x}\right)\Bigg|_{x=\frac{L}{2}} = -k_L\left[L_e\left(t,\frac{L}{2}\right) - L_f(t)\right] \tag{3}$$

$$t = 0 \quad \Rightarrow \quad \begin{cases} L_e(0,x) = 0 \\ L_f(0) = L_f^0 \end{cases} \tag{4}$$

where $L_e(t,x)$ and $L_f(t)$ are the dissolved lignin concentrations in the entrapped and free liquors, ε is the chip porosity, r is the chemical reaction rate, L is the chip thickness, D_{eff} is the effective diffusion coefficient and k_L is the mass transfer coefficient in the external film. By using the spatial average of the lignin concentration profile, $\tilde{L}_e(t)$, and average reaction rate, $\tilde{r}$, in the entrapped liquor, and assuming that this profile is represented by an inverted second-order polynomial, symmetric at $x = 0$, the following lumped parameter model is obtained where the microscopic balance is expressed as a function of $\tilde{L}_e(t)$:

$$\frac{\partial(\varepsilon \tilde{L}_e)}{\partial t} = \frac{12 D_{eff} k_L}{L(6D_{eff} + Lk_L)}\left[L_f(t) - \tilde{L}_e(t)\right] - \tilde{r} \tag{5}$$

On the other hand, the macroscopic balances to the lignin concentration in the free and entrapped liquors are expressed by Eq. 6 and 7:

$$\frac{d(V_f L_f)}{dt} = -K_{OL} A_T\left[L_f(t) - \tilde{L}_e(t)\right] \tag{6}$$

$$\frac{d(V_e^T \tilde{L}_e)}{dt} = K_{OL} A_T\left[L_f(t) - \tilde{L}_e(t)\right] - V_{chip}^T \tilde{r} \tag{7}$$

where V_e^T and V_f are the total volumes of entrapped and free liquor in the system, V_{chip}^T is the total volume of chips and A_T is the total mass transfer area. By multiplying Eq. 5 by V_{chip}^T, the microscopic balance can be related to the macroscopic balance in Eq. 7, and therefore the following relationship is inferred:

$$\frac{1}{K_{OL}} = \frac{1}{k_L} + \frac{L}{6D_{eff}} \tag{8}$$

The mass transfer coefficient in the film k_L was determined using correlations for liquid-solid systems published by Dwidevi and Upadhyay (1977) and the experimental data for the properties of free liquor.

The effective diffusion coefficient was considered to follow an Arrhenius-type equation for diffusion, multiplied by the cooking yield (η) raised to an exponent:

$$D_{eff} = \varepsilon k_D \sqrt{T}\, e^{-\frac{E_a}{RT}} \eta^n \quad (13)$$

where k_D is the preexponential constant, E_a is the activation energy for diffusion and R is the gas constant. The yield factor was added to account for a high decrease in the lignin transfer rate along cooking time which was found to occur. This strategy is similar to the one used by Gustafson et al. (1983) in their kinetic model, where the cooking yield was related to the lignin content in the solid phase.

4 Results and Discussion

Some of the experimental results are illustrated in figures 2 and 3. Unlike the liquor reagents, the lignin is dissolved within the chips and diffuses from the entrapped liquor to the free liquor. Therefore, the lignin concentration in the entrapped liquor is much higher than that in the free liquor. A decrease in the lignin concentration in the entrapped liquor is also observed later in the cook, for the cooks with a high temperature. The maximum lignin concentration value corresponds to the equilibrium between the rates of chemical reactions that produce the dissolved lignin and the rate of mass transfer towards the outside of the chip. Once this equilibrium is reached, the mass transfer rate becomes higher than the chemical reaction rate, and the lignin concentration in the entrapped liquor begins to decrease.

The lignin concentration increased, both in the free and in the entrapped liquors, for higher temperatures and alkali charges, as also shown in figures 2 and 3. The same effect was observed when the sulphidity was increased (results not shown). This behaviour was expected, since it is known that an increase in temperature, alkali charge or sulphidity leads to a higher reaction rate of wood lignin, and consequently to a higher dissolved lignin concentration.

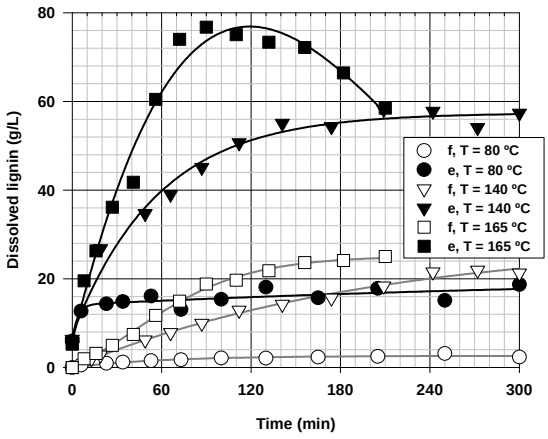

Figure 2. Effect of temperature (T) on the dissolved lignin concentration in the free (f) and entrapped (e) liquors (effective alkali charge = 15 g Na_2O / 100 g odw, sulphidity = 30%)

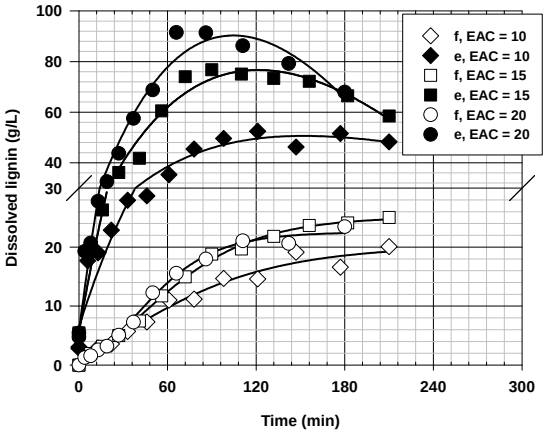

Figure 3. Effect of effective alkali charge (EAC) on the dissolved lignin concentration in the free (f) and entrapped (e) liquors (temperature = 165 ºC, sulphidity = 30%)

The proposed model contains a total of three parameters to estimate: the preexponential constant and the activation energy for the effective diffusion coefficient and the exponent of the cooking yield (Eq. 14). From the 35 cooking experiments available for model development, 22 were chosen to solve the parameter estimation problem, while the remaining 13 were left for model validation. Re-parametrization was performed in k_D and E_a, being the estimated parameters $\beta_1 = \ln(k_D) - E_a / 300R$ and $\beta_2 = E_a / 300R$.

Figures 4 and 5 show the experimental and predicted values for the dissolved lignin in the free liquor in cooks used for model development (Fig. 4) and for model validation (Fig. 5). Taking into account that the lignin concentration in both free and entrapped liquors is subject to experimental error, a good fit of the model predictions to the experimental values was obtained, with R^2 values of 0.968 for the data used for parameter estimation and 0.909 for the validation data.

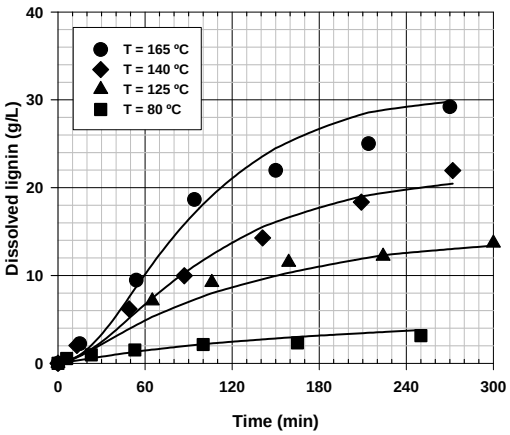

Figure 4. Experimental values and model predictions for the dissolved lignin in the free liquor in cooks used for parameter estimation (effective alkali charge = 15 g Na_2O / 100 g odw, sulphidity = 30%).

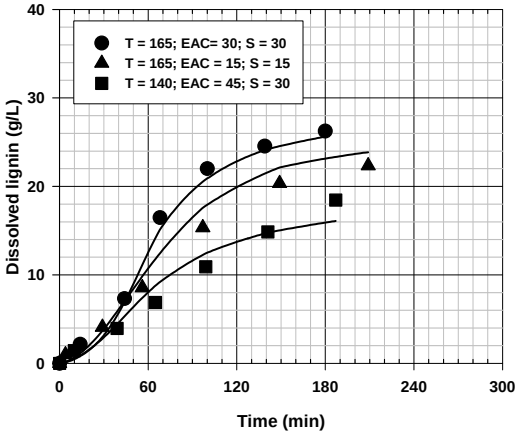

Figure 5. Experimental values and model predictions for the dissolved lignin in the free liquor in cooks used for model validation (temperature, T, in ºC, effective alkali charge, EAC, in g Na_2O / 100 g odw, sulphidity, S, in %)

The estimated values of the parameters and their standard deviations are presented in Table 1. The estimated values show a high confidence level, with deviations reaching a maximum of 7.6% of these values. The activation energy (29 kJ/mol) is in the range of literature values for diffusion (Gustafson et al., 1983), while being higher than the one found for the diffusion of alkali (21 kJ/mol) in a previous model developed by the authors (Simão et al., 2008). This is to be expected since the diffusion of lignin is supposedly slower than alkali diffusion.

However, the diffusion of lignin is also significantly affected by the cooking yield, as suggested by the high value of the yield exponent. The high influence of the yield factor is reflected on a continuous increase of the resistance to lignin diffusion within the chip throughout the cook, as illustrated in Figure 6 where the overall, internal and external resistances to mass transfer are shown. The increase in the internal resistance is only compensated at the beginning of the cook, where the temperature increase would normally lead to a lower resistance to mass transfer. This occurrence can be tentatively explained by the molecular weight distribution of the dissolved lignin: the lignin with lower molecular weight diffuses faster to the free liquor, leaving behind the lignin of higher molecular weight whose diffusion is slower. The increase in the viscosity of the entrapped liquor also contributes to hinder the diffusion of lignin out to the free liquor. On the other hand, the resistance to mass transfer in the external film decreases along the cook, influenced by the temperature and the surface velocity of the free liquor. At the beginning of the cook, as shown in Figure 6, it has a relatively high value, reaching almost 30% of the overall mass transfer resistance in some cooks. This indicates that, at least during the heating stage of the cook, the mass transfer in the film should not be neglected. However, after this period the internal resistance to mass transfer starts to increase, and the importance of the external film resistance fades away as the cook progresses.

Estimated parameter	β_1	β_2	n
Parameter value	– 48,8	11,8	5,07
Standard deviation	1,3	0,9	0,25
Model parameter	k_D	E_a (J/mol)	
Parameter value	$8{,}58 \times 10^{-17}$	29×10^3	

Table 1. Optimal parameter estimates for the mass transfer model.

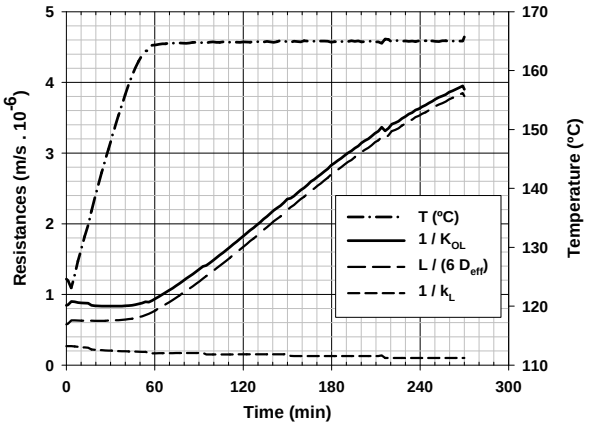

Figure 6. Evolution of the overall ($1/K_{OL}$), internal ($L/6D_{eff}$) and external ($1/k_L$) resistances to mass transfer along pulping time for a particular cook. (T = 165 ºC; CAE = 15 g Na_2O/100 g odw; S = 30%).

5 Conclusions

The proposed model for the mass transfer of dissolved lignin is fully based on experimental data on the dissolved lignin concentration in both free and entrapped liquors, and therefore is independent of the chemical reactions that produce the dissolved lignin. The model provides a good prediction of the lignin transferred to the free liquor at each instant of the cook in a wide range of operating conditions.

According to the model, the diffusion of lignin is dependent on the cooking yield, resulting on a significant increase of the corresponding resistance to mass transfer along the cook. This increase may be explained by an increase in the liquor viscosity and in the average molecular weight of the dissolved lignin that are believed to occur during the cook. The resistance to mass transfer of lignin in the film surrounding the chips was found to be significant at the beginning of the cook, up to 30% of the overall mass transfer resistance.

Abstract

In this paper was presented the assessment of an liquid-liquid extration column, without mechanical agitation, by experimental and theoretical determination of axial dispersion data from related equipment and also posterior analyses of these results.
Experimentally, the method used for determination of axial dispersion number,it was about the test of tracer (type pulse), using water as solvent and the orange of metila as soluto, however for attainment of the axial dispersion values, it was used the Levenspiel model (1962), always to the ambient temperature (25ºC).
In the theoretical part was proposal an equation based on pi of Buckingham theorem of dimensional analysis, so that also the behavior of the axial dispersion in function of selected variable , using a program elaborated in FORTRAN language.
In this study was analyzed influence of outflow continuous phase, the number of compartments utilized and the free area of draining perforateed plates in the extractor column liquid-liquid, it based on the comparison final values of axial dispersion, these gotten in experimental way against the theoretical values, formulated for empirical correlations.

Key Word: Separation, Extraction, Axial Dispersion.

1. Introduction

The liquid-liquid extraction studied hear has as object an extractor column of perforated plates, without mechanical agitation and laboratorial scale. It´s operating with water (continuous phase) and orange of metila (tracer) in countercurrent and normal conditions of bench. Some references about axial dispersion and their areas had been produced throughout these years. Moustiri (2001) considered the study of the axial dispersion in a column with bubbles considering the two-phase flow. It also admitted an unified empirical correlation, to predict the coefficient axial dispersion of the liquid, the holdup of gas and the size of the bubble at column in operation. On another study for Thanos (2001) studied the axial dispersion and holdup of mix at high pressures and temperatures, also it´s using empirical correlations to predict the coefficient of axial dispersion. In other source, Zítný (2004) considered the determination of the values of axial dispersion through the theorem of the finite values for making a perfect analogy with the transfer of heat and mass. Another premise of its model none case that will have bigger velocity for disturbance influence at temperature in the flow.
Already Góis (1995), exactly not being one of the studies most recent related to the axial dispersion, however including a relation to the hydraulical study of extractor columns, this contribution spoken about the performance of an extractor column evaluated through tree distinct groups, as demonstrated in Figure 1 below.
Of this study, it was possible for the Laboratory of Separation in the Chemical Engineer Masters Degree (MAEQ) on politécnica School at UFBA, to be bred 3 sources of study, it related to the hydarulical of columns extractor, as mentioned in Figure 1.

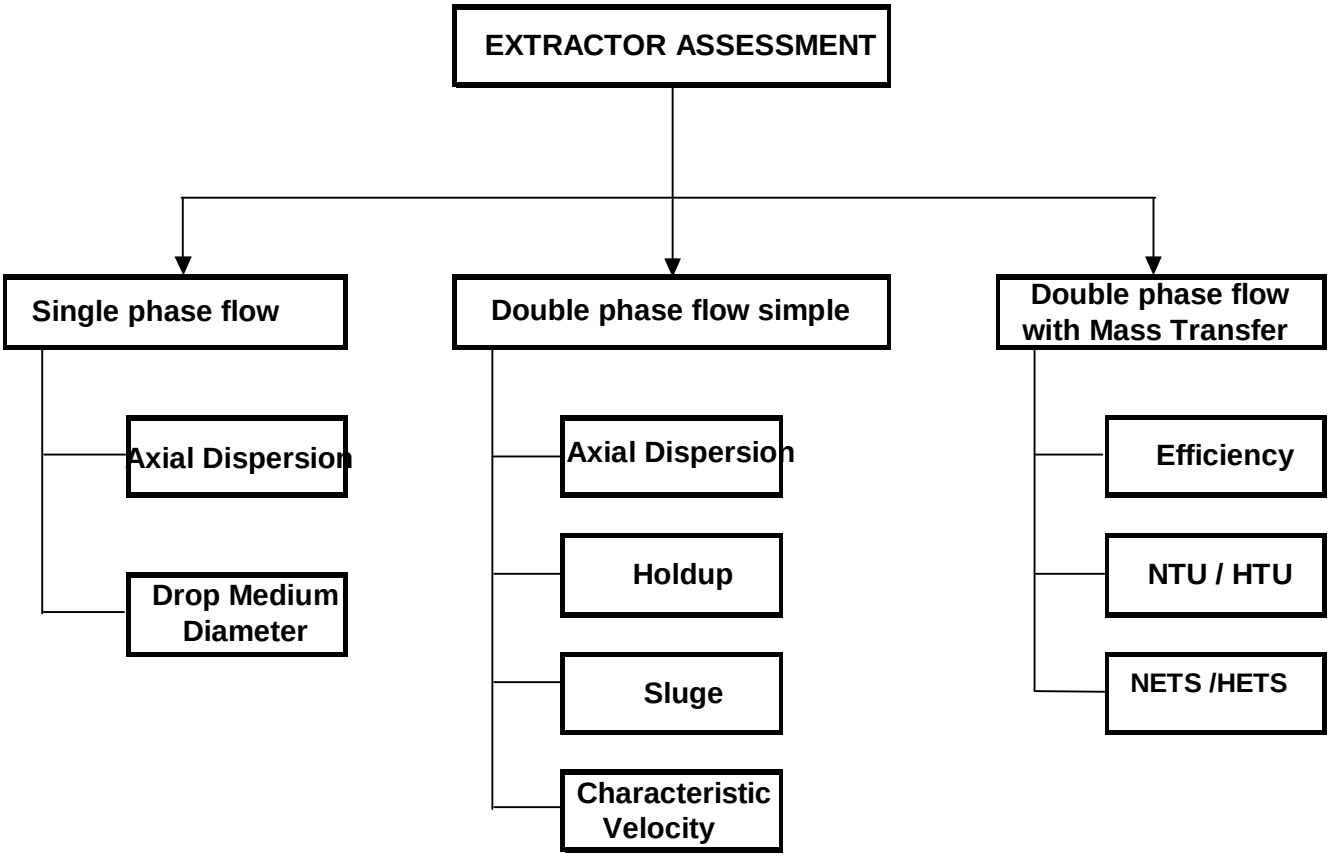

Figure 1- Diagram of assessment for+ extractor columns (Góis, 1995)

Amongnst the cited, the study of the single-phase flow through the assessment of coefficient axial dispersion is the focus of the present work, until presented here.

2. Experimnt

For accomplishment the present work was used na extracting column with perforated Prates, as demonstrated in figure 2.

2.1. Apparatus Describe

The configuration operational geometric of the extracting column was 3 and 4 compartments, with height of 72 ou 92 cm and an internal diameter of 9,50 cm.
This extracting column also is composed of aluminumm perforated plates. So, each plate have diameter of 11,72 cm, an area of 108,82 cm^2 and a fixed area of puncture for plate. The area of each puncture is 0,55 or 0,35 cm, it providing, respectively, a free area of flow approximately of 6% or 29%.

2.2. Experiment Procedure

For experimental determination of the axial dispersion number was used the test of tracer type pulse, which consists in injection one pulse of plotting (orange of metila) with know concentration, in the base of the extracting column under flowed phase (water), It followed of collections of samples (plotting + solucion) in the top of the same.

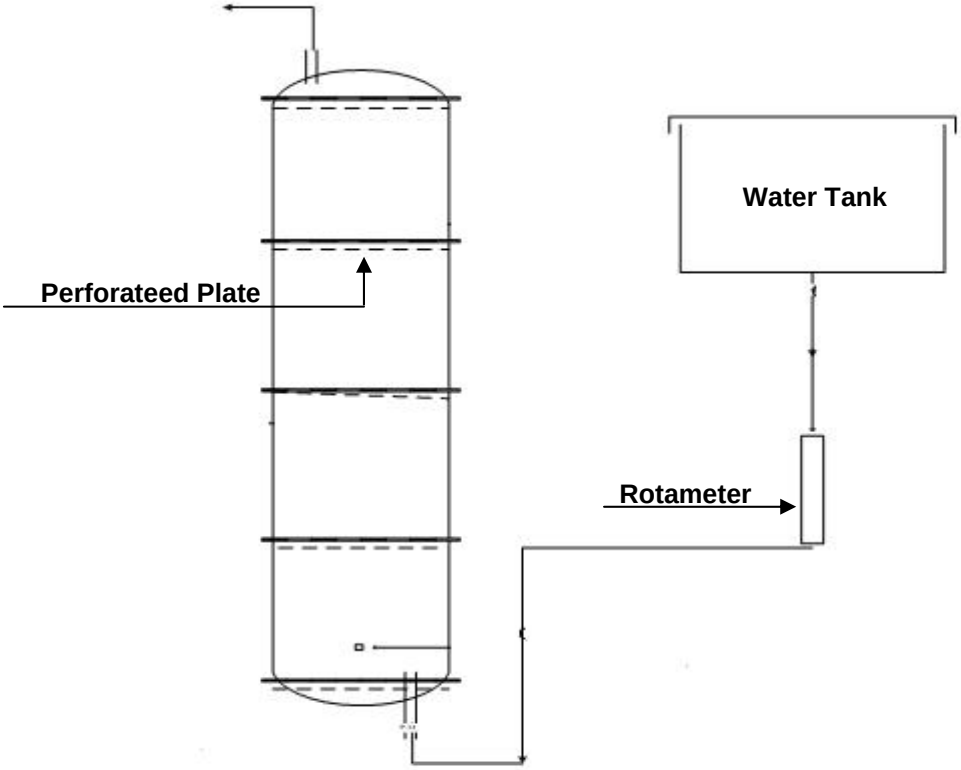

Figure 2- Diagram of laboratorial apparatus of extractor column with perforated plates.

The extracting columnn perforateed plates endowed terminals for feeding/sampling is fed by a hose, which the flowed phase (water) from the feeding, it compound for action of gravity the extractor column in vertical and ascending direction at maximum level operation.
Therefore, 5 ml of orange of metila (plotting), was injected, with know concentration in the base. So, itself collecting samples in the top of the column of 30 in 30 seconds, logically at different values of the same one.
Each experimental attempt was repeated 3 times, for reduce experimental error quantity and attributed an average value of same one sample, independent of evaluated parameter.

2.3. Axial Dispersion Determination

With the experimentally values obtained of, it was determined axial dispersion number by differential model propost at Levenspiel (1962).
The model Levenspiel (1962), affirms that since that mixture process involves a redistribuition of material for agitation, but this reflect a considerable time in the flow, such redistribuition can be considered as statistical nature and analogous to molecular diffusion. So, the author describes the axial dispersion similar form then molecular diffusion (Fick Law).
In such way, for each experiment, with their respective times and measured concentrations, it possible to be gotten experimental numbers of axial dispersion at na axial dispersion of small intensity.

3. Results

The evaluated operational variable are continuous phase flow and axial dispersion efficiency at the operational geometry of perforateed plate column with 3 or 4 compartment, free area or 6% or 29%, according the table 1 on the sequence this topic.

Table 1. Resume of parameters and operational variables used.

Parameters	Operational Range
Outflow continuous phase (cm^3/s)	14 – 63
Compartments number	3 ou 4
Plates number	4 ou 5
Lenght of column (cm)	72 ou 92
Free Area (%)	6 ou 29

The axial dispersion values in this present work are presented for graphs D/vL (axial dispersion number) double Qc (flow continuous phase flow), for differents free areas of operation and geometric arrangements, in accordance with Figures 3 and 4.

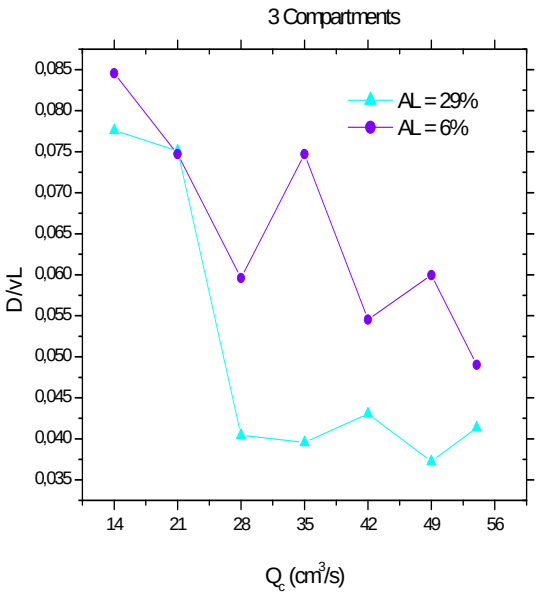

Figure 3 – Variability of axial dispersion number with outflow continuous phase at an extracting column with 3 compartments

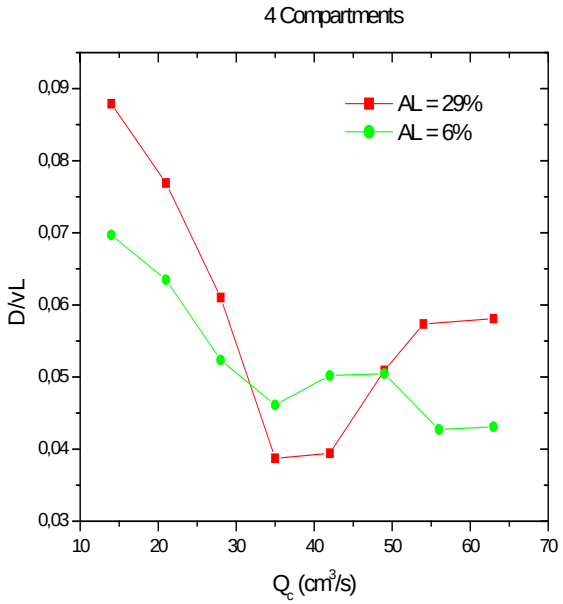

Figure 4 – Variability of axial dispersion number with outflow continuous phase at an extracting column with 4 compartments

3.1. Efficiency Analysis of Axial Dispersion

Analyzing the graph of Figure 3, it was observed that for operation of the extrcating column with 3 compartments and a free area of 6% for each plate (puncture), It had been gotten higher values of axial dispersion, since, for this arrangement in the tested operational band (range), it happens a bigger recirculation of the fluid in interior of each compartment. In such a way, it has an increase of the contact time enters the phases per compartment. Therefore, it also increasing the time of residence on same ones of samples in each compartment.

Already analyzing the graph of Figure 4, it was observed that for operation of the extracting column with 4 compartments and a free area of 6% or 29% for plate, it had been gotten for operational range, different efficiencies. Firts, for low outflows (14 - 34 cm^3/s) with a free area of 29%, it had been gotten the biggest performances, because in this arrangement it has a bigger contact between the dispersed phases and continuous (bigger free area) and also decreases outflows (bigger time of residence for solution in extractor column). But, for intermediate outflows (28 - 44 cm^3/s), it was obtained an optimum performance with free area of 6%. In this study case had to

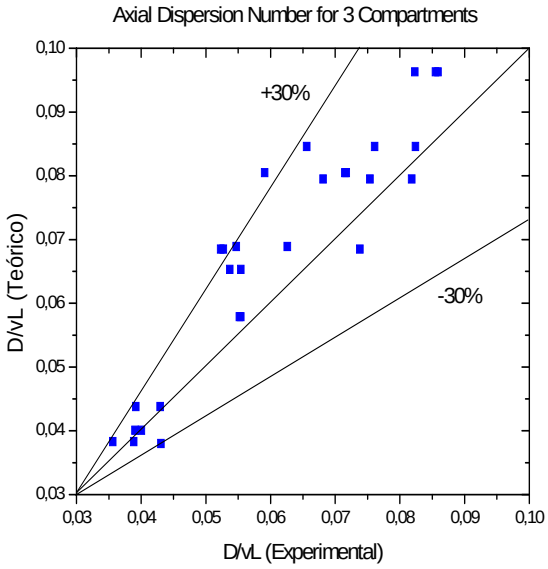
propitiate the arrangement an increase of contact time enters phases in each compartment, so it also raising the time of residence of same in extracting column in each compartment and then getting bigger values of axial dispersion, for this arrangement in question.
Finally, for high outflows (above of 49 cm^3/s), with free area of 29%, it had been gotten the best performances of this experiment, because in this scene is necessary a bigger area of contact between phases. Being thus, with a free area of 29%, it has a higher contact between phases, proportional the operational outflows.
After analysis of efficiency at two arrangements, it was consisted that the extractor column with 3 compartmentes and a free area of 6%, it presents raised average values of axial dispersion in all experiment.
However, on the graphs of Figures 3 and 4, it was observed that for outflows continuous phase (Qc) between 35 and 49 cm^3/s in both geometric arrangements, it had occurred an inversion of values on axial dispersion. These facts had been possible, for the occurrence of Backmixing. This phenomenom, that means inversion of sense in axial direction (longitudinally).

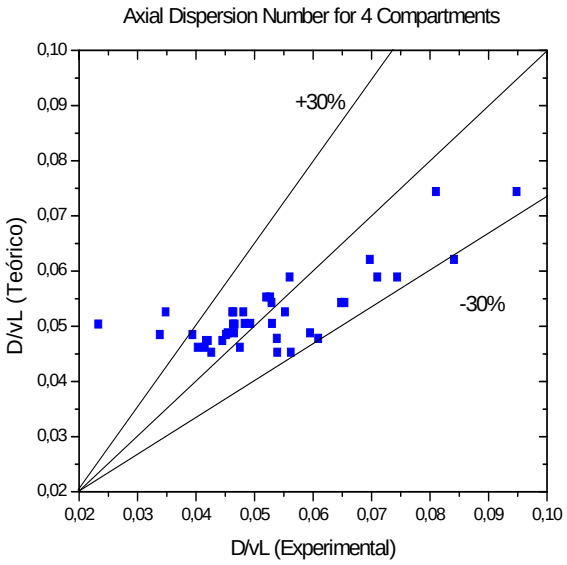
3.2. Efficiency Analysis of Outflow Continuous Phase

The analysis of influence on outflow continuous phase in the axial dispersion was also based on graphs D/vL double Qc, presented in Figures 4 and 5.
In all the graphs are observed that the reduction of the values of the axial dispersion is characteristic of the experiment, with the gradual increase of the outflow continuous phase (water). This fact occurs, because with the increase on outflow of water, the phase that contains the tracer, it will consequently have little time of contact with the flowed phase and it will be less dispersed longitudinally in direct current (water), thus originating an axial dispersion of low intensity.

4. Empirical Equations

In this currently study has too the attainment of empirical correlations, that will predict theoretical values of experiment, so that is possible to compare theoretical double experimental, these obtained accord with section 3.
When is respect with a situation, which doesn't exist a distinguishing equation that governs clearly the phenomenon study in this work, the theorem Pi de Buckingham was applied. It based on the technique of dimensional analysis.
So, the admitted admensional groups were created matrixes and this premised to use method of Square Minimum.
After that, with an implementation one program in FORTRAN language, it has possible to obtain 2 empirical equations, in the sequence this topic. They empirical equations conduct each operational arrangement, in time which it isn't possible to attribute only one empirical equation to present good results, for both arrangements.
After analysis of the graphs in figures 5, it was observed that pairs of values for axial dispersion number experimental and theoretical are inside the limits of permissible error (+/- 30%). This range is applicable for works at this search area, over all that their objective the comparison the results experimental with theoretician.





$$D/vL = 0{,}186\,(D/L)^{-0{,}202}\,(1/Fr)^{0{,}308}\,(Re)^{0{,}0243} \quad (1)$$

$$D/vL = -\,0{,}198\,(1/AL)^{-0{,}368}\,(1/Fr)^{0{,}226}\,(Re)^{0{,}0189} \quad (2)$$

Topic: Advancing the chemical and biological engineering fundamentals

Abstract

Three-dimensional gas-liquid simulations in a cylindrical bubble reactor with an external loop were performed. The effects of average bubble size, bubble size distribution and gas inlet plate geometry were evaluated. The population balance models of Luo and Svendsen (1996) and Prince and Blanch (1990) were used in order to simulate the breakup and coalescence effects, respectively. The drag force was modeled using the Ishii-Zuber model, which takes into account bubble deformation effects. The k-epsilon turbulence model was applied only for the continuous phase and the dispersed one was considered laminar. Lift, Magnus and added mass forces were neglected. Simulations at different superficial gas velocities were performed using two different inlets: a uniform and a perforated plate entrance. Breakup and coalescence effects were studied only for the uniform gas inlet geometry and the particle size distribution was obtained using a probability density function. Results show that the approach used in this work provided physically consistent results with transient effects in the column. Good agreement of the time-averaged gas holdup with experimental data on gas holdup available in the literature was obtained. It was found that the simulation approach used in this work was able to capture the complex transient fluid dynamics in bubbly flows.

1 Introduction

Reactors based on bubbly flows, such as bubble column and airlift reactors, have been widely used in biochemical, petrochemical and metallurgical industries due to their simple construction and operation, high mass and heat transfer rates. In spite of the cited advantages, the multiphase flow behavior exhibited in such reactors is not fully understood due to its complexity. However, the use of adequate numerical models can be very important in understanding flow behavior and in developing scale-up strategies. Due to the emergence of high speed computers and the advancement of numerical techniques, numerical studies of bubbly flows have increased. These numerical techniques are now capable of performing three-dimensional simulations of multiphase flows in complex geometries (Santos, et al., 2007).

Gas-liquid fluidization systems operate by the injection of the gas phase at the bottom of a column filled with liquid. This operation depends on several factors, such as fluid physical properties, column dimensions and inlet gas velocity. There are basically two types of flow regime: the homogeneous and the heterogeneous. The homogeneous flow regime is characterized by low superficial gas velocity, bubbles that are nearly uniform in size and shape and bubble breakup and coalescence phenomena that are considered to be insignificant. On the other hand, in the heterogeneous flow regime, where the superficial gas velocity is high, higher turbulence is observed and bubble breakup and coalescence effects become significant. In this case, models able to capture these phenomena are necessary. Thus, for a good reactor design and operation, it is very important to know the parameters

* Corresponding author. Phone + 55 19 3521-9363. E-mail:mori@feq.unicamp.br

over which the respective regime prevails (Mena, et al., 2005).

In the past decade, computational fluid dynamics (CFD) emerged as an important tool for modeling multiphase flows. Currently, in order to evaluate bubbly flow behavior using CFD it is necessary to combine it with population balance models. These models were implemented as the so-called multiple size group method (MUSIG) in the commercial CFD package ANSYS-CFX (Wang, et al., 2007). The present work shows three-dimensional gas-liquid simulations in a cylindrical bubble reactor with an external loop using the Eulerian-Eulerian approach with the commercial CFD package CFX 11 from ANSYS. The aim of this study was to present the effects of important parameters in CFD simulations, such as bubble size and geometrical modeling of the gas sparger.

2 Mathematical Modeling

The equations used to describe bubbly flows in the present work are the mass and momentum conservation equations, which consider the interaction between the phases using an Eulerian-Eulerian approach, given respectively by

$$\frac{\partial}{\partial t}\left(\varphi_\alpha \rho_\alpha\right) + \nabla \bullet \left(\varphi_\alpha \rho_\alpha \vec{U}_\alpha\right) = 0 \qquad (1)$$

$$\frac{\partial}{\partial t}\left(\varphi_\alpha \rho_\alpha \vec{U}_\alpha\right) + \nabla \bullet \left(\varphi_\alpha (\rho_\alpha \vec{U}_\alpha \vec{U}_\alpha)\right) = \varphi_\alpha \nabla P_\alpha + \nabla \bullet \left(\varphi_\alpha \mu_\alpha \left(\nabla \overrightarrow{U_\alpha} + \left(\nabla \overrightarrow{U_\alpha}\right)^T\right)\right) + M_\alpha + \rho_\alpha \vec{g} \qquad (2)$$

Here, ρ is the density, φ is the volume fraction, $\vec{U}$ is the velocity vector, μ is the viscosity and M_α are the interphase forces, which are the sums of all forces:

$$M_\alpha = \sum_{\beta \neq \alpha} M_{\alpha\beta} = M_{\alpha\beta}^D + M_{\alpha\beta}^L + M_{\alpha\beta}^{LUB} + M_{\alpha\beta}^{VM} + M_{\alpha\beta}^{TD} + \ldots, \qquad (3)$$

where α and β indicate continuous and dispersed phases, $M_{\alpha\beta}^D$ is the drag force, $M_{\alpha\beta}^L$ is the lift force, $M_{\alpha\beta}^{LUB}$ is the wall lubrification force, $M_{\alpha\beta}^{VM}$ is the virtual mass force and $M_{\alpha\beta}^{TD}$ is the turbulence dispersion force. In this study only the drag force, which is the main interphase force affecting the bubble column flow was considered. The mathematical term is given by

$$M_{\alpha\beta}^D = \frac{C_D}{8} A_{gl} \rho_l \left(\overrightarrow{U_l} - \overrightarrow{U_g}\right)\left|\overrightarrow{U_g} - \overrightarrow{U_l}\right| \qquad (4)$$

where C_D is the drag coefficient and $A_{gl} = 6r_g/d_g$ is the interfacial area per unit of volume of an ensemble of particles of diameter d_g and volume fraction r_g. The expression for the drag coefficient varies according to the multiphase system; in this work the drag force model used was the Ishii-Zuber model, which considers the bubble deformation:

$$\begin{aligned} C_D^{(dist)} &= \min\left(C_D(\text{ellipse}), C_D(\text{cap})\right) \\ C_D &= \max\left(C_D(\text{sphere}), C_D(\text{dist})\right) \end{aligned} \qquad (5)$$

$$C_D^{ellipse} = \frac{2}{3} E_O^{1/2} E(r_d) \qquad (6)$$

$$E(r_d) = \frac{\left(1 + 17.67 f(r_d)^{6/7}\right)}{18.67 f(r_d)}, \quad f(r_d) = \frac{\mu_l}{\mu_m}\left(1 - r_d\right)^{1/2}, \quad E_O = \frac{g \Delta\rho d_p^2}{\sigma} \qquad (7)$$

where, E_O is the Eotvos number, $\mu_m = \mu_l(1\text{-}r_g/r_{dm})^{-2.5 r g \mu^*}$ is the bulk viscosity and $\Delta\rho = \rho_l - \rho_g$.

$$C_D^{sphere} = \frac{24}{Re}\left(1 + 0.15 Re_m^{0.687}\right), \quad Re_m = \frac{\rho_l \left|\overrightarrow{U_g} - \overrightarrow{U_l}\right|}{\mu_m} \qquad (8)$$

$$C_D^{cap} = \frac{8}{3}(1-r_d)^2 \qquad (9)$$

The turbulence model used was the standard k-epsilon, which was used only for the continuous phase. This model was chosen because of its satisfactory results in bubble columns simulations (Krishna and Van Baten, 2004). The parameters values of $C_\mu = 0.09$, $C_{\varepsilon 1} = 1.44$, $C_{\varepsilon 2} = 1.92$, $\sigma_k = 1$ and $\sigma_\varepsilon = 1.3$ were used.

The MUSIG model was used for modeling the bubble size distribution. The population balance discretized equation in this model is written as

$$\frac{\partial}{\partial t}(\rho_d r_d f_i) + \frac{\partial}{\partial x^i}(\rho_d r_d U_d^i f_i) = S_i \qquad (10)$$

Defining the size fraction as $f_i = r_i / r_d$, r_i is the volume fraction of the i-group; r_d is the bubbles total volume fraction; x^i is the position component; and S_i is the source term, which contains the rates of bubble birth and death due to the breakup and coalescence:

$$S_i = B_{Bi} - D_{Bi} + B_{Ci} - D_{Ci} \qquad (11)$$

The contributions to birth and death due to the breakup and coalescence processes are given respectively by

$$B_{Bi} = \rho_d r_d \left(\sum_{j>i} g(v_j; v_i) f_j \right); \quad D_{Bi} = \rho_d r_d \left(f_i \sum_{j<i} g(v_i; v_j) \right) \qquad (12)$$

$$B_{Ci} = (\rho_d r_d)^2 \left(\frac{1}{2} \sum_{j \le i} \sum_{k \le 1} Q(v_j; v_k) X_{jki} f_j f_k \frac{m_j + m_k}{m_j m_k} \right); \quad D_{Ci} = (\rho_d r_d)^2 \left(\sum_j Q(v_j; v_k) f_i f_j \frac{1}{m_j} \right) \qquad (13)$$

where $g(v_j; v_i)$ is the specific breakup rate, $Q(v_j; v_k)$ is the specific coalescence rate and X_{jki} is the fraction of mass due to coalescence between the jth and the kth groups which goes to group i.

$$X_{jki} = \begin{cases} \dfrac{(m_j + m_k) - m_{i-1}}{m_i - m_{i-1}} & \text{if} \quad m_{i-1} < m_j + m_k < m_i \\ \dfrac{m_{i+1} - (m_j + m_k)}{m_{i+1} - m_i} & \text{if} \quad m_i < m_j + m_k < m_{i+1} \end{cases} \qquad (14)$$

In this work the Luo and Svendsen breakup model was used to describe the bubble breakup. The breakup rate is written as

$$g(v_i; f_B v_i) = 0.923 F_B (1-r_d) \left(\frac{\varepsilon_C}{d_i^2} \right)^{1/3} \int_{\xi_{min}}^{1} \frac{(1+\xi)^2}{\xi^{11/3}} e^{-\chi} d\xi \qquad (15)$$

$$\text{where } \chi = \frac{12\left[f_{BV}^{2/3} + (1-f_{BV})^{2/3} - 1\right]\sigma}{\beta \rho_c \varepsilon_c^{2/3} d_i^{5/3} \xi^{11/3}} \qquad (16)$$

Here, F_B is a calibration coefficient, β=2 and ξ is the dimensionless size of eddies in the inertial subrange of isotropic turbulence:

$$\xi_{min} = 11.4 \frac{\eta}{d_i}; \qquad \eta = \left(\frac{1}{\varepsilon_c} \nu_c^3 \right)^{1/4} \qquad (17)$$

ε_C is the continuous phase eddy dissipation rate, ν_c is the continuous phase kinematic viscosity and σ is the surfance tension coefficient.

For the coalescence process, the model used was that of Prince and Blanch, which models the coalescence by a collision rate of two bubbles and a collision efficiency relating to the time required for coalescence:

$$Q(v_i;v_j) = (\theta_{ij}^T + \theta_{ij}^B + \theta_{ij}^S)\eta_{ij}; \quad \eta_{ij} = e^{-t_{ij}/\tau_{ij}} \tag{18}$$

$$t_{ij} = \left(\frac{\rho_c r_{ij}^3}{16\sigma}\right)\ln\left(\frac{h_0}{h_f}\right); \qquad \tau_{ij} = \frac{r_{ij}^{2/3}}{\varepsilon_c^{1/3}}; \qquad r_{ij} = \left[\frac{1}{2}\left(\frac{1}{r_i}+\frac{1}{r_j}\right)\right]^{-1} \tag{19}$$

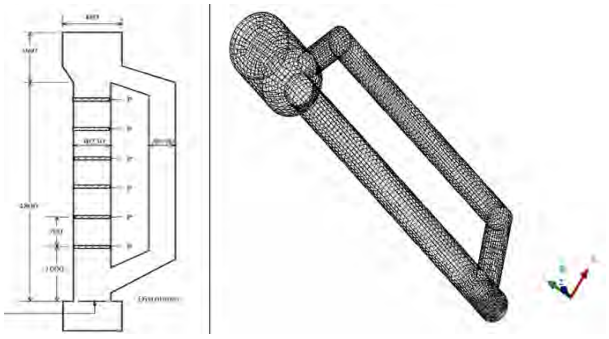
where η_{ij} is the collision efficiency; t_{ij} is the time required for coalescence; τ_{ij} is the actual contact time during the collision; h_0 is the initial film thickness and h_f is the critical film thickness when the bubble rupture occurs, which are chosen as 1.10^{-4} and 1.10^{-8}m respectively; and r_{ij} is the equivalent radius.

The expressions for the collision contributions due to θ_{ij}^T turbulence and θ_{ij}^B buoyancy are shown below; the share contribution θ_{ij}^S is neglected:

$$\theta_{ij}^T = F_{CT}S_{ij}(u_{ti}^2 + u_{tj}^2)^{1/2}; \quad \theta_{ij}^B = F_{CB}S_{ij}\left|U_{rj} - U_{ri}\right| \tag{20}$$

where: $S_{ij} = \frac{\pi}{4}(d_i + d_j)^2$ is the interfacial area, $u_{ti} = \sqrt{2}\varepsilon_c^{1/3}d_i^{1/3}$ is the tubulence velocity, F_{CT} and F_{CB} are calibration factors and $U_{ri} = [(2.14\sigma/\rho_c d_i) + 0.505 g d_i]^{1/2}$.

3 Simulation Parameters



The geometry used in this work consisted in a cylindrical bubble reactor with an external loop, as shown in Figure 1. The mesh used contained approximately 55 thousand control volumes, which were chosen after performing mesh independence tests. The results were compared with the experimental data of Wang, et al., (2004), who present data for a column heigth of 4.6m.

Figure 1: Bubble column reactor and mesh.

Simulations were performed considering air and water at 25ºC as dispersed and continuous phases, respectively. The column was assumed to be initially filled up to a height of 5 m. Non-slip conditions were adopted for both phases and the time step used was 0.01s. Two kinds of inlets were tested: one uniform and the other with a gas distributor with 133 holes, each 1mm in diameter; the former referred to a sintered plate entrance and the latter to a perforated plate entrance in the experimental system. Gas superficial velocities of 0.08, 0.016 and 0.032 m/s were simulated for both geometries. The tests referring to the breakup and coalescence phenomena were achieved only with the uniform inlet and the air superficial velocity of 0.032 m/s. For the test with the population balance models, air was assumed to be the polydispersed phase, with six bubble size groups varying according to a probability density function (Wang, et al., 2004). The bubble diameter is shownin Table 1.

Table 1: Bubble groups used in population balance simulations.

Group	1	2	3	4	5	6
Diameter (mm)	0.5	1.5	2.4	3.3	4.2	7.0

For the initial condition, bubble group 2 was considered as 1 because of the correlation proposed by Chen, et al., (2005), in which the bubble diameter at the inlet is a function of the orifice diameter given by $d_b = 2.9(\sigma.d_o/\rho_l g)^{1/3}$, d_b is the bubble diameter, σ is the surface tension coefficient, ρ_l is the liquid density and d_o is the orifice diameter, considered to be 30μm, which is the average pore size of the sintered plate used in the work of Wang, et al., (2004). All simulations were performed in a commercial CFD package, CFX 11 from ANSYS; in all tests real-time simulation was approximately 200 seconds.

4 Results and Discussion

The gas holdup results from the two different inlets are presented in Figure 2.

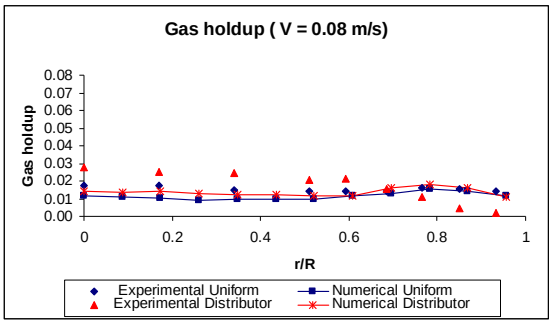


Figure 2a: Gas holdup at 0.08 m/s

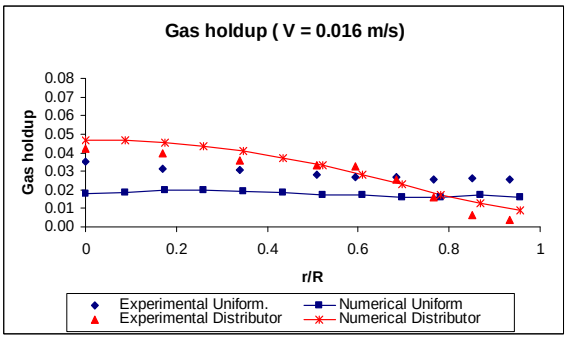

Figure 2b: Gas holdup at 0.016 m/s.

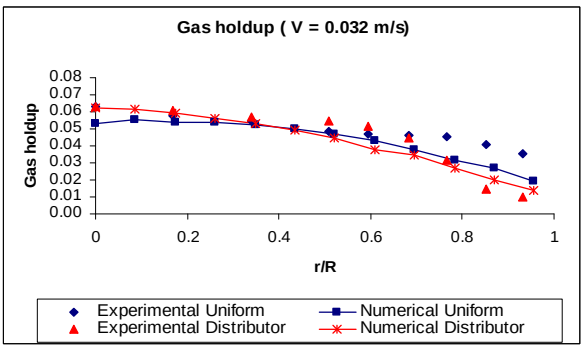

Figure 2c: Gas holdup at 0.032 m/s

For the gas superficial velocity of 0.08 m/s (Figure 2a), it is observed that the simulation results for the uniform gas entrance were in good agreement with experimental data; however, for the perforated plate case, simulations show an increase in the gas holdup near the wall, which is not corroborated by the experimental data. For the gas superficial velocity of 0.016 m/s (Figure 2b), different behaviors are observed for the two inlets; for the uniform inlet a uniform radial profile is noted, whereas for the perforated plate lower values of gas holdup near the wall are observed. For both gas entrances, simulations were in qualitative agreement with experimental data. For the case in which the gas superficial velocity was 0.032 m/s (Figure 2c) is observed a decrease in gas holdup near the wall for both geometries. In this case, good agreement was obtained for the perforated plate distributor.

The simulation data referring to the influence of the breakup and coalescence models are shown in Figure 3 (a and b) for the gas superficial velocity of 0.032 m/s.

It is noted that the breakup and coalescence models underpredict the average gas holdup in the region close to center of the column, whereas the gas holdup prediction is similar to that without the population balance models in the region close to the column wall. Although that homogeneous flow regime would be expected for an air/water system at the gas superficial velocity of 0.032 m/s, effects on the flow field due to the population balance modeling can be observed. In Figure 3b the gas holdup profile for both kinds of regime is shown. A bigger concentration of air at the external loop is observed when the population balance was used. Further studies are currently being performed in the heterogeneous regime.

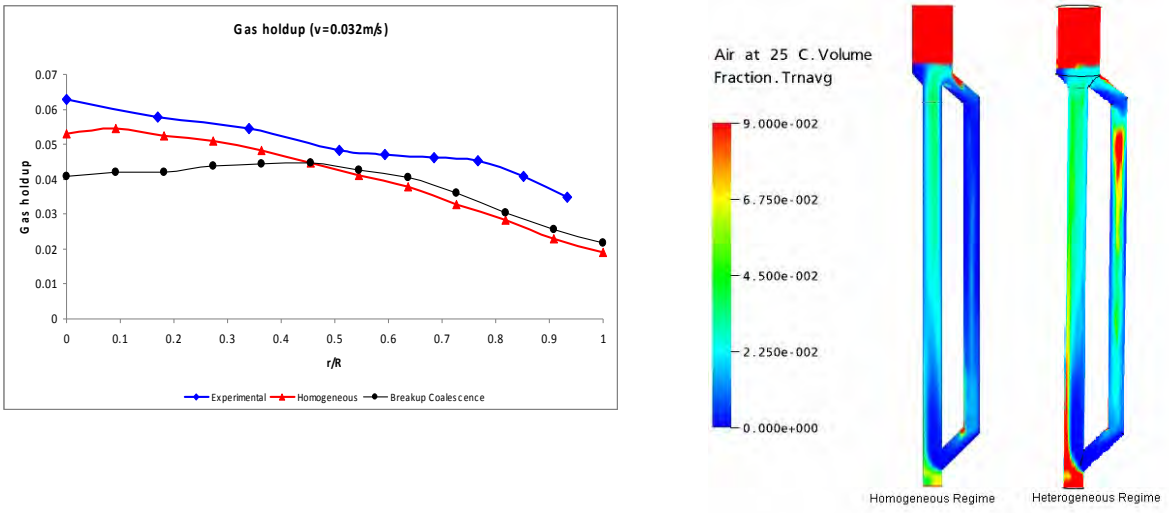

Figure 3: Comparison of heterogeneous and homogeneous regimes: (a) Gas holdup at the 4.6m height**;** (b) Gas holdup profile

5 Conclusions

This article presented gas-liquid flow CFD simulations in a cylindrical bubble reactor with an external loop, where the effects of differents kinds of inlets and the influence of the implementation breakup and coalescence models were evaluated. The results corresponding to the different kinds of inlet show good agreement with the experimental data. The inlet geometrical modeling showed that this consideration is important in simulations considering the perforated plate geometry presented. In evaluating the breakup and coalescence models the results showed a decrease in the gas holdup at the center of the column, suggesting the influence of the population balance implementation.

Keywords: airlift reactor, scale-up, Newtonian fluid, volumetric oxygen transfer coefficient.
Topic: Advancing the chemical engineering fundamentals

Abstract

Oxygen transfer was evaluated in three internal-loop airlift reactors (ALR) of different working volumes (2, 5 and 10 dm^3) with similar geometric configuration utilizing eight Newtonian fluids. The effects of superficial gas velocity (U_{GR}) and liquid viscosity (ν_L) had contrary effects on k_La, however they presented the same orders of magnitude, showing that the viscosity effect on oxygen mass transfer cannot be neglected. A correlation for k_La based on dimensional analysis, taking into account the effects of geometric parameters, physical properties of the fluid and operational conditions proposed and a very good fitting between calculated and experimental data were obtained. The influence of the internal diameter of the reactor on k_La was analyzed as positive, showing that in larger-scale reactors an appropriate oxygen transfer can be reached under smaller aeration conditions.

1 Introduction

Internal-loop airlift reactors are a special class of pneumatic reactors. Using this type of reactor is attractive for chemical and biological reactions due to their inexpensive and simple construction without moving mechanisms and low energy costs, when compared with stirred tank reactors (Blažej *et al.,* 2004a).

One of the most significant parameters in the design of such airlift reactors is the volumetric mass transfer coefficient (k_La) commonly used to evaluate the capacity of oxygen transfer in bioreactors. This quantity depends on the system geometry and fluid properties which are related to several other parameters (Ruen-ngam *et al.*, 2008).

The application of airlift reactors in industry is still limited due to several reasons. The most important one is the lack of methods able to measure primary hydrodynamic parameters (e.g. gas hold-up, gas-liquid mass transfer, linear circulation velocity) and the absence of appropriate hydrodynamic models that take into account the reactor scale (Blažej *et al.*, 2004b).

Although scale-up studies related to airlift reactors are important for industrial applications, few studies have been found in literature focusing on this matter, in comparison with scale-up of conventional stirred and aerated tank bioreactors. For an appropriate study on the performance and scale-up of bioreactors, obtaining correlations to foresee hydrodynamic and heat and mass transfer parameters are important. Correlations based on dimensional analysis offer advantages given that the correlations obtained for a known system can be used to estimate more precisely the parameters in other similar systems with different dimensions. Meanwhile, it is more secure for scale-up use, to obtain dimensionless correlations for a wide range of fluids, experimental conditions and bench and pilot scales of bioreactors. The literature presents several works related to obtaining dimensional correlations for bubble column bioreactors. One of the first works that employed dimensional analysis to investigate the behavior of pneumatic bioreactors was by Hughmark (1967), which used Yoshida and Akita's (1965) experimental data to obtain a dimensional correlation that describes the oxygen transfer in a bubble column bioreactor. Some years later, Akita

and Yoshida (1973) proposed a classical work to investigate the effects of the reactor diameter, liquid height, superficial gas velocity (U_G) and liquid density (ρ_L), liquid kinematic viscosity (ν_L) and liquid surface tension (σ_L) on global gas hold-up (ε_G) and on volumetric oxygen transfer coefficient (k_La) in different scales of bubble column bioreactor, ranging from 18 to 63 dm^3. The empiric correlations were proposed based on dimensional analysis for Newtonian fluids**.** With respect to airlift bioreactors, few works related with obtaining correlations for k_La based on dimensional analysis are found in the literature. Thus, the aim of the present work was to investigate the oxygen transfer coefficient three bench-scale internal-loop airlift bioreactors (2, 5 and 10 dm^3) utilizing different Newtonian fluids.

2. Materials and Methods

Fluids: Distilled water and glycerol solutions were used as Newtonian fluids. Liquid dynamic viscosity (μ_L) of the distilled water and glycerol solutions were determined from rheograms using a digital concentric-cylinder rheometer (Brookfield Engineering Laboratories) model LV-DVIII+, at 28ºC. Table 1 shows the physical properties of the fluids used in this study.

Table 1. Physical properties of the Newtonian fluids

Fluid	Concentration (% $v.v^{-1}$)	$\mu \cdot 10^3$ (Pa.s)	ρ_L ($kg.m^{-3}$)	$D_L \cdot 10^9$ ($m^2.s^{-1}$)	σ_L ($kg.s^{-2}$)
GS12	58.0	12.54	1164.7	0.39	0.068
GS10	55.0	10.77	1158.1	0.42	0.069
GS8	50.0	8.90	1149.5	0.48	0.069
GS6	46.1	6.84	1136.9	0.57	0.069
GS5	40.3	5.33	1124.0	0.63	0.070
GS3	32.3	3.76	1104.5	0.81	0.070
GS2	26.1	2.75	1085.3	1.10	0.071
water	-	0.84	996.0	2.84	0.072

Equipments: concentric-tube airlift reactors (ALR) with 2, 5 and 10 dm^3 total working volume were used in this study. The external tube was made of glass, but the bottom and top plates, the draft tube, the gas sparger, and the condenser were made of stainless steel. The temperature of the reactor was controlled by the circulation of water through the hollow draft tube. A scheme of the concentric-tube airlift bioreactor is shown in Figure 1. Geometrical characteristics and relationships between distances are shown in Table 2 for the three different scales of the airlift bioreactor. The type of sparger was designed to obtain a system with efficient heat and mass transfer. The holes of the cross-piece type sparger are 0.5 mm diameter and are spaced 5 mm along the length of the sparger rods (Badino *et al.*, 2006).

Volumetric oxygen transfer coefficient (k_La): the volumetric oxygen transfer coefficient (k_La) was determined by the dynamic pressure-step method (Blažej et al. 2004c). In this experimental method, the pressure in the vessel is changed abruptly by approximately 15 kPa, and an increase in the dissolved oxygen concentration (C_e) in the bubble dispersion occurs regardless of the gas flow pattern. Equation 1 was fitted to the experimental data (C_e as a function of time) and k_La values were estimated through the procedure that uses the least squares non-linear regression.

$$C_e = C_{e0} \cdot e^{-k_e \cdot (t-t_0)} + C_{es} \cdot (1 - e^{-k_e \cdot (t-t_0)}) + \frac{k_e \cdot (C_{es} - C_{e0})}{k_e - k_L a} \cdot (e^{-k_e \cdot (t-t_0)} - e^{-k_L a \cdot (t-t_0)}) \quad (1)$$

In Equation 1, C_{e0} is the signal of the electrode in the initial condition when $t = t_0$; C_{es} is the signal of the electrode or the dissolved oxygen concentration in the liquid phase in the saturation with air, and k_e is the time constant of the oxygen probe calculated from the inverse of the response time (τ_e). The response to a unit step function, in triplicate, allowed the calculation of k_e = 0.125 s^{-1} assuming the "first order response". The dissolved oxygen concentration was measured with a sterilizable amperometric electrode (Mettler-Toledo,

model InPro 6800) bearing a Teflon membrane (Mettler-Toledo, model InPro T96). Values of k_La were obtained in duplicate for Newtonian and non-Newtonian systems with the superficial gas velocity (U_{GR}) for the three scales of the airlift bioreactor.

Global gas hold-up (ε_G): The gas holdup was determined by measuring the increase in height of the dispersion upon aeration as follows (Chisti, 1989):

$$\varepsilon = \frac{h_D - h_L}{h_D} \tag{2}$$

where h_D is the height of the gas-liquid dispersion and h_L is the height of gas free liquid.

3. Results and Discussion

When only one fluid is used in the oxygen mass transfer study, simpler correlations are found in the literature. Shah *et al.* (1982) proposed the following correlation, in which k_La is related to only the superficial gas velocity (U_G) for water aerated in a bubble column reactor.

$$k_La = 0.47 \cdot U_G^{0.82} \tag{3}$$

The experimental dependency of k_La on U_{GR} is plotted in Figure 2 for the three scales of airlift bioreactors utilized in the present work. A positive influence of the gas flow rate on k_La is evident from the almost linear dependency of k_La on U_{GR}. Values of k_La were practically equal for the three scales up to U_{GR} of 0.04 $m.s^{-1}$. For higher values of U_{GR}, the values of k_La for the scale of 2 dm^3 were greater than for the k_La values of 10 dm^3, which were greater than the 5 dm^3. The correlations of k_La as function of U_{GR} are presented as follows:

2 dm^3 - $k_La = 0.760 \cdot U_{GR}^{0.954}$ R^2=0.991 (4)

5 dm^3 - $k_La = 0.440 \cdot U_{GR}^{0.864}$ R^2=0.994 (5)

10 dm^3 - $k_L a = 0.550 \cdot U_{GR}^{0.898}$ R^2=0.995 (6)

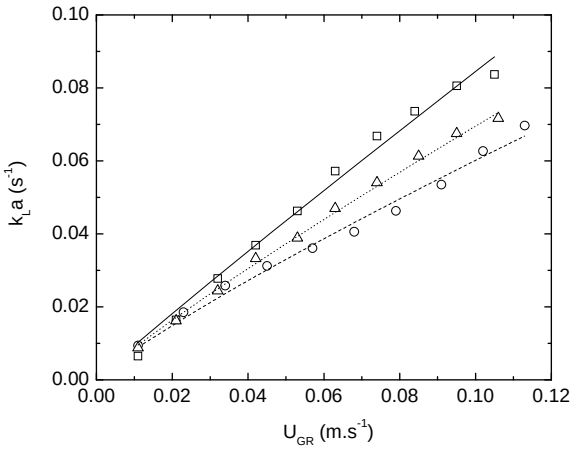

Figure 2. Volumetric oxygen transfer coefficient ($k_L a$) as a function of the superficial air velocity in the riser (U_{GR}) for water in the 3 scales of airlift bioreactors: (□) 2 dm^3, (○) 5 dm^3, (Δ) 10 dm^3, (—) correlation 2 dm^3, (-----) correlation 5 dm^3, (·····) correlation 10 dm^3.

In spite of the difference between the reactors, the values estimated by the correlations of the present work are close to the values estimated by the correlation proposed by Shah et al. (1982). The close values of $k_L a$ obtained in the reactors of 2, 5 and 10 dm^3 under equal aeration conditions are due to the geometric similarity of the scales used in the present work. This is a good indicative for the scale-up of this bioreactor model, when the volumetric oxygen transfer coefficient ($k_L a$) is the criterion of the chosen scale-up.

According to Moo-Young and Kawase (1987), the $k_L a$ depends on the superficial gas velocity (U_{GR}), the geometry of the reactor and the physical properties of the fluid. Liquid viscosity has a significant effect on the gas-liquid oxygen transfer. Figure 3 illustrates the effect of the dynamic viscosity on the $k_L a$ in the scale of 2 dm^3. At constant U_{GR} of 0.053 m.s^{-1}, the $k_L a$ decreased from 0.046 s^{-1} (water: μ=0.84 mPa.s) to 0.015 s^{-1} (GS2: μ=2.75 mPa.s).

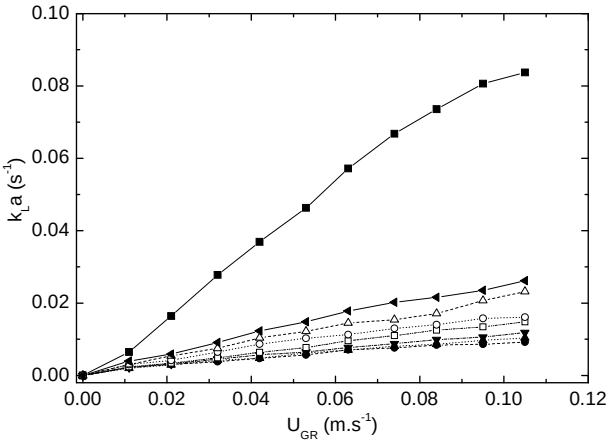

Figure 3. Volumetric oxygen transfer coefficient ($k_L a$) as a function of the superficial air velocity in the riser (U_{GR}) in a scale of 2 dm^3 for Newtonian fluids: (■) water, (●) GS12, (▲) GS10, (▼) GS8, (□) GS6, (○) GS5, (Δ) GS3, (◄) GS2.

Shariati *et al.* (2007) investigated the oxygen transfer in an ALR with internal loop using Newtonian petroleum fluids (diesel and microemulsions of water and diesel). The authors observed the strong influence of the viscosity on k_La and proposed the following correlation to show the effects of U_{GR} and kinematic viscosity ($\nu_L=\mu_L/\rho$) on k_La:

$$k_La = 1.552 \cdot 10^{-4} \cdot U_{GR}^{0.935} \cdot \nu_L^{-0.683} \quad (7)$$

In the present work equation 8 was fitted to the experimental data of the three scales of airlift bioreactors. It can be observed that the exponents of U_{GR} and ν_L were very close.

$$k_La = 10^{-5} \cdot U_{GR}^{0.847} \cdot \nu_L^{-0.746} \qquad R^2=0.98 \quad (8)$$

According to equation 8, k_La increases with the increase of the U_{GR} and decreases with the increase of the viscosity (ν_L). Although U_{GR} and ν_L have contrary effects on k_La, its effects presented the same orders of magnitude. The results show that the effect of the viscosity on oxygen mass transfer cannot be neglected.

The effects of the internal tube diameter (D_{12}), superficial gas velocity (U_{GR}), liquid density (ρ_L), liquid viscosity (μ_L), liquid surface tension (σ_L) and oxygen diffusivity in the water (D_L) on the volumetric oxygen transfer coefficient (k_La) were evaluated in the three scales of the airlift reactors (2, 5 and 10 dm^3) utilizing eight Newtonian fluids. A correlation based on those originally proposed by Akita and Yoshida (1973) for different scales of bubble column bioreactor ranging from 18 to 63 dm^3 was fitted to the experimental data. It is based on dimensional analysis related to modified Sherwood number (Sh) to Schmidt (Sc), Galileo (Ga) and Bond (Bo) numbers, to global gas hold-up (ε_G) and additionally to Froude number (Fr):

$$Sh = 0.00041 \cdot Fr^{0,31} \cdot Sc^{0,81} \cdot Ga^{0,68} \cdot Bo^{0,197} \cdot \varepsilon^{0,554} \qquad R^2=0.98 \quad (9)$$

$$\left(\frac{k_La \cdot D_{l2}^2}{D_L}\right) = 0.00041 \cdot \left(\frac{U_{GS}}{\sqrt{g \cdot D_{l2}}}\right)^{0.310} \cdot \left(\frac{\mu_L}{\rho_L \cdot D_L}\right)^{0.810} \cdot \left(\frac{g \cdot D_{l2}^2 \cdot \rho_L^2}{\mu_L^2}\right)^{0.680} \cdot \left(\frac{g.D_{l2}^2.\rho_L}{\sigma}\right)^{0.197} \cdot \varepsilon_G^{0.554} \quad (10)$$

230 experimental data were utilized in the fitting. The ranges of dimensionless numbers were the following: 4921<Sh<256768; 0.011<Fr<0.143, 297.0<Sc<27544.5, 410.1<Bo<1509.7, $1.4 \cdot 10^7$<Ga<$1.8 \cdot 10^{10}$ and 0.009<ε_G<0.17.

A very good fitting represented by the high value of R^2 can be noted. Figure 4 illustrates the quality of the fitting, where the differences between calculated and experimental data were lower than 15%.

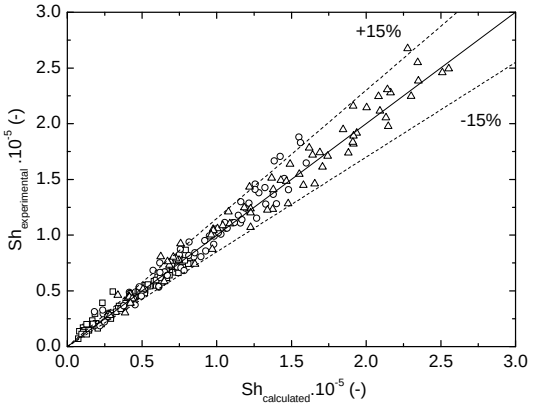

Figure 4. Comparison between calculated and experimental data of the Sherwood number for Newtonian fluids in three scales of internal loop ALR (□) 2 dm^3, (○) 5 dm^3, (Δ) 10 dm^3.

With the rearrangement of equation 10, the dependence of the k_La in relation to internal diameter of the reactor (D_{l2}) is given by:

$$k_La \propto D_{l2}^{0.17} \quad (11)$$

Akita and Yoshida (1973) also observed similar behavior in bubble column reactors. The exponent value of D_{I2} equal to 0.17 found in the present work was the same found by Akita and Yoshida (1973) for reactors with D_I in the 0.15 to 0.60 m range. According to equation 11, the influence of the internal diameter of the reactor on k_La is important for the scale-up of this bioreactor model, because the larger the reactor, the larger the k_La. Therefore, in larger-scale reactors an appropriate oxygen transfer can be reached under smaller aeration conditions.

4. Conclusions

The effects of geometric parameters (D_{12}), physical properties of the fluid (ρ_L, μ_L, σ_L and D_L) and operational conditions (U_{GR}) on the volumetric oxygen transfer coefficient (k_La) were evaluated in the three scales of airlift reactors (2, 5 and 10 dm^3) utilizing eight Newtonian fluids. The effects of U_{GR} and μ_L had contrary effects on k_La, however they presented the same orders of magnitude, showing that the effect of the viscosity on oxygen mass transfer cannot be neglected. A correlation for k_La based on dimensional analysis was proposed and a very good fit between calculated and experimental data was obtained. The influence of the internal diameter of the reactor on k_La was analyzed as positive. This observation is important for scale-up strategies, because in larger-scale reactors an appropriate oxygen transfer can be reached under smaller aeration conditions.

Keywords: Permselective membrane, Mathematical modeling, Ethylbenzene dehydrogenation.
Topic: Advancing the chemical and biological engineering fundamentals.

Abstract

One of the most important raw materials of the industry of thermoplastic is the styrene. Its demand grows considerably due its recyclable nature. The main chemical route for styrene production is the ethylbenzene dehydrogenization. The kinetic model presenting six reactions with only one reversible proposed by Shell and Crowe (1969) was adopted here. The presence of produced hydrogen affects the styrene productivity provoking the reversibility of the main reaction and undesirable secondary reactions. Therefore, the use of permselective composed membranes for removal of hydrogen is suggested, increasing the process productivity.

In this context, a mathematical model was developed taking in account the different mechanisms of transport that take advantage in the fixed bed and in the various layers of the membrane proposal. The system presented in this paper involves a catalytic tubular reactor of fixed bed wrapped with permselective composed membrane. The membrane is composed by three layers: A macroporous layer used as a support; a microporous intermediate layer to increasing the separation factor; and a metal dense layer which promote the selectivity at hydrogen.

The system simulation was carried out with application transmembrane pressure differential to promote the removal of permeated hydrogen. The computational program was implemented to determine the productivity of the styrene. The effect of various parameters on this system performance was analyzed.

The process simulation with all conditions determined for its better industrial development presented an increase of 40.98% in the styrene productivity compared with the process developed with conventional fixed bed reactor.

1 Introduction

In reactors of catalytic fixed bed, commonly used in industrial processes, the application of connected membranes provides to these multi-functional characteristics.

The membranes allow the separation of the key component, what reduces the tax of the reversible and secondary reactions (Armor, 1989). Its more important characteristics are the selectivity and permeability, which depend on the configuration of the membrane layers, of the pores structure, the process temperature, the molecular weight of the components and the different mechanisms of transport through membrane.

According to Hermann et al. (1997), there is in the literature, three different types of membranes proposals: dense metal membranes (e.g. Pd or Pd-Alloys), porous membranes

* Paulo Jardel Araujo. + 55-3521-3978. E-mail: jardelengenharia@gmail.com

(e.g. alumina, zirconia), and composites membranes (e.g. metal/stainless steel, metal/alumina).

The composite membranes are most applied, because they combine the advantages of other types of membrane: the high permselectivity of the dense membranes and the high permeability of the porous support. The stainless steel support is commonly used in these membranes, because its structural properties are clearly superior to other types of porous supports and the great domain of its manufacture technology for setting of the palladium (Mardilovich et al., 1998).

An important application for such reactor configuration is the catalytic dehydrogenization of the ethylbenzene. This chemical route represents 90% of the total styrene production. This reaction is reversible and endothermic, and the maximum conversion of the ethylbenzene in real process conditions, is limited about 45% due to the thermodynamic equilibrium (Wu and Liu, 1992).

1. C_6H_5-C_2H_5 (EB) ⇆ C_6H_5-C_2H_3 (ST) + H_2
2. C_6H_5-C_2H_5 (EB) → C_6H_6 (BEN) + C_2H_4
3. C_6H_5-C_2H_5 (EB) + H_2 → C_6H_5-CH_3 (TOL) + CH_4 (MET)
4. ½C_2H_4 (ET) + H_2O → CO + $2H_2$
5. CH_4 (MET) + H_2O → CO + $3H_2$
6. CO + H_2O → CO_2 + H_2

The industrial process is lead to a temperature of 550-650ºC, normally atmospheric pressure or subatmospheric, and in the presence of Fe_2O_3-catalysts doped with other metallic oxides. To supply the necessary energy, the reaction is carried out in great excess of steam.

The presented equations, show the reversibility of the reaction of styrene production, and the secondary reactions that occur in the hydrogen presence. Therefore, this paper propose the removal of hydrogen providing increase of productivity of styrene. It will be also analyzed some parameters that control the performance of the reactor fixed bed wrapped in membrane.

2 Mathematical Modeling

A computational program in Fortran 95 was developed for the simulation. A pseudo-homogeneous model with plug flow was assumed to describe the catalyst bed. The membrane configuration proposal is composed of a macroporous stainless steel support, a fine microporous layer, and a Pd-film.

The heat transfer resistance through the membrane is neglected. The balances of mass, energy and momentum are described to follow:

Mass balance.

$$\frac{d\dot{n}_i}{dz} = A\rho_b \sum_{j=1}^{n} v_{ij} r_j - 2\pi R J_i \Big|_R \quad (1)$$

Energy balance.

$$\frac{dT}{dz} = \left[\sum_j -\left(\Delta H_{R,j}\right) r_j \right] \frac{A_R \rho_b}{n_{tot}\left(c_p\right)_m} \quad (2)$$

Momentum balance.

The pressure drop in fixed bed is described by Ergun equation:

$$\frac{dp}{dz} = -150 \frac{\eta u}{d_{cat}^2} \frac{(1-\varepsilon_B)^2}{\varepsilon_B^3} - 1.75 \frac{\rho u^2}{d_{cat}} \frac{(1-\varepsilon_B)}{\varepsilon_B^3} \quad (3)$$

Stagnant gas film

To describe the multicomponent diffusion in a stagnant gas film, it was applied the Stefan-Maxwell equation (Deckman et al. 1995):

* Paulo Jardel Araujo. + 55-3521-3978. E-mail: jardelengenharia@gmail.com

$$\frac{dy_i}{dr} = \frac{RT}{P} \sum_{j=1}^{n} \frac{J_j y_i - y_j J_i}{D_{ij}} \qquad (4)$$

Temperature and pressure are supposed to be constants in this stagnant gas film.

Macroporous support

In this layer, the mechanism of diffusion include effective multicomponent diffusion, effective Knudsen diffusion and viscous flow. Therefore, it was used the *Dusty Gas* model (Sloot et al., 1992):

$$\frac{dy_i}{dr} = \frac{RT}{P}\left(\sum_{j=1}^{n} \frac{J_j y_i - y_j J_i}{(\varepsilon/\tau) D_{ij}} - \frac{J_i}{D_{iK}^{e}} \right) \qquad (5)$$

Microporous layer

The flux through this layer is controlled by Knudsen diffusion. Hence, the flux is given by:

$$J_i = -D_{iK}^{e} \frac{dc_i}{dr} \quad (6)$$

Pd-Film

According to the Sievert's law (Abdalla and Elnashaie, 1994):

$$J_{H_2} = \frac{D_{H_2} C_0}{P_0^{1/2} \ln \frac{r_{m2}}{r_{m1}}} \frac{1}{r} \left[(P)_{m1}^{1/2} - (P)_{m2}^{1/2} \right] \qquad (7)$$

with:

$$D_{H_2} = 2.3x10^{-7} e^{\left(-\frac{21700}{RT}\right)} \qquad (8) \qquad C_0 = 3.03x10^{2} T^{-1.0859} \qquad (9)$$

As the Pd-Film is permeable only for hydrogen, the minimum condition is assumed for the other species in the membrane wall.

The equations (1) at (3) are resolved by Runge-Kutta 4th order method.

Considering the membrane is inert and the process occurs in steady state, the ODE system (Equations 4-7) is resolved with a generalized Newton-Raphson method.

3 Simulations and Results

The styrene productividy is the main parameter of analysis of the reactor performance, therefore reflects the amount of styrene produced from initial ethylbenzene. This parameter was determined by equation 10 at follow:

$$PDT_{ST}(\%) = \frac{ST_f}{EB_i}.100 \qquad (10)$$

i – Inlet amount in the reactor.
f – Outlet amount in the reactor.

The driven force for removal of hydrogen from catalyst bed was established by application of a pressure differential between retentate and permeate.

The simulations are carried out with the range of parameter described in Table 1.

TABLE 1 – Range of operational parameters, configuration of reactor and membrane.

Operational conditions		*Reactor configuration*	
Inlet temperature	873.15 – 953.15K	Lenght	0.39 – 1.2m

* Paulo Jardel Araujo. + 55-3521-3978. E-mail: jardelengenharia@gmail.com

Inlet pressure	100.0 – 250.0kPa	D_{in} (fixed bed)	¾" – 2"
WHSV	1 – 1.6h^{-1}	*Membrane configuration*	
S/O ratio	6 – 12	Thickness (Macro)	1 – 3mm
Catalyst proprieties		Thickness (Micro)	10 – 30µm
Void fraction	0.5	Thickness (Pd)	1 – 20µm
Density	2150kg/m^3	*Membrane proprieties*	
Diameter	3mm	Void Fraction (Macro e Micro)	0.5
		Tortuosity (Macro e Micro)	3
		Pore diameter (Macro)	0.2µm

The range permitted in this analysis it was fixed as given of industrial operation (Kumar et al., 2006) and taking care of the process restrictions.

To conduct a comparative analysis, the system was simulated with the proposed model for a conventional fixed bed reactor, without membrane, in standard conditions of industrial process (Hermann et al, 1997), resulting in a styrene productivity of 52.76%.

- Inlet temperature and steam to oil ratio (S/O).

The inlet temperature was analyzed in a range that took care of energy necessity of the process, as well as to avoid the degradation of the equipment.

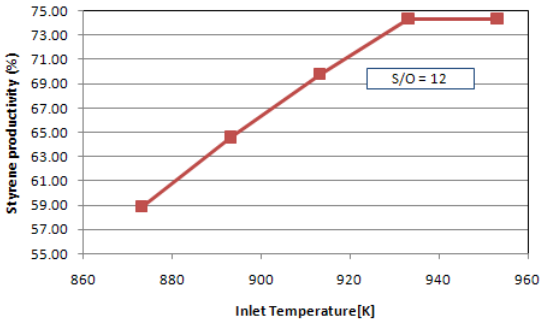

FIGURE 1 – Influence of inlet temperature in the styrene productivity.

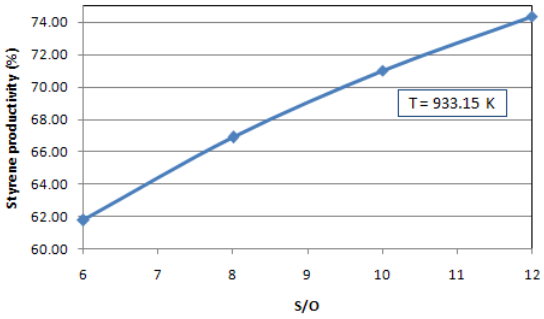

FIGURE 2 – Influence of S/O ratio in the styrene productivity.

It was observed for Figure 1 that, as waited, the styrene productivity increases with the increase of inlet temperature, however, from 933.15K was not observed any alteration in the productivity.

The common range used in literature of 6-12 was admitted for S/O ratio analysis. The S/O ratio must be enough high to supply, together with inlet temperature, the energetic necessity of the endothermic reaction. According to for Figure 2, the S/O equal to 12 reached satisfactory value of styrene productivity, hence this value is recommended for development of the process.

- Fixed bed sizing.

Industrially, the cost related to the sizing of the equipment is decisive for promoting the project. Therefore, the lesser size possible for the reactor is primordially searched.

It was analyzed the sizing of the fixed bed to a constant inlet feeding of the reactants, that is, without depending of a already established WHSV.
The analysis was conducted with stainless steel tubing of constant internal diameter of 0.0254m (1in). The variation of volume was obtained through the change in the reactor length. Considering a fixed mass flow of 9.08x10^{-5}kg/s, determined according data in Table 1, it was realized the simulation with reactor length in a range of 0.39 at 1.2m, corresponding at volumes between 197.62 and 608.05cm^3. The Figure 3 presents the results.

* Paulo Jardel Araujo. + 55-3521-3978. E-mail: jardelengenharia@gmail.com

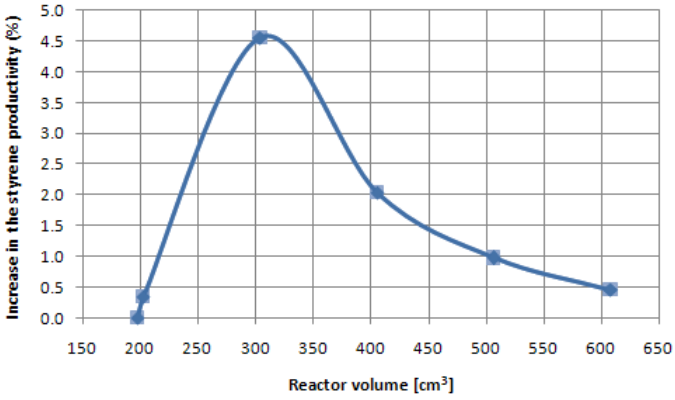

FIGURE 3 – Influence of reactor length in the styrene productivity.

According with Figure 3, can be determined that the recommended reactor volume that take care of the process restrictions and reduces cost of implantation of the system and is of 304.02 cm^3, which represents in a internal diameter of 1in, a reactor length of 0.6m.

- Membrane sizing.

The configuration of the membrane proposal is treated by accounting for up to three membrane layers: a macroporous support, a microporous providing molecular sieving and a Pd-film ensuring selectivity at the membrane.

In the simulation it was obtained a better value of styrene productivity (74.38%) in lesser thickness of macroporous and microporous layer, as well as in Pd-film. Presenting thickness of $1x10^{-3}$m for macroporous layer, 10µm for microporous layer and 1µm for Pd-film. Such result reflects that a lesser way to permeates, provides a bigger hydrogen flux through of membrane. This behavior is ideal for applications of composite palladium membranes in industrial processes, because to the high cost of acquisition of this material. And ahead the manufacture techniques available currently, such configuration is perfectly possible to achieve (Ma et al., 2004).

4 Conclusions

Analysing the styrene productivity, the carried simulations allowed the determination of the operational condition of the process, of the sizing of reactor and of membrane that was provided better system performance.

With the process simulation using the recommended values for each analyzed parameter, the styrene productivity was gotten 40.98% superior to the styrene productivity in the process with conventional fixed bed. This increase proves how is important the determination of favorable conditions for better development of the process.

Effect of kinds of gas on gas holdup in bubble columns

Fukuji Yamashita* and Megumi Nakajima
Dept. of Applied Chemistry, Kanagawa Institute of Technology, Atsugi, 243-0292, Japan;

Keywords: Gas holdup, Bubble column, Gas, Gas density, Bubble coalescence
Topic: Advancing the chemical engineering fundamentals-Multiphase flow

Abstract

The effect of kinds of gas on gas holdup in bubble columns was experimentally studied. Average gas holdup E_G for H_2, He, Ar, O_2 and CO_2 gas – tap water system was visually measured in bubble columns. E_G increased with increasing gas density and was correlated. The gas holdup data of Ozturk et al. (1987) for H_2, He, N_2, Air, CO_2 gas -xylene system were correlated by nearly the same equations as those in this work. The frequencies and volumes of bubbles which generated from horizontal single nozzles (7 and 10 mm I.D.) into tap water did not depend on kinds of gas. The reason why E_G increases with increasing gas density may be because the rate of coalescence of bubbles into larger ones is much larger for the gas of lower gas density.

1 Introduction

Bubble columns are widely used as bioreactors and gas-liquid reactors. Gas holdup E_G is a very important parameter for design and scale-up of bubble columns. Therefore, there have been many studies about gas holdup in bubble columns. It has been reported that gas holdup depends on many factors such as gas and liquid velocity, physical property of gas and liquid, type and arrangement of gas spargers, gas inlet height and inclination angle of bubble columns. However, the effect of kinds of gas on E_G is not yet clear. In this work, the effect of kinds of gas on E_G was experimentally studied.

1.1 Previous studies

Akita and Yoshida (1973) have reported that E_G does not depend on kinds of gas in a 15cm square bubble column with 4.5 mm orifice, although the gas holdup with He appears slightly lower at higher gas velocities. They used Air, O_2, He, CO_2 / water system. Hikita et al. (1980) studied the effect of gas and liquid properties on gas holdup in the bubble column of 10 cm inner diameter and 1.5 m height. They have reported that E_G depends on $\rho_G^{0.062}\rho_L^{0.069}\mu_G^{0.107}\mu_L^{-0.053}$ and presented the following correlation:

$$E_G = 0.672\,(U_G\mu_L/\gamma)^{0.578}[\mu_L^4 g/(\rho_L\gamma^3)]^{-0.131}\,(\rho_G/\rho_L)^{0.062}(\mu_G/\mu_L)^{0.107} \quad (1)$$

Koetsier and Van Swaaij (1976) studied the effect of kinds on E_G in a bubble column with porous gas sparger. In pure water system, E_G for N_2 gas is much larger than that for He gas.

*Corresponding author. Tel +81- 046-291-3083. E-mail:yamasita@chem.kanagawa - it.ac.jp

However, in 0.6 mol/dm^3 Nacl aqueous solution, E_G for N_2 gas is nearly equal to that for He gas. They concluded that bubbles for He gas coalesced into larger ones much easier than those for N_2 gas and rise faster in the pure water system and that E_G for He gas is much lower than that for N_2 gas.

Ozturk et al. (1987) have also studied the effect of kinds of gas on E_G in the 9.5 cm I.D. and 85 cm tall bubble column with organic liquids and reported that E_G depends on kinds of gas. They have concluded that the gas-specific effects are probably related to the bubble formation at the sparger rather than the hydrodynamics in the bulk of the dispersion. Therefore, E_G depends on kinds of gas in bubble columns with small height (H_T < 1 m), however, E_G does not depend on kinds of gas in tall bubble columns (H_T > 2 m). H_T means a bubbling height.

2. Experimental

Two bubble columns were used. They were made of transparent acrylic resin. They are a rectangular and a circular bubble columns. The rectangular bubble column whose cross section is 5cm x 10cm is 60 cm high with a perforated plate as a gas sparger. The diameter, number and pitch of holes were 1 mm, 18 and 10 mm, in order. The circular bubble column has 8 cm inner diameter and 165 cm height with a 6mm I.D. single nozzle as a gas sparger. H_2, He, Ar, O_2 and CO_2 gas from cylinders were used as gases. The flow rate of gases was controlled by the mass flow controller made by Alicat. Tap water was used as a liquid. Liquid was used in a batch. All runs were conducted at room temperature. Average gas holdup E_G was measured visually.

When the effect of kinds of gas on frequencies and volumes of bubbles which generated from a nozzle was studied, single horizontal 7 and 10 mm I.D. glass tubes were used as a nozzle. The nozzles were set on a bottom of a rectangular water bath at room temperature. The water bath was 16 cm wide, 29 cm deep and 21 cm high. Water depth was 15 cm. Frequencies of bubbles were measured by the electric resistance probe.

3. Experimental results and discussion

3.1 Effect of kinds of gas on E_G

Fig.1 shows the effect of kinds of gas on E_G in the rectangular bubble column with 35 cm clear water height. E_G depended slightly on kinds of gas at small superficial gas velocity U_G. However, E_G depended remarkably on kinds of gas at large U_G and increased with density of gas.

Fig.2 shows the effect of kinds of gas on E_G in the circular bubble column with 165cm bubbling height. E_G also depended slightly on kinds of gas at small U_G. However, E_G depended remarkably on kinds of gas at large U_G and increased with density of gas.

Fig.3 shows photos of bubbles in rectangular bubble column. Bubbles for O_2-tap water system are much denser than those for He-tap water. Therefore, E_G for O_2 becomes much larger than that for He.

Ozturk et al (1987) have concluded that the gas-specific effects are probably related to the bubble formation at the sparger rather than the hydrodynamics in the bulk of the dispersion. Therefore, E_G depends on kinds of gas in bubble columns with small height (H_T < 1 m), however, E_G does not depend on kinds of gas in tall bubble columns (H_T > 2 m). But, E_G depended on kinds of gas in the bubble column with H_T = 165 cm in this work. This finding shows that E_G may depend on kinds of gas in tall bubble columns (H_T > 2 m).

3.3 Correlation of average gas holdup E_G

3.3.1 E_G for the circular bubble column

Fig.4 shows the effect of U_G on E_G in the circular bubble column. E_G increased with U_G and was expressed by the following equation:

$$E_G = AU_G^{\ B} \tag{2}$$

Where A and B are constants. Table 1 shows the effect of kinds of gas on values of A and B. Figs.5 and 6 show the effect of gas density ρ_G on A and B, respectively. A and B were expressed by the following equations, respectively.

$$A = 3.23\rho_G^{-0.0121} \tag{3}$$

$$B = 1.05\rho_G^{0.122} \tag{4}$$

Eqs.(3) and (4) are applicable in the range of ρ_G = 0.083-1.83 kg/m^3.

Fig.7 shows the comparison between $E_{G,exp}$ and $E_{G,cal}$. $E_{G,exp}$ means experimental values of E_G. $E_{G,cal}$ means values of E_G calculated by Eqs.(2)-(4). It is clear from Fig.7 that $E_{G,cal}$ shows a good agreement with $E_{G,exp}$.

3.3.2 E_G for the rectangular bubble column

Fig.8 shows the the effects of U_G on E_G in the rectangular bubble column. E_G increased with U_G and was expressed by the following equation:

$$E_G = CU_G^{\ D} \tag{5}$$

Where C and D are constants. Table 2 shows values of C and D. Figs.9 and 10 show the effect of gas density ρ_G on C and D, respectively. C and D were expressed by the following equations, respectively.

$$C = 5.7\rho_G^{0.042} \tag{6}$$

$$D = 0.96\rho_G^{0.114} \tag{7}$$

Eqs.(6) and (7) are applicable in the range of ρ_G = 0.083-1.83.

Fig.11 shows the comparison between $E_{G,exp}$ and $E_{G,cal}$. $E_{G,cal}$ means E_G calculated by Eqs.(5)-(7). It is clear from Fig.11 that $E_{G,cal}$ shows a good agreement with $E_{G,exp}$.

3.3.3 E_G for H_2, He, N_2, Air, CO_2 gas -xylene system by Ozturk et al. (1987)

E_G data for H_2, He, N_2, Air, CO_2 gas -xylene system by Ozturk et al. (1987) in a 9.5cm I.D. and 85 cm tall bubble column were correlated by the following equations:

$$E_G = EU_G^{\ F} \tag{8}$$

$$E = 3.22\rho_G^{-0.0122} \tag{9}$$

$$F = 0.91\rho_G^{0.122} \tag{10}$$

Fig.12 shows the comparison between Eqs.(8)-(10) and the experimental data of Ozturk et al.

(1987). $E_{G,cal}$ obtained from Eqs.(8)-(10) shows a good agreement with $E_{G,exp}$.

3.4 Frequencies *N* and volumes of bubbles *V* generated from a horizontal single nozzle
